The Chemofusor is lightweight and compact and can be worn with the carrying holster provided. Pumping pressure is by the peristaltic method and a single roller is used instead of the usual two or three rollers. Power is supplied for the Chemofusor motor by miniature mercury cell batteries which give a continuous running time of six weeks. The motor unit has an important fail safe factor which ensures that under no circumstances can the pump head increase its speed.

The drug sac and pumping tube, incorporating a miniature non-return valve, is supplied complete as a disposable item.

The pump will deliver 5 ml. per 24 hours and the capacity of the drug sac is 50 ml.

CYTOTOXIC PERFUSION OF THE LIVER VIA THE UMBILICAL VEIN FOR LIVER METASTASES IN CARCINOMA OF THE COLON

By P. G. BEVAN
DUDLEY ROAD HOSPITAL, BIRMINGHAM

SUMMARY

Four patients with carcinoma of the large bowel and liver metastases have been treated by primary resection and perfusion of the liver with 5-fluoro-uracil via an umbilical vein cannula.

Two patients survived for 14 and 17 months respectively, 1 is still alive after 17 months, and 1 was relieved of deep obstructive jaundice but died 4 months after treatment. The patients were studied clinically, by serial haematological and liver-function tests, and by hepatography and liver scanning. The only severe toxic effect was diarrhoea in 1 patient. The rationale of this method of treatment is discussed along with other applications. It is considered justifiable to use this technique in this group of patients in an attempt to improve the poor prognosis.

A TECHNIQUE for cannulating the umbilical vein in the adult to gain direct access to the portal vein was first described by Carbalhaes in Mexico in 1959 (*Fig.* 1). The method can be used for diagnostic purposes to measure portal pressure, for biochemical estimations of the portal blood, and to record radiological appearances; to investigate the liver metabolism; and therapeutically for portal venesection or porta-systemic shunts in portal hypertension, or to introduce antibiotics or cytotoxic drugs into the portal circulation.

This paper reports 4 cases of carcinoma of the large bowel in which portal cannulation of the umbilical vein has been utilized to perfuse liver metastases with a cytotoxic agent after resecting the primary growth. It is important for the primary carcinoma to be operable in the conventional sense, apart from the liver metastases, without local infiltration beyond the bowel wall and widespread lymph-node involvement.

METHODS

The technique of cannulating the 'obliterated' umbilical vein in the adult has been described in detail by Watts and Douglas (1971). An improved success rate is obtained if the vein is dilated with gum-elastic filiform bougies, avoiding metal probes which may perforate the vein wall. A No. 9 plastic umbilical catheter has been used for the perfusions. Trickle hepatograms have shown that complete perfusion of the whole liver can normally be achieved by drip infusion at ordinary pressure.

5-Fluoro-uracil has been used as the perfusing agent in a dosage of 15 mg. per kg. body-weight per 24 hours. The total dose given in each case is stated below. Response to treatment has been monitored in five ways: clinically, by serial haematological studies, serial liver-function tests, portal hepatograms, and liver scanning. The serial haematological estimations and liver-function tests for each patient are shown in the form of graphs in *Figs.* 2–5.

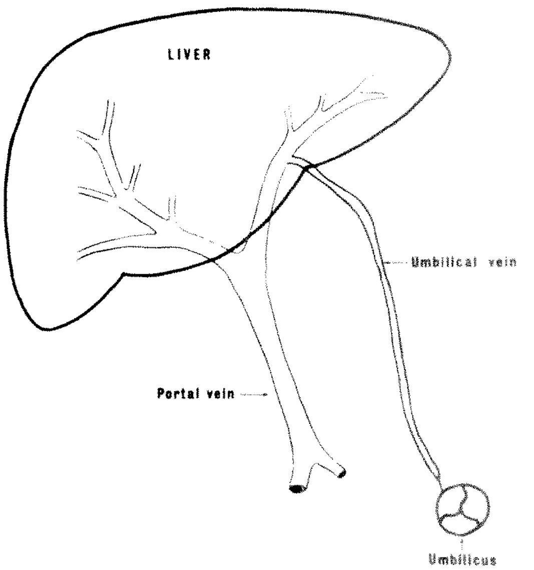

FIG. 1.—Cannulation of the obliterated umbilical vein in the adult gives direct access to the left branch of the portal vein.

CASE REPORTS

Case 1.—A male, aged 65 years, gave a 2-year history of diarrhoea which had become worse over the previous 3 months. On rectal examination there was a palpable carcinoma in the upper third of the rectum. At laparotomy a second carcinoma was found in the sigmoid colon, and the liver contained multiple, moderate-sized metastases (*Fig.* 6). Both carninomas were mobile and limited to the bowel wall, and the local lymph-nodes were not involved. The remainder of the colon appeared normal. Abdominoperineal resection of the rectosigmoid was performed, removing both growths, with a terminal left iliac colostomy. Ten days later the umbilical vein was cannulated through a short supra-umbilical midline incision and an operative hepatogram confirmed complete perfusion of the liver. 5-Fluoro-uracil was given in a dosage of 840 mg. per day for 4 days, followed by a 7-day pause, and then 420 mg. per day for 4 days (a total of 5 g.). There were no toxic effects. The umbilical perfusion ran for 25 days with no trouble, and the catheter was then removed.

The preinfusion hepatogram (*Fig.* 7) demonstrated the larger metastases, but the postinfusion hepatogram was a failure due to spasm of the portal venous radicles. The haematological studies showed that the white-cell and

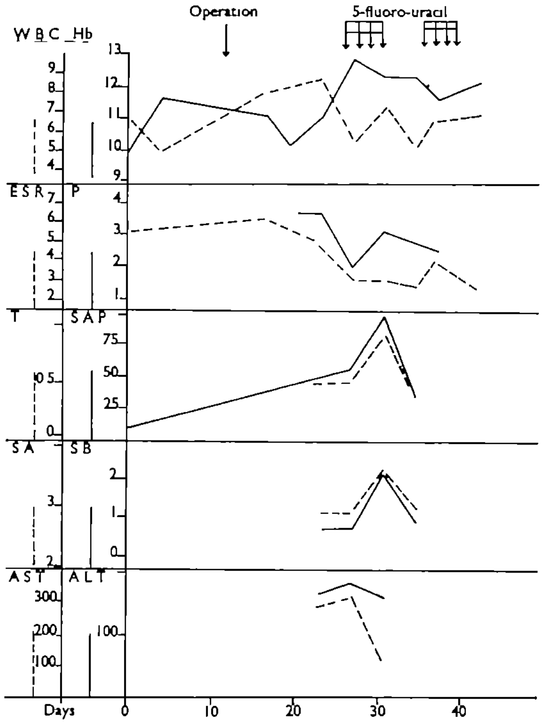

FIG 2.—*Case* 1. Serial haematological investigations and liver-function tests. The figures for the white blood-count (W.B C.) are $\times 10^3$ per mm.^{3}, the haemoglobin (Hb) in g. per cent, the platelet (P) count $\times 10^5$ per mm.^{3}, and the erythrocyte-sedimentation rate (E.S.R.) × 10 mm. per hour (Westergren). Serum bilirubin (S B.) is in mg. per cent, alkaline phosphatase (S A P.) × 10 units per cent, thymol turbidity (T) in units per cent, albumin (S.A) in g. per cent, and alanine (A.L T) and aspartate transaminase (A.S.T.) × 10 international units per litre. The date of the operation is marked. The 5-fluoro-uracil doses are represented by a large arrow for 1 g. and a small arrow for 0·5 g.

platelet counts remained within normal limits. The serum alkaline phosphatase and bilirubin rose during the early part of the perfusion but fell towards normal by the end. The serum transaminases, which were initially high, became higher during the perfusion but then fell to their original level. The serum albumin showed no significant change (*Fig.* 2). The patient remained well and symptom-free for 15 months after the operation, and then developed anorexia, loss of weight, upper abdominal pain, and rapidly increasing hepatomegaly, and died 2 months later.

Case 2.—A male, aged 60 years, was admitted as an emergency with gross intestinal obstruction. The previous history was of only 3 weeks' duration: anorexia, central abdominal colic, and constipation. Operation was performed on the morning after admission and revealed an operable carcinoma of the splenic flexure of the colon with diffuse small liver metastases, and two larger ones just above the hilum (*Fig.* 8). A one-third colectomy was performed with end-to-end anastomosis after decompressing the proximal colon; a safety-valve caecostomy was added and umbilical vein cannulation was carried out. 5-Fluoro-uracil was then infused at a dose of 960 mg. per day for 4 days, followed by a few days' pause, and then 480 mg. per day for 4 days. The patient then developed mild diarrhoea but this settled in a few days. Two further divided doses each of 2 g. of 5-fluoro-uracil were given, and the patient received 10 g. in all. The caecostomy was closed 16 days after the first operation, and the umbilical catheter was removed after the infusion had been running without trouble for 29 days. The preinfusion hepatogram

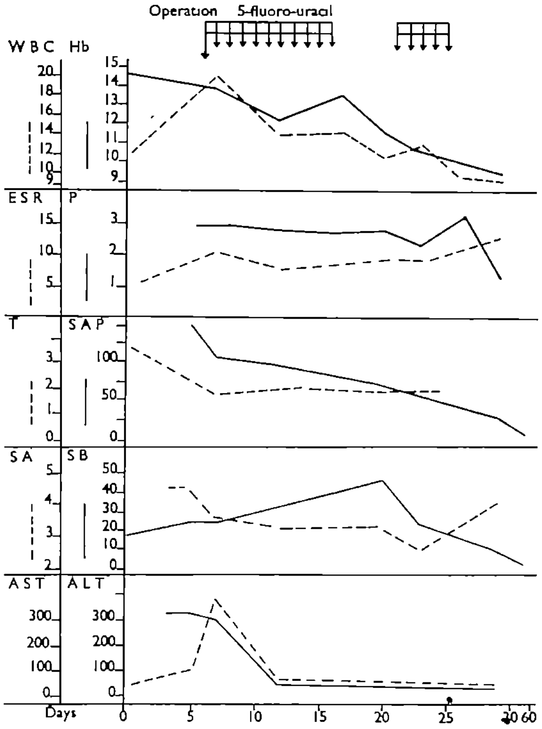

FIG 4.—*Case* 3. Serial haematological investigations and liver-function tests. The units and abbreviations are as in *Fig.* 2.

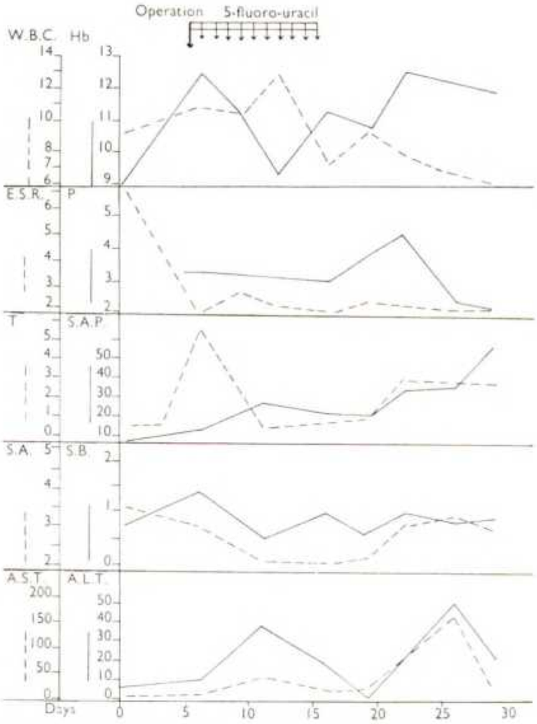

FIG. 5.—*Case* 4. Serial haematological investigations and liver-function tests. The units and abbreviations are as in *Fig*. 2.

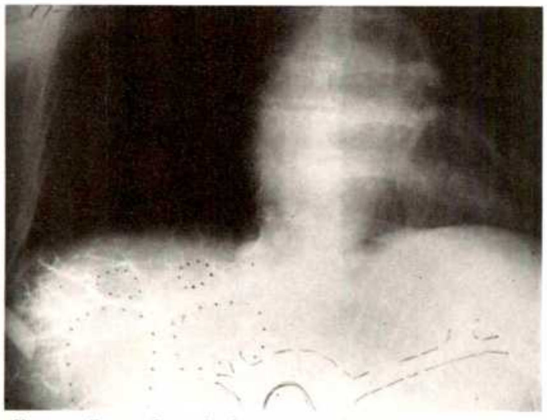

FIG. 7.—*Case* 1. Operative hepatogram, showing large metastases, and complete perfusion of the liver.

(*Fig*. 9) showed the large central metastases clearly and there was diminution in their size on the postinfusion films (*Fig*. 10). The preinfusion liver scan also showed these metastases (*Fig*. 11), but on the scan performed 4 weeks later they had disappeared (*Fig*. 12). There was a slight fall in the white-cell and platelet count towards the end of the perfusion, but not below normal limits. The serum alkaline phosphatase was initially high, rose during the perfusion, and then fell to the previous high level. The serum bilirubin showed a slight rise towards the end of the perfusion, and the transaminases were still rising at this stage. The serum albumin remained unchanged (*Fig*. 3).

The patient remains well and free of symptoms 17 months later.

Case 3.—A male, aged 60 years, was admitted with upper abdominal pain and deep obstructive jaundice of 3 weeks' duration. Fifteen months previously he had undergone abdominoperineal resection for carcinoma of the rectum and there had been no apparent secondaries in the liver. A limited upper midline laparotomy was now performed, revealing multiple, large liver metastases, with one large deposit in the hilum (*Fig*. 13). Umbilical vein cannulation was carried out, and during the next 3 weeks 15 g. of 5-fluoro-uracil were given in divided doses (1 g. per day) with no untoward effects. There was a dramatic response in that the jaundice disappeared clinically by the end of the perfusion. The cannula was removed after the drip had been running for 29 days.

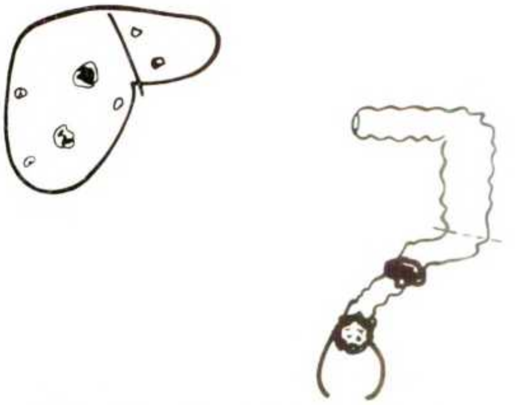

FIG. 6.—*Case* 1. Diagram of the operative findings.

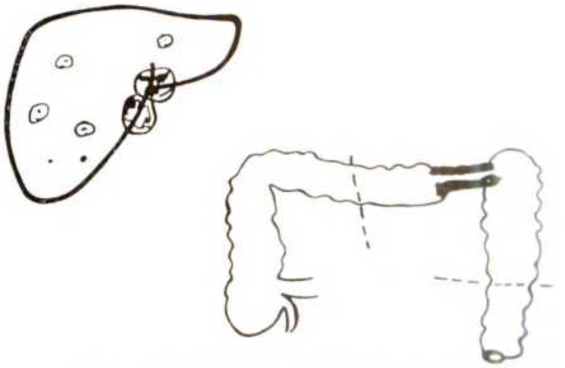

FIG. 8.—*Case* 2. Diagram of the operative findings.

The initial hepatogram showed some of the deposits (*Fig*. 14) which were seen to be diminished on a later examination. The white-cell and platelet count fell slightly at the end of the perfusion but not below normal. The initial serum alkaline phosphatase of 151 mg. per cent fell sharply during the perfusion and was normal at 8·1 mg. per cent 2 months later. The initial serum bilirubin was 17·8 mg. per cent rising to 45 mg. at mid-perfusion and then falling sharply; it was 2·2 mg. per cent 2 months later. The serum transaminases were very elevated before the perfusion, falling to just above normal by the end of the perfusion. The serum albumin showed a slight fall towards the end of the perfusion (*Fig*. 4).

The patient remained well and free of icterus for 3 months after leaving hospital but then developed rapid and severe recurrence of the jaundice and died a few weeks later.

Case 4.—A male, aged 68 years, gave a 6-week history of diarrhoea and rectal bleeding. Rectal examination revealed a carcinoma in the upper rectum that could just be reached with the finger. At operation a carcinoma of the rectosigmoid junction was found, and anterior resection was performed with end-to-end anastomosis (*Fig*. 15). There were multiple, small, diffuse liver metastases present and the umbilical vein was cannulated. Subsequently, 10 g. of 5-fluoro-uracil were given in divided doses, but severe diarrhoea developed and took 3 weeks to settle, so that the infusion was terminated after running for 32 days without giving any more 5-fluoro-uracil. The patient's general condition was poor, and therefore no hepatogram or scan was done for the sake of the patient's comfort. Again, the white-cell and platelet count fell a little during the perfusion, but remained within normal limits. The serum alkaline phosphatase and transaminases rose considerably towards the end of the perfusion, but the serum bilirubin remained normal. The serum albumin showed an early fall at the start of the perfusion but then returned to normal (*Fig*. 5). The patient remained in good health for 12 months after leaving hospital but then deteriorated rapidly and died 1 month later.

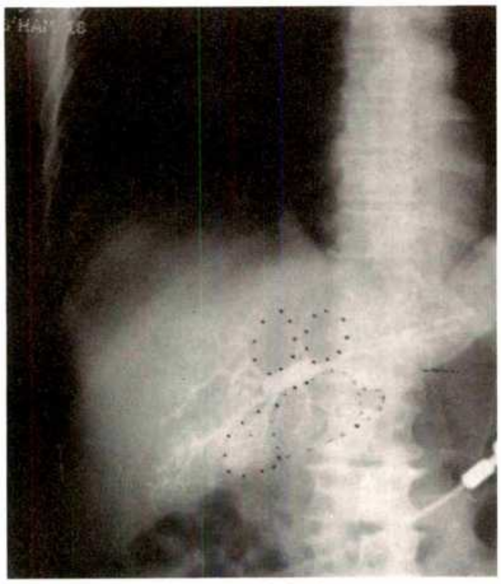

FIG. 9.—*Case* 2. Preinfusion hepatogram.

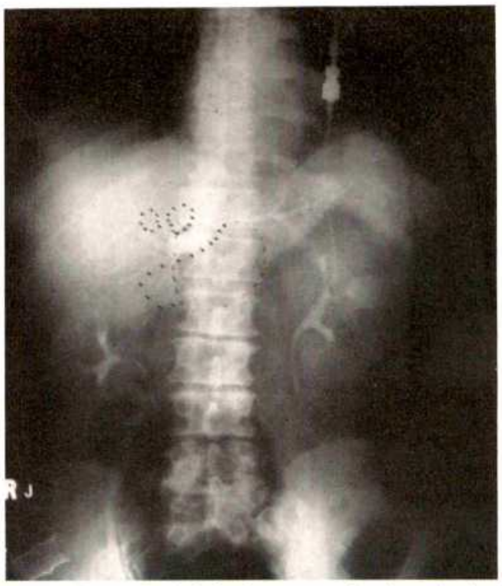

FIG. 10.—*Case* 2. Postinfusion hepatogram showing reduction in size of the metastases.

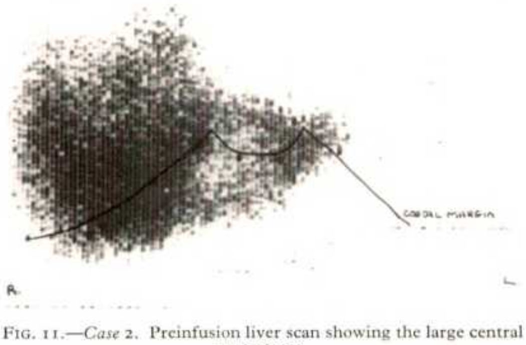

FIG. 11.—*Case* 2. Preinfusion liver scan showing the large central metastases.

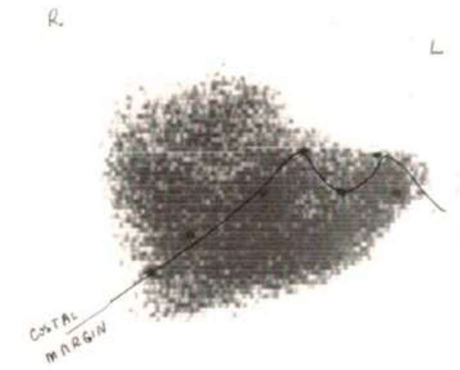

FIG. 12.—*Case* 2. Postinfusion liver scan showing disappearance of these large metastases.

Biopsies of the liver metastases were taken in each case and confirmed secondary carcinoma.

RESPONSE TO TREATMENT

In each of the 4 cases there was evidence of clinical response to the cytotoxic perfusion. The disappearance of the jaundice was striking in *Case* 3, where there was palpable regression of the liver masses; regression of the metastases also occurred in the other 3 cases. *Case* 3 died 4 months after treatment, *Cases* 4 and 1 died 14 and 17 months after treatment respectively, and *Case* 2 is still alive and well after 17 months. Each of the 3 deaths was characterized by sudden and severe deterioration associated with rapid enlargement of the liver metastases, anorexia, loss of weight, and increasing cachexia, leading to a fatal outcome within a few weeks. In 1 patient (*Case* 4) widespread subcutaneous and lymph-node deposits appeared. Until the fairly acute terminal phase each patient had been in good health.

The only side-effect of the cytotoxic perfusion encountered in this series was diarrhoea in 2 cases: mild in *Case* 2 and not leading to curtailment of the drip, but fairly severe in *Case* 4, taking 3 weeks to settle and limiting the amount of 5-fluoro-uracil given to 10 g. Diarrhoea is an indication that the drug has passed through the liver into the systemic circulation and has affected the intestinal mucosa which is particularly sensitive to the drug. In *Fig.* 10 the radio-opaque dye has produced a pyelogram confirming this systemic effect.

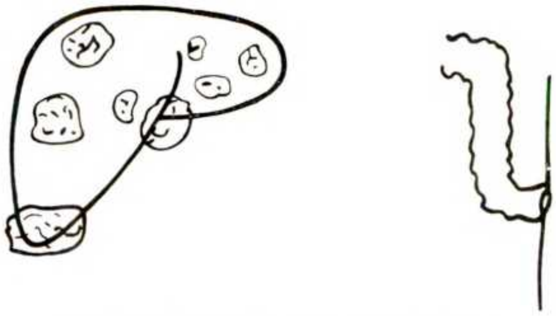

FIG. 13.—*Case* 3. Diagram of the operative findings.

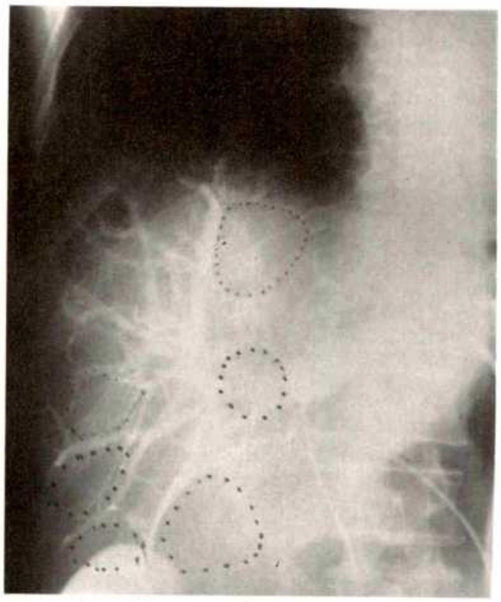

FIG. 14.—*Case* 3. Hepatogram showing the very large metastases. The obstructive jaundice was due to the deposit at the hilum.

Hepatography has not proved a completely reliable method of showing metastases, although large deposits are well demonstrated, and were seen to have decreased in size in *Cases* 2 and 3. It was difficult to visualize the smaller metastases, although Lavoie, Legare, and Viallet (1967) claim that metastases as small as 1 cm. in diameter can be detected in the venous phase. However, hepatography did show that the tip of the catheter was accurately sited in the left branch of the portal vein and that a trickle method will perfuse the whole liver. The liver scans also showed only the larger deposits, and care had to be taken to avoid false-positives. This was possible, as the liver was seen in each case at laparotomy and the metastases mapped. Liver scanning in *Case* 2 showed striking diminution in the size of the central deposits.

From the haematological studies none of the 4 patients developed leucopenia or thrombocytopenia. They received 5, 10, 15, and 10 g. of 5-fluoro-uracil respectively. Administered systemically, a dose of 5 g. in an average adult usually causes some degree of medullary depression.

The results of the liver-function tests were difficult to interpret as it was not always possible to distinguish the effects of the metastases from those of the 5-fluoro-uracil, and in *Case* 3 there was obstructive jaundice in addition. The results indicate that metastases have little effect on liver function unless jaundice occurs, although the alkaline phosphatase was a little raised before infusion in *Case* 2. In *Cases* 1, 2, and 4 the serum alkaline phosphatase and transaminases rose during the perfusion and there was a slight transient reduction in the serum albumin, with some elevation of the thymol turbidity. In view of this evidence of hepatocellular change it would seem that the perfusion had some deleterious effect on liver function in these 3 patients, but it was only of a temporary nature and to a mild degree. In *Case* 3 the severe initial derangement of the liver-function tests was presumably due to the deep obstructive jaundice, and as this faded with the perfusion the liver-function tests showed rapid improvement.

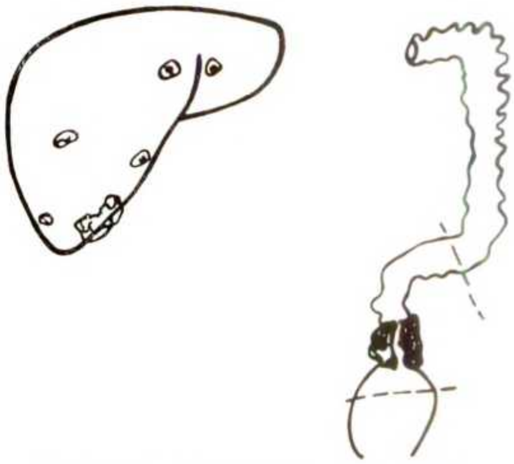

FIG. 15.—*Case* 4. Diagram of the operative findings.

In all 4 cases the perfusion had no effect on marrow function as judged by the haematological results. By introducing the cytotoxic agent directly into the portal system the liver appears to have taken the brunt of the reaction and to have had a cushioning effect on the bone-marrow, preventing haematopoietic medullary depression and allowing the patient to receive two or three times the normal intravenous dose of 5-fluoro-uracil. While this applies to the normal liver containing metastases the position is probably very different in cirrhosis. A patient not included in this series has subsequently been treated for multiple malignant hepatoma with cirrhosis by cytotoxic liver perfusion; he went into irreversible liver failure after receiving only 2 g. of 5-fluoro-uracil.

DISCUSSION

An attempt has been made to extend the treatment of carcinoma of the large bowel with liver metastases in the hope of an improved prognosis. The technique of liver perfusion by a cytotoxic agent via an umbilical vein cannula has proved straightforward to perform and the drip has been easy to maintain, comfortable for the patient, and with no serious side-effects apart from diarrhoea in 1 case. The cannula is turned off at a three-way tap and disconnected for periods during the day to allow full mobility, and there has been no difficulty in removing it without anaesthesia after 30 days.

The number of cases in this series is too small to justify conclusions but does perhaps show a trend. Comparison must be made with the survival time of patients treated by the conventional methods who fall into three groups: laparotomy only, laparotomy with palliative by-pass or colostomy, and palliative resection. From this point of view the figures quoted by Ellis (1971) are of interest and have been tabulated in *Table I*. The results of laparotomy alone and of palliative by-pass are poor, but one-third or more survive for more than 1 year after palliative resection. Of the 4 patients presented here, 3 were alive and well at 1 year, but 2 died during the next few months.

Table I.—RESULTS OF TREATMENT OF CARCINOMA OF THE LARGE BOWEL WITH LIVER METASTASES

AUTHORS	LAPAROTOMY ONLY	PALLIATIVE BY-PASS	PALLIATIVE RESECTION
Cady, Monson, and Swinton (1970)	—	—	33 per cent survived 1 year; 14 per cent survived 2 years
Ellis (1971)	All dead within 5 months	—	32 out of 86 cases survived for more than 1 year; longest survivor: 66 months
Flanagan and Foster (1967)	Average survival 6 months	—	—
Jaffe, Donegan, Watson, and Spratt (1968)	Average survival 5 weeks	—	—
McSherry, Cornell, and Glenn (1969)	Average survival 1·7 months	Average survival 8·9 months	Average survival 12·4 months

The only other report discovered of chemotherapy for hepatic neoplasms via the umbilical portal vein (Storer and Akin, 1966) gives depressing results; of 6 patients receiving 5-fluoro-uracil infusions, 4 had advanced hepatoma, 2 of these dying within a week and 2 showing some response. Two patients with carcinoma of the sigmoid colon and liver metastases were treated; 1 died 2 months after therapy and 1 was still alive at 5 months. It does seem that most of the patients in this series were at an advanced stage of terminal malignant disease.

The route of vascular access to the liver must be considered, as it has been claimed that the hepatic artery plays a more important part in the blood-supply to tumours of the liver than the portal vein. However, in 2 of the cases in the present series there was definite evidence that portal perfusion influenced the metastases; the deep jaundice disappeared in *Case* 3, and the metastases were seen to diminish on hepatography and liver scanning in *Case* 2. As metastases from carcinoma of the colon reach the liver via the portal blood it is logical that they may react to a cytotoxic drug introduced by the same route. Certainly an umbilical vein infusion is technically easier to institute and to maintain than a hepatic artery catheter which needs a major operation to insert and an apparatus producing supra-arterial pressure to bring about adequate liver perfusion. It may be suggested that the effect of portal vein perfusion is due to penetration of the drug into the systemic circulation, although some action on the liver must be allowed for, and it is likely that a cytotoxic agent passing through the liver is probably broken down fairly rapidly. Confirmatory evidence is supplied by the fact that far larger doses of 5-fluoro-uracil have been given via the umbilical vein without serious toxic side-effects than can be given systemically; in a recent patient not included in this series 24 g. were introduced into the portal vein in a 3-week period with no untoward complications. Further studies are needed to settle this point, with estimations of the level of the drug in the systemic blood. This method of treatment must be assessed in a much larger number of patients before its clinical value can be fully established. The present series can be regarded as a pilot study, demonstrating that the technique is practical and safe.

Other types of carcinoma of the gastro-intestinal tract with liver metastases may be suitable for treatment by umbilical vein perfusion, although carcinoma of the large bowel is the most appropriate as it not uncommonly metastasizes to the liver before producing local infiltration and lymph-node involvement. Carcinoma of the stomach and pancreas frequently show early infiltration and lymph-node involvement and only a few will be suitable for liver perfusion. Malignant hepatoma is another indication for this method of treatment, but has the disadvantage of a common association with cirrhosis, limiting the amount of cytotoxic agent that can be delivered to the liver, as in the case quoted above.

All 4 cases reported here had large metastases in the liver and there is obviously a limit to the regressive action of a cytotoxic drug on deposits of such dimensions. It is likely that smaller metastases would be more successfully dealt with, and microscopic aggregates of malignant cells might be eliminated if treated at an early stage. In *Case* 3 it seems probable that undetectable metastatic foci were present in the liver at the time of the original abdominoperineal resection, and these developed into the large metastases encountered 15 months later. This provides an argument for instituting a cytotoxic umbilical vein perfusion in all patients with operable carcinoma of the large bowel at the time of the primary resection. This method of treatment has now been embarked upon, but it will need some years and a large number of patients to assess whether the liver can be protected against metastases by this method. At the moment each patient is given 1 g. of 5-fluoro-uracil per day for 5 days after the operation. This does not delay discharge, and so far has not led to any side-effects or delay in healing.

A final point concerns the cytotoxic drug used, as there may be a better alternative to 5-fluoro-uracil. Melikian, Paton, Leeming, and Portman-Graham (1971) have shown that the liver plays an important part in folic acid metabolism, and absorption studies suggest that folic acid is converted into an active form in the liver, and this reaction may be depressed by 5-fluoro-uracil. Furthermore, 5-fluoro-uracil given in large doses can produce megaloblastic anaemia through inhibition of DNA–thymine synthesis, and macrocytosis with low serum-folate levels was recorded in 2 patients towards the end of chemotherapy which responded to folic acid. Thus, patients undergoing liver perfusion with this drug need to be given extra folic acid, especially if cirrhosis is present. Possibly, methotrexate may be preferable to 5-fluoro-uracil as its toxic effects can be reversed by folinic acid (Melikian, 1972).

Acknowledgements.—I should like to express my gratitude to Dr. A. Paton who indicated the possibility and uses of umbilical vein cannulation; to Dr. V. Melikian for his advice and encouragement, and for the metabolic studies he has done on patients with umbilical perfusions; to Mr. A. Clain, who referred *Case* 3; to Dr. P. Carpenter for the radiological studies and Dr. K. Chackett for the liver scans; to Dr. S. Kelly, who organized the investigations so competently; to Sister C. Walsh and the nursing staff for their care in looking after the perfusions; and to the patients for their willing co-operation.

THE CHEMOFUSOR: A NEW APPARATUS FOR MAINTAINING CONTINUOUS INTRA-ARTERIAL INFUSION CHEMOTHERAPY

BY J. I. BURN AND E. GAINS
DEPARTMENT OF SURGERY, HAMMERSMITH HOSPITAL AND ROYAL POSTGRADUATE MEDICAL SCHOOL

SUMMARY

A new apparatus for continuous intra-arterial infusion cancer chemotherapy in ambulant patients is described.

CONTINUOUS intra-arterial infusion chemotherapy has now been in use for some years and has acquired a small but important role in the management of patients with malignant disease (Burn, Johnston, Davies, and Selwood, 1966). When the technique was first introduced, gravity was used to overcome arterial pressure and thus maintain a continuous forward flow. The chamber containing the infusate was set at a sufficient height above the cannulated artery to prevent back-flow.

The 'gravity-feed' method worked but it was cumbersome. Large volumes of infusate were necessary during each 24-hour period and mobility of the patient was restricted. With therapy often continuing for many weeks the disadvantages of the 'gravity-feed' method were prohibitive.

Later methods used to maintain constant intra-arterial flow included a variety of electrically driven slow-injection pumps and the portable Fenwall pressure infusor (Krant, Hall, Lloyd, and Pasterson, 1961). The former again had the disadvantage of confining the patient to bed or chair. The latter was a device in which the required pressure was transmitted to the container by means of an inflatable cuff. It allowed the patient mobility but required constant surveillance because the pressure within the inflated cuff dropped with use.

Subsequently, more refined apparatuses have been designed which obviate most of the previous disadvantages. The Watkins chronometric infusion pump, designed in the U.S.A., is an example whereby long-term continuous intra-arterial chemotherapy is possible in ambulatory patients (Watkins, 1963).

We have recently designed a small portable infusion pump which is easy to assemble, is reliable, can be safely used in out-patients, and is relatively inexpensive. We have named the apparatus the 'Chemofusor'.

THE CHEMOFUSOR

The Chemofusor is illustrated in *Figs.* 1 and 2. The outer casing (a) is of circular construction measuring 10·5 cm. in diameter by 4·5 cm. in depth. The casing is made of anodized aluminium with a Perspex cover plate (n). The cover screws on to three threaded locating pins (o). The assembled apparatus weighs 312 g.

The Chemofusor's power is supplied by a miniature mercury battery cell (g), manufactured by Mallory Batteries Ltd., No. RM 625-N. Two cells are used with a capacity of 300 mAH and weighing 8 g. each, with a minimum working life of 4 weeks. The voltage supply of 2·7 V. is fed through a dropping resistor to a transistorized circuit which stabilizes and boosts the pulsed supply to the motor unit. This motion is transmitted to a capstan positive-drive movement and then through nylon gear trains to the output shaft. A single roller (e) fixed to the drive plate rotates against the infusion tubing and creates the pumping action. Miniature stainless-steel ball races and jewelled bearings are used on the drive system. A clutch is incorporated to protect the movement from any misuse. The required rate of delivery of the infusate is predetermined within the range of 5–10 ml. every 24 hours as required. The movement has the fail-safe factor that if any component fails it is impossible for the pumping head to increase its speed.

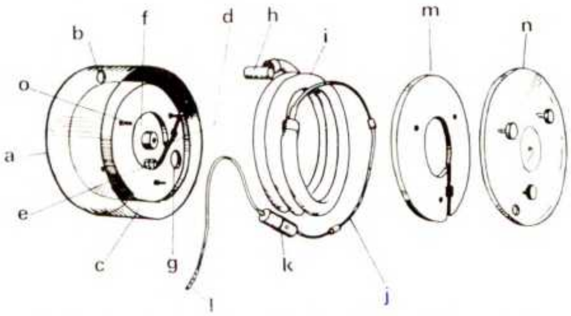

FIG. 1.—The components of the Chemofusor. a, Outer case. b, Reservoir location hole. c, Reservoir-containing space. d, Pump tube location. e, Pump roller. f, Bottom pump track. g, Battery recess. h, Self-sealing cap. i, Reservoir. j, Pump tube. k, Non-return valve. l, Graduated catheter. m, Top pump plate. n, Cover plate. o, Locating pins.

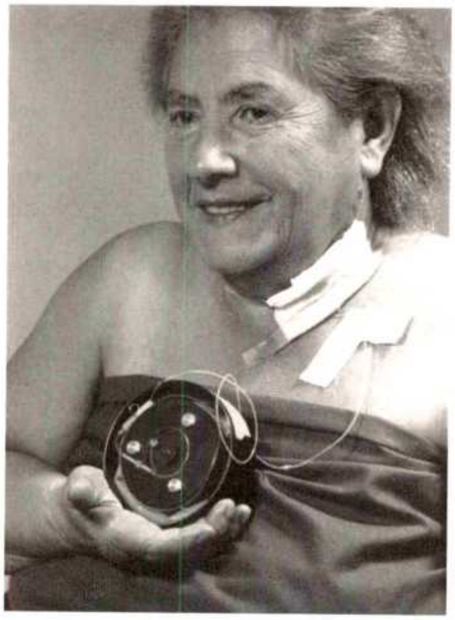

FIG. 3.—A patient undergoing continuous intra-arterial infusion chemotherapy for a carcinoma of the tongue.

The electromechanical movement and pump head are enclosed in a central metal container, measuring 7·7 cm. in diameter and 3·8 cm. in depth. This container is rigidly fixed inside the larger outer casing.

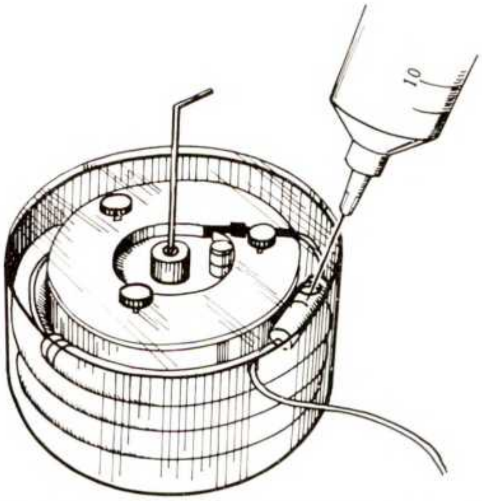

FIG. 2.—The complete Chemofusor, illustrating the self-sealing diaphragm on the non-return valve which can be used for independent injection. The central key shown on the figure is detachable and is used to prime the pumping tube manually when the cover plate is in position.

The cavity between the two containers (c) is used to house the drug-reservoir (i). This sac is made of 1-cm. diameter 'lay-flat' latex rubber tube and has a volume of 50 ml. One end of the reservoir has a self-sealing membrane (h) which is located on the underside hole of the outer casing (b). This enables the Chemofusor to be refilled without removal of the reservoir, which is retained in position until treatment is completed.

The drug reservoir is coiled into the cavity and its exit end connects to the pump tubing (j). This tubing, which is made of 1-mm.-bore silicone rubber, lies in the pump track (d) and is positioned by two locating sleeves.

The pump track is in two parts. The bottom track (f) is situated in the main pump container and the upper track (m) is removable. The pumping tube can be primed manually by rotating the roller (e). The sleeves on the pump tubing fit into the recessed locations in the separate halves of the pump track.

A special graduated intra-arterial catheter (l) made of PTFE is attached to a miniature disposable non-return valve (k). The valve is 3·2 cm. long and 6 mm. in diameter and it contains a self-sealing diaphragm for independent injection (*Fig.* 2). When connected to the pump tubing the valve is located in the undersurface of the cover plate (n).

The drug reservoir, pump tubing, intra-arterial catheter, and non-return valve are all provided prepacked by the C.S.S.D. These disposable components may be sterilized at 120° C., 15 p.s.i. in the autoclave or by gamma radiation.

When assembled the Chemofusor is worn by the patient in a carrying holder and the position can be adjusted for comfort. When in action the pump produces an unobtrusive ticking which indicates to the patient that the device is working. *Fig.* 3 shows a patient undergoing continuous infusion therapy for a malignant lesion of the tongue.

Acknowledgements.—We are grateful to Mr. P. Clark and Mr. G. Williams for the illustrations and to Miss D. Lippiatt for secretarial assistance.

The Chemofusor is manufactured by Keymex Engineering (Sales Ltd.), Oldfield Trading Estate, Sutton, Surrey (Tel. 01-644-7932). The batteries are supplied by Mallory Batteries Ltd., Gatwick Road, Crawley, Sussex.

PERIPHERAL GANGRENE AS THE PRESENTATION OF MYELOPROLIFERATIVE DISORDERS

By GORDON GILLESPIE*

PERIPHERAL VASCULAR UNIT, GLASGOW ROYAL INFIRMARY AND BELVIDERE HOSPITAL, GLASGOW

SUMMARY

Six cases of myeloproliferative disorders (polycythaemia vera in 4, idiopathic thrombocythaemia in 2) are reported. In every case the presenting feature was pain associated with peripheral ischaemia and gangrene. Initial treatment by chemical sympathectomy affords symptomatic relief and improvement in foot circulation, though correction of the haematological abnormality is probably the most important factor in reversing the ischaemic process.

THE myeloproliferative diseases may be defined as disorders of myeloid tissue which result in the inappropriate and excessive production of one or more of the formed elements of the blood. They include such diseases as polycythaemia vera, idiopathic thrombocythaemia, and myeloid leukaemia.

Over the years since the original descriptions of polycythaemia vera as a clinical entity by Vaquez (1892) and Osler (1903) it has become increasingly recognized that this disease may be accompanied by complications involving the vascular system, and the incidence of such complications in polycythaemia vera is around 30 per cent (Brown and Griffin, 1930; Norman and Allen, 1937; Burris and Arrowsmith, 1953). Only a small proportion of cases, however, have been associated with peripheral vascular lesions of the limb vessels and it is rare for peripheral gangrene to be the presenting feature of the disease. Similarly, ischaemic necrosis of the extremities is an uncommon manifestation of idiopathic thrombocythaemia and only an occasional case report exists of peripheral gangrene as a presentation of either polycythaemia vera (Moore, Blaisdell, and Hall, 1964) or of the closely related disorder, idiopathic thrombocythaemia (Wellens, 1967).

This paper reports 6 patients with a myeloproliferative disorder (polycythaemia vera in 4, idiopathic thrombocythaemia in 2), all of whom presented within a 10-month period with peripheral gangrene as the initial manifestation of their disorder.

CASE REPORTS

Case 1.—J. C., a 37-year-old male, presented in April, 1970, with pain and a gangrenous plaque on the pulp of the left thumb. He was known to have had a right lumbar sympathectomy in 1964 for intermittent claudication and gangrene of the right great toe, but he had remained symptom-free thereafter. Examination revealed mild atrophic changes of the toes and fingers and a necrotic plaque 1·5 cm. in diameter in the pulp of the left thumb. The radial and ulnar pulses were absent in the right arm. Lower-limb examination showed the posterior tibial pulse to be diminished in the right leg and absent in the left leg. Dorsalis pedis pulses were absent. The pulse-rate was 64 per minute and the rhythm regular. The blood-pressure was 120/80 mm. Hg, the heart-sounds normal, and the electrocardiogram showed no abnormality. The chest radiograph was also normal. There was no splenomegaly. Blood examination showed the following results (*Table I*): haemoglobin, 18·9 g. per cent; packed-cell volume, 54 per cent; white-cell count, 11,700 per c.mm.; platelet count, 275,000 per c.mm. Random blood-sugars were 144 and 105 mg. per cent and the Wassermann reaction, Khan test, and Reiter complement-fixation test were negative.

Further blood examination in May, 1970, revealed a haemoglobin of 16·4 g. per cent and a packed-cell volume of 49 per cent. The patient was admitted in September, 1970, for further haematological investigations. Blood-volume studies by the ^{51}Cr method (*Table I*) revealed a red-cell mass of 41·38 ml. per kg., a plasma volume of 39·8 ml. per kg., and a total blood-volume of 81·2 ml. per kg.

A diagnosis of polycythaemia vera was made and venesection of 400 ml. of whole blood was performed; 5 m.c. of radioactive phosphorus (^{32}P) were then injected intravenously. Healing occurred with minimal loss of tissues and the patient remained symptom-free until February, 1971, when he presented with pain and gangrene of the tips of the middle and index fingers of the right hand (*Fig.* 1). Elevated haematological values were again found. Venesection was performed and a further 5 m.c. of ^{32}P were given intravenously. Although the haematological values were rapidly restored to normal, residual swelling and pain due to superadded infection in relation to the right middle finger prevented full symptomatic relief for several months.

Case 2.—C. W., a 74-year-old female, presented in May, 1970, with a 2-week history of pain, coldness, and cyanosis in the distal two phalanges of the index, middle, and ring fingers of the right hand. One transient similar episode had occurred 3 months previously. She had suffered from rheumatic fever 40 years previously. Examination showed a dusky cyanosis with punctate necrotic plaques in the pulps of the right second, third, and fourth fingers. Light touch sensation was absent in the distal phalanges of these fingers. All the pulses were palpable in both arms. The pulse-rate was 80 per minute and the rhythm regular. The blood-pressure was 200/100 mm. Hg, the heart-sounds were normal, and an electrocardiogram showed no abnormality. A chest radiograph was also normal. Blood examination showed the following results (*Table I*): haemoglobin, 18·2 g. per cent; packed-cell volume, 57 per cent; white-cell count, 11,300 per c.mm.; platelet count, 370,000 per c.mm. Blood-volume studies using the ^{51}Cr method revealed a red-cell mass of 36·5 ml. per kg., a plasma volume of 35·2 ml. per kg., and a total blood-volume of 71·7 ml. per kg. The Wassermann reaction, Khan test, and Reiter complement-fixation test were all negative. A diagnosis of polycythaemia vera was made. Venesection of 500 ml. of whole blood was performed and 4 m.c. ^{32}P were injected intravenously.

---

* Present address: Victoria Infirmary, Glasgow G42 9TF.

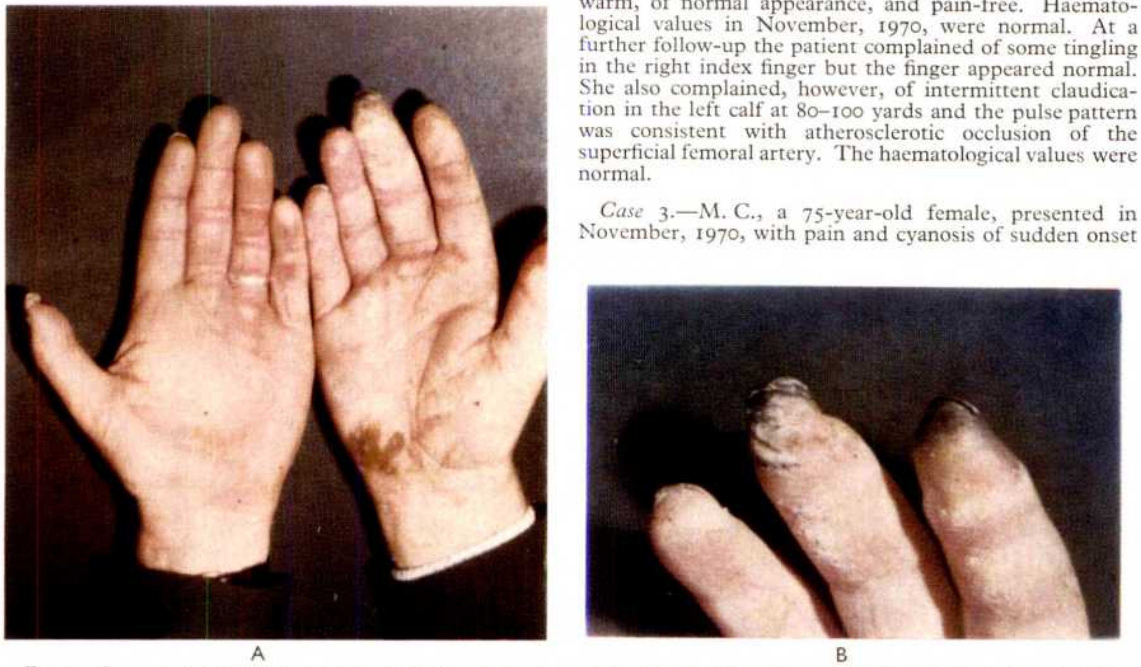

FIG. 1.—*Case* 1. A, The necrotic area at the tip of the middle finger of the right hand is shown at its early stage. Note that the earlier lesion at the tip of the left thumb has healed with minimal loss of pulp tissue. B, A few weeks later the line of demarcation of the necrotic tip of the right middle finger is evident. Gangrenous change is also evident in the index finger and a small necrotic plaque with a blister is seen at the tip of the ring finger.

Table I.—DETAILS OF 6 PATIENTS WITH MYELOPROLIFERATIVE DISEASE AND PERIPHERAL GANGRENE

CASE	AGE AND SEX	SITE OF GANGRENE	HAEMOGLOBIN (g. per cent)	PACKED-CELL VOLUME (per cent)	PLATELET COUNT (per c.mm.)	RED-CELL MASS* (mg. per kg.)	DIAGNOSIS
1. J. C.	37 M.	Upper limb	18·9	54	275,000	41·38	Polycythaemia vera
2. C. W.	74 F.	Upper limb	18·2	57	370,000	36·5	Polycythaemia vera
3. M. C.	75 F.	Lower limb	17·9	60	280,000	41·7	Polycythaemia vera
4. E. A.	62 M.	Lower limb	18·1	51	1,790,000	50·7	Polycythaemia vera and thrombocythaemia
5. J. F.	75 M.	Lower limb	12·3	36	1,500,000	—	Idiopathic thrombocythaemia
6. M. C.	67 M.	Lower limb	12·2	35	859,000	—	Idiopathic thrombocythaemia

* Upper limit of normal range for red-cell mass is 35 ml. per kg. for males and 30 ml. per kg. for females (Nadler, Hidalgo, and Bloch, 1962).

At follow-up review 1 month later the fingers were warm, of normal appearance, and pain-free. Haematological values in November, 1970, were normal. At a further follow-up the patient complained of some tingling in the right index finger but the finger appeared normal. She also complained, however, of intermittent claudication in the left calf at 80–100 yards and the pulse pattern was consistent with atherosclerotic occlusion of the superficial femoral artery. The haematological values were normal.

Case 3.—M. C., a 75-year-old female, presented in November, 1970, with pain and cyanosis of sudden onset in the left middle toe and a small area of gangrene of its pulp. There was also a painful gangrenous patch of skin, 2 cm. in diameter, over the lateral aspect of the left lower leg. Examination showed oedema of both ankles and pallor of the left foot on elevation. The left posterior tibial pulse, left dorsalis pedis pulse, and right posterior tibial pulse were absent. The right dorsalis pulse was present though diminished. An abdominal aortic bruit was audible at the aortic bifurcation consistent with stenosis due to atherosclerosis at that level. A plain radiograph revealed calcification of the abdominal aorta. The pulse-rate was 70 per minute and the rhythm regular. The blood-pressure was 150/75 mm. Hg, the heart sounds were normal, and an electrocardiogram showed no abnormality. A chest radiograph and intravenous pyelography were normal. Blood examination gave the following results (*Table I*): haemoglobin, 17·9 g. per cent; packed-cell volume, 60 per cent; white-cell count, 12,500 per c.mm.; platelet count, 280,000 per c.mm.; fasting blood sugar, 70 mg. per cent. Blood-volume studies using the ^{51}Cr method revealed a red-cell mass of 41·7 ml. per kg., a plasma volume of 34·7 ml. per kg., and a total blood-volume of 76·5 ml. per kg. A diagnosis of polycythaemia vera was made. Initial treatment was by left lumbar chemical sympathectomy by phenol injection and this resulted in pain relief and improvement in the foot circulation. Thereafter, venesection of 500 ml. of whole blood was performed and 5 m.c. of ^{32}P were given intravenously.

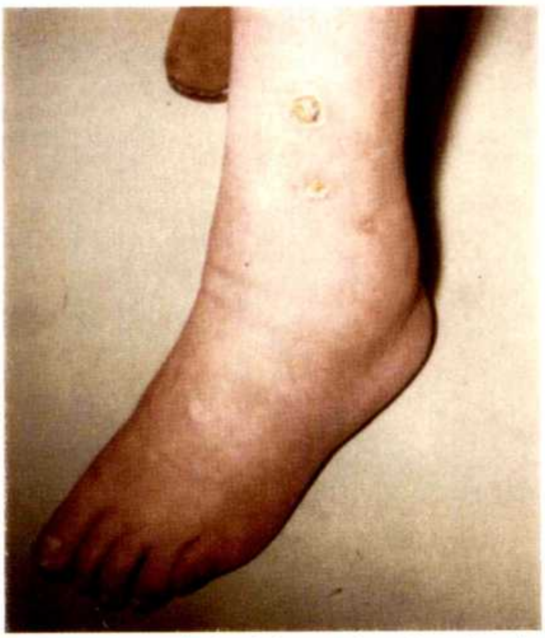

FIG. 2.—*Case* 3. The sharply demarcated area of necrosis on the lateral aspect of the left lower leg is seen in the healing phase. The left third toe has resumed a virtually normal appearance with minimal loss of tissue.

At follow-up in December, 1970, the foot was pain-free and the toe had healed with minimal loss of tissue. The area of necrosis in the lower left leg was pain-free and well localized (*Fig.* 2). In January, 1971, the haematological values were normal.

Case 4.—E. A., a 62-year-old male with plethoric facies, presented in September, 1970, with a 2-month history of rest pain in the left great toe and forefoot. There was no history of intermittent claudication. He had suffered from chronic bronchitis for 4 years. Examination showed a gangrenous plaque (1 × 0·75 cm.) on the tip of the left great toe and cyanosis of all the toes. There was no evidence of trophic changes. All the pulses were palpable in both legs though the dorsalis pedis pulses were diminished. The pulse-rate was 80 per minute and the rhythm regular. The blood-pressure was 150/100 mm. Hg, the heart-sounds were normal, and an electrocardiogram showed no abnormality. A chest radiograph showed changes of chronic bronchitis and emphysema. The tip of a firm spleen was palpable. Arteriography showed patency of all the main vessels including the tibial vessels in both limbs. Blood examination gave the following results (*Table I*): haemoglobin, 18·1 per cent; packed-cell volume, 51 per cent; white-cell count, 14,100 per c.mm.; platelet count, 1,790,000 per c.mm. Blood-volume studies using the ^{51}Cr method revealed a red-cell mass of 50·7 ml. per kg., a plasma volume of 48·8 ml. per kg., and a total blood-volume of 99·6 ml. per kg. Sternal marrow examination revealed normoblastic erythropoiesis, normoblastic granulopoiesis, and megakaryocyte hyperplasia. There was no evidence of Philadelphia chromosome.

A diagnosis of myeloproliferative disease with both polycythaemia and thrombocythaemia was made. Initial treatment by chemical sympathectomy of the left lumbar chain by phenol injection gave considerable relief from pain and, thereafter, venesection of 1000 ml. of whole blood was performed and 5 m.c. of ^{32}P were given intravenously.

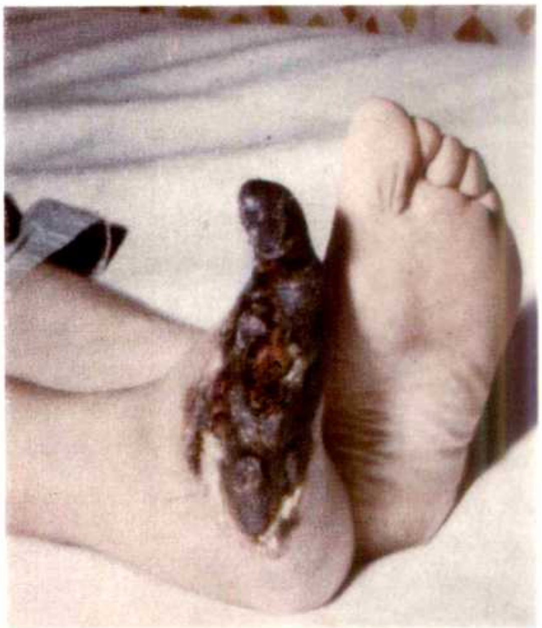

FIG. 3.—*Case* 5. Extensive gangrene of the right forefoot with loss of the lateral four toes.

At the follow-up review in January, 1971, the patient was pain-free and the left great toe had healed with minimal loss of tissue.

Case 5.—J. F., a 69-year-old male, presented in February 1970, with rest pain in the right foot of 2 months' duration. There was no history of intermittent claudication. Examination showed gangrene of the entire right third toe and signs of incipient gangrene in the fourth toe. All the lower limb pulses were palpable except for an absent right dorsalis pedis pulse. There were no atrophic changes and there was a good angle of vascular sufficiency. The pulse-rate was 96 per minute and the rhythm regular. The blood-pressure was 150/100 mm. Hg, the heart-sounds were normal, and an electrocardiogram showed no abnormality. A chest radiograph was also normal. The Wassermann reaction, Khan test, and Reiter complement-fixation test were all negative. Arteriography revealed a right proximal popliteal atherosclerotic occlusion but the distal vessels were patent. The left popliteal artery was narrowed but the distal vessels were patent. Blood examination gave the following results (*Table I*): haemoglobin, 12·3 g. per cent; packed-cell volume, 36 per cent; white-cell count, 7900 per c.mm.; platelet count, 1,500,000 per c.mm. Sternal marrow examination revealed normoblastic erythropoiesis, normal granulopoiesis, and well-marked megakaryocyte hyperplasia. A diagnosis of idiopathic thrombocythaemia was made. Initial treatment was by right lumbar chemical sympathectomy by phenol injection. Thereafter 3 m.c. of ^{32}P were given intravenously.

At follow-up in April, 1970, the platelet count had fallen to 603,000 and the pulse pattern remained unchanged. However, gangrene had spread to involve all of the toes, and although by July, 1970, the platelet count had fallen to 470,000, gangrene had extended to involve the lateral part of the forefoot (*Fig.* 3). Below-knee amputation was performed, and at operation all the stem arteries at the level of division bled briskly. In November, 1970, the patient was well and symptom-free but the platelet count was again markedly elevated, at 2,050,000 per c.mm. A further injection of 4 m.c. of ^{32}P was given intravenously. In January, 1971, he remained well and the platelet count was 460,000 per c.mm.

Case 6.—M. C., a 67-year-old male, presented in October, 1970, with pain and discoloration of the toes of both feet of 2 weeks' duration. The symptoms were worse on the left foot and had become more severe over the 2 days prior to presentation. Examination revealed purple discoloration of all the toes of the left foot which was more marked in the medial three toes, where there was loss of capillary flow, coldness, and loss of light touch sensation. The right foot showed cyanosis of the medial three toes and a gangrenous plaque, 1·5 cm. in diameter, on the pulp of the right great toe with loss of light touch sensation of the first and second toes. Apart from slightly diminished dorsalis pedis pulses all the limb pulses were present and normal. The pulse-rate was 112 per minute and the rhythm regular. The blood-pressure was 160/70 mm. Hg, the heart-sounds were normal, and an electrocardiogram showed sinus rhythm with right bundle branch block. A chest radiograph was normal. There was no splenomegaly. Blood examination gave the following results (*Table I*): haemoglobin, 12·2 g. per cent; packed-cell volume, 35 per cent; white-cell count, 8300 per c.mm. The platelet count on 9 Nov. was 859,000 and on 16 Nov. 775,000. A provisional diagnosis of idiopathic thrombocythaemia was made and initial treatment by chemical sympathectomy to the left lumbar chain by phenol injection afforded some relief of pain but did not materially alter the circulatory status of the foot. Two m.c. of ^{32}P were injected intravenously. However, before further investigations could be planned the patient died as a result of peritonitis from an unknown cause. Autopsy revealed minimal atherosclerosis and patency of all the arteries including those in the lower limbs.

DISCUSSION

Ischaemic gangrenous changes in the digits are most often seen in relation to arterial occlusions in atherosclerosis, but are also found in diabetes mellitus, rheumatoid arthritis, and scleroderma. Other causes include cervical rib, cardiac gangrene, drug-induced angiopathy, and syphilis. Much less common in producing gangrene of the extremities are polycythaemia vera and idiopathic thrombocythaemia. In particular, it is unusual for peripheral gangrene to be the presenting feature, although isolated case reports exist of this presentation of polycythaemia (Moore and others, 1964) and of idiopathic thrombocythaemia (Wellens, 1967).

The group of 6 patients reported here is unusua that they all presented within a 10-month period. the time of their presentation there was no histor a myeloproliferative disorder but routine bl examination indicated the diagnosis. A diagnosi polycythaemia may be suspected from elevated le for haemoglobin and packed-cell volume, but si these values may on occasions be only margin raised, or in the normal range, blood-volume stu to measure the red-cell mass are essential. interest in the present group of patients is the existence of atherosclerosis in every case, and it r be that for the full development of the periph ischaemia and necrosis a diseased arterial tree essential in addition to the myeloproliferative disor Nevertheless, this group of patients would not h been expected to suffer a threat to viability on basis of their arterial lesions alone.

The problem of management of these patient complex. Initial relief of pain and improvement local vascularity may be provided by chem sympathectomy, and in the present series symp matic relief was afforded to the patients with low limb ischaemia, all of whom received a phenol blo In these patients it is difficult to assess, therefore, respective parts played by chemical sympathecto as opposed to correction of the haematologi abnormality in the management of their sympto However, it is of interest that benefit followed resto tion of the haematological values to the norr range in the 2 patients with upper-limb ischaemia whom no sympathectomy was performed. It see likely, therefore, that correction of the blood abn mality may be the most important factor in reversi the ischaemic process.

Acknowledgements.—I wish to thank William Reid, Consultant Surgeon in charge of Peripheral Vascular Unit, Glasgow Royal Infirm and Belvidere Hospital, for his permission a encouragement to publish these case reports. I m also acknowledge the expert haematological adv freely given by Dr. MacDonald, Consultant Haematology, Glasgow Royal Infirmary. The help criticism provided by Mr. Reid and Dr. MacDon during preparation of the manuscript is mu appreciated.

You may not know about Avon sets, but you'll know someone who does.

If you're a newcomer to the medical profession there's a chance you may not know about us, after all, we haven't been around so long ourselves.
Well, very briefly, Avon Medicals manufacture a whole range of disposable products for transfusion and dialysis.

In many hospitals, all over the world, they're an accepted way of life.
Most of the more experienced people you work with will be able to tell you a good deal about us. And if they feel they'd like to know even more, drop us a line, and we'll get someone to call.

MANAGEMENT OF THE THROMBOSED EXTERNAL AND INTERNAL ARTERIOVENOUS SHUNTS

By E. J. HADJIYANNAKIS*
DEPARTMENT OF SURGERY, UNIVERSITY OF CAMBRIDGE

SUMMARY

Two methods for salvaging thrombosed internal and external arteriovenous shunts are described. Thrombosed external shunts have been cleared by phlebotomy or arteriotomy, while internal shunts have been reconstructed by end-to-end anastomosis of the artery and vein proximal to the occlusion.

LONG-TERM haemodialysis became possible when Quinton, Dillard, and Scribner (1960) introduced the external arteriovenous shunt: a Teflon Silastic conduit connecting a peripheral artery and vein. This means of access to the circulation has been well accepted, but problems are numerous (Byrne, Stevens, Weaver, Maxwell, and Reemtsma, 1971; Haimov, Singer, and Schupak, 1971; Klauber, Belinsky, Morehouse, and Mackinnon, 1971). Thrombosis in the arterial or venous cannula is common, often requiring resiting of the tip. The internal arteriovenous fistula introduced by Brescia, Cimino, Appel, and Hurwich (1966) is preferred, but thrombosis still occurs occasionally at the site of the fistula (Haimov and others, 1971; Hadjiyannakis, 1972).

Two methods are described for salvaging shunts which have thrombosed and which conventional methods have failed to clear. For external shunts the thrombus is removed via an incision in the vessel beyond the Teflon tip. A rather unusual case prompted the author to employ open thrombectomy and this method is described first. Thrombosed internal fistulae are refashioned by end-to-end anastomosis of the vessels proximal to the block. Seven initial cases are described in which these methods have been utilized.

THROMBOSED EXTERNAL TEFLON SILASTIC SHUNTS

Five external shunts were restored to normal function after conventional means had failed. Most thrombi, if recognized early, can be removed by heparinized saline and suction. Resistant thrombi can frequently be dispersed with urokinase; 5000 units are instilled into vessels and left for 1 hour, and suction is then applied with heparinized saline to rinse the vessel. If thrombi persist the shunt may still be salvaged by the following surgical manœuvres.

Method.—Angiograms were performed to establish the extent of the thrombosis (Berne, Turner, and Barbour, 1971). In all 5 cases the veins were thrombosed and in 2 there was also arterial thrombosis.

Under local anaesthesia a 2-cm. transverse skin incision was made over the site of the thrombosed vessel. A sphygmomanometer cuff was inflated to prevent embolization of the thrombus and to facilitate the phlebotomy. The vein was then opened transversely 0·5 cm. proximal to the thrombus. When the thrombus extended into a venous branch the phlebotomy was made above the junction to facilitate clearing (*Fig.* 1). The incision need only to be 2–3 mm. across the front of the vein. In the majority of cases the thrombus discharged itself spontaneously through the incision but this was aided by irrigation with heparinized saline via the Silastic tube of the shunt.

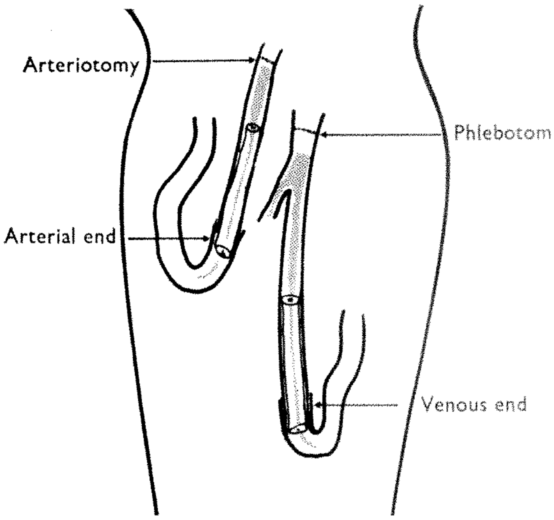

FIG. 1.—Technique of clearing thrombosed external shunts.

The transverse incision in the vein was closed with continuous 0000000 silk and the skin was closed with 0000 silk. To clear thrombi from the arterial side a similar incision was made, the vessel being occluded with a bulldog clamp proximal to the arteriotomy, and the artery was opened transversely 0·5 cm. proximal to the thrombus. The clot was removed by irrigation and the vessel closed with 0000000 silk.

CASE REPORTS.—Four of the 5 cases had had two or three previous revisions of shunts in the same forearm.

Case 1.—A 13-year-old girl with a 4-month-old Teflon Silastic shunt complained of acute pain at the venous end. Five minutes later blood started to ooze from the venous exit site. At the same time swelling of the arm was noted. By clamping the arterial end of the tube the haemorrhage was controlled. Under local anaesthesia the old wound was explored and it was found that the Teflon tip had been dislodged further up the vein and the Silastic tube was free in the subcutaneous tissues. The proximal part of the cephalic vein was ligated. Because of the swelling the exact position of the Teflon cannula could not be established. A new venous end was inserted higher up in an adjacent vein through a new incision but the flow was poor. A phlebogram showed that the missing Teflon tip was blocking the lateral branch of the main cephalic vein. Fortunately it had stopped near the elbow (*Fig.* 2). A 2-cm. transverse skin incision was made over the tip and a sphygmomanometer cuff was inflated. A 2-mm. transverse incision was made in the vein and the Teflon tip with a 4-cm. thrombus attached to it was removed. The incision was closed with 0000000 silk and the shunt remained patent for a further 3 months when the patient had a successful cadaveric renal transplant.

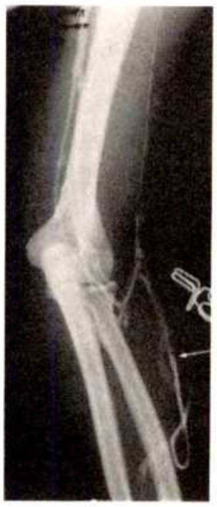

FIG. 3.

FIG. 2.—*Case* 1. Angiogram, showing (1) the dislodged Teflon tip blocking the adjacent vein, (2) the Teflon tip of the new shunt. (3) Photograph of the removed tip which is full of thrombus.

FIG. 3.—*Case* 3. Angiogram of the thrombosed vein.

The success in this patient led to the use of phlebotomy in the following cases.

Case 2.—A 21-year-old female had had a functioning external shunt for 2 years. Because of a thrombosis both arterial and venous ends had been revised and the tips were now near the elbow. Three months later the new shunt thrombosed. Angiography showed that both the artery and vein were thrombosed. The vein and artery were declotted by phlebotomy and arteriotomy. Four months later the shunt was still in use.

Case 3.—A 21-year-old female had had three revisions of an external shunt in her right arm. This shunt eventually thrombosed again and angiography showed extensive thrombus in the vein (*Fig.* 3). A thrombectomy was performed and the shunt functioned for 25 days. The patient was started on anticoagulants but the venous end of the shunt again thrombosed and was cleared twice by the above technique, each new incision being 0·5 cm. proximal to the previous one. Following this the vein remained patent for 3 months.

Case 4.—A 38-year-old female developed a thrombosis in an external shunt after 6 months, and 10 days after the construction of an internal fistula in the other arm. The artery was declotted easily with heparinized saline, and the vein was declotted via a phlebotomy (*Fig.* 1). One month later the shunt was still functioning.

THROMBOSED INTERNAL ARTERIOVENOUS FISTULAE

Of 40 internal fistulae constructed during the past 2 years, 4 thrombosed and local attempts to clear the vessels were consistently unsuccessful. Two further fistulae which thrombosed have been reconstructed by end-to-end anastomosis proximal to the occlusion by the following technique.

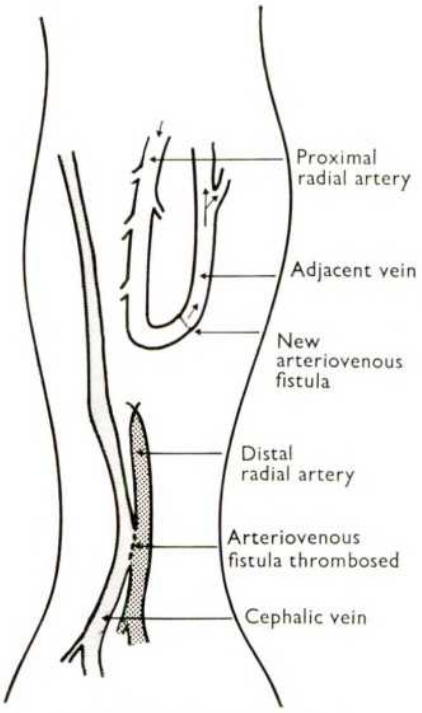

FIG. 4.—Technique used in *Case* 6.

Method.—Arterial and venous patterns were mapped out on the forearm. Under local anaesthesia a transverse incision was made 3–4 cm. proximal to the previous thrombosed fistula. In both cases the artery and vein were occluded. The artery was cleared and anastomosed end-to-end to an adjacent vein with 0000000 silk. The artery was formed into a loop, leaving the vein in a straight line.

A thrombosed vein can be used after declotting but it is recommended to utilize a fresh vein if there is one close by.

Cases 5, 6.—A 51-year-old male with chronic renal failure and congestive cardiac failure was started on home dialysis. He had had a functioning internal fistula for 7 months and an external shunt in the other arm which had been revised twice. The venous end of the shunt thrombosed and was declotted via a phlebotomy (*Case* 5). Twenty days later during a hypercoagulation episode (platelets over 1 million per c. mm.) both the internal and external shunts thrombosed. The patient arrived at hospital 48 hours later and it was not possible to salvage the external shunt. A transverse incision was made above the thrombosed internal fistula. Both the artery and vein contained clots. The adjacent vein was found and anastomosed end-to-end to the proximal part of the thrombosed artery (*Fig.* 4). One week later the fistula was

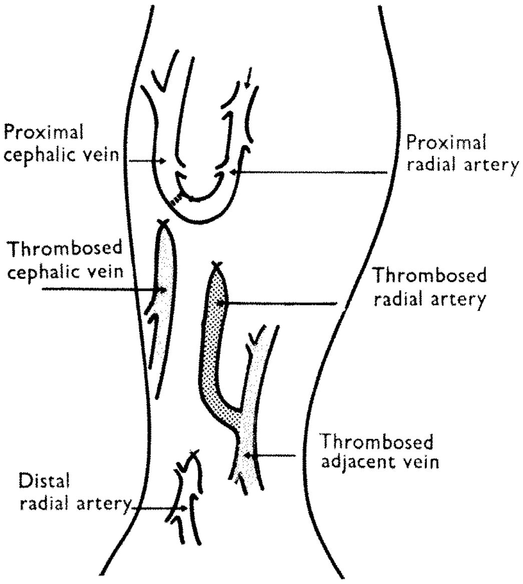

FIG. 5.—Technique used in *Case* 7.

used and 3 months later it was still functioning very well.

Case 7.—A 38-year-old female had an end-to-side radial artery internal fistula which never functioned. Ten days later an end-to-end arteriovenous fistula was created after declotting the cephalic vein which was the only vein in the vicinity (*Fig.* 5). Five days later this fistula was used and was still functioning after the patient had received a cadaveric kidney graft.

Acknowledgements.—I wish to thank Professor R. Y. Calne of the Department of Surgery, University of Cambridge, for permission to perform these techniques on his patients; the Radiology and Photographic Departments of Addenbrooke's Hospital, Cambridge, for their support and help, and Miss Patricia Hagan for secretarial assistance.

THE AUTOGENOUS SAPHENOUS VEIN LOOP FOR HAEMODIALYSIS

BY K. C. CALMAN, R. O. QUIN, A. M. PATON, J. D. BRIGGS, AND P. R. F. BELL
UNIVERSITY DEPARTMENT OF SURGERY AND RENAL UNIT, WESTERN INFIRMARY, GLASGOW

SUMMARY

Eleven autogenous saphenous vein loops have been used in 9 patients on haemodialysis in order to gain access to the circulation. All the patients lacked peripheral vessels available for alternative procedures. These grafts have functioned satisfactorily for over 18 months and have proved technically easy to construct and efficient to use. Three loops thrombosed after successful renal transplantation, and 1 developed an aneurysm which was repaired. One vein loop failed during dialysis. In 1 patient the graft enlarged considerably and she died of congestive cardiac failure; the part played by the graft in the development of the cardiac failure remains uncertain.

PRIOR to the introduction of the Cimino-Brescia fistula for regular haemodialysis (Brescia, Cimino, Appel, and Hurwich, 1966) access to the circulation was usually achieved by the Quinton-Scribner shunt (Quinton, Dillard, and Scribner, 1960). Although the external shunt was found to be satisfactory for haemodialysis its use was limited by the number of peripheral vessels available. In consequence a group of patients presented after several years of successful dialysis with a lack of shunt sites. The wider use of the Cimino-Brescia arteriovenous fistula from the time of commencement of haemodialysis has largely eliminated this problem. Unfortunately, however, a proportion of patients remain in whom the lack of peripheral vessels prevents the construction of a suitable arteriovenous fistula. These patients usually have had numerous arteriovenous shunts previously inserted, or have a failed renal transplant with a thrombosed fistula. May, Tiller, Johnson, Stuart, and Sheil (1969) introduced the use of saphenous vein loops in these difficult patients, and other reports have followed (Girardet, Hackett, Goodwin, and Friedman, 1970; Moses, Hurwich, Adar, Eliahov, and Bogokowsky, 1970; Perez-Alvarez, Vargus-Rosendo, Gutierrez-Bosque, Matos Diaz-Ordaz, and Santo-Atherton, 1970; Ton That, Lazorthes, Conte, Gouzi, Escat, and Suc, 1970; Hehrlein, Abe, and Goubeaud, 1971). This paper reports on the construction, usefulness, and complications of such loops in 9 patients.

PATIENT SELECTION

During the past 2 years 9 patients on regular dialysis therapy have required saphenous vein autotransplants to provide continued access to the circulation. The 9 patients were from the three dialysis units in Glasgow, the total dialysis population during this period being 74. Five of the patients were female and 4 male with an age range of 18–41 years. In 6 of the patients the vein loop was in situ prior to transplantation and of these, 4 have subsequently had a renal transplant. In 3 patients the vein loop was inserted following failure of a renal transplant, 1 of whom has had a total of 3 loops inserted.

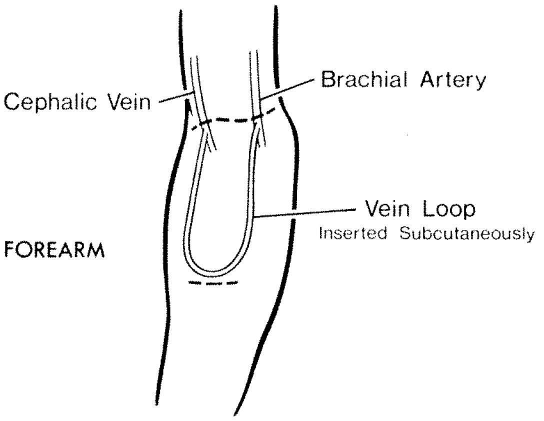

FIG. 1.—Method of subcutaneous insertion of a saphenous vein loop.

Table I.—FUNCTIONAL RESULTS AND COMPLICATIONS FOLLOWING SAPHENOUS VEIN LOOP INSERTION

PATIENT	DIALYSIS	LENGTH OF TIME (mth.)	COMPLICATIONS

G. W.	Good	3*	—
C. R.	Good	2*	—

* Continues to function at present time.
† This patient required 3 autogenous vein-grafts.

OPERATIVE TECHNIQUE (*Fig.* 1)

Under general anaesthesia an oblique incision is made in the antecubital fossa to allow access to the brachial artery and a suitable vein. Both vessels are mobilized over a distance of about 6 cm. and controlled with appropriate slings.

A long saphenous vein is next removed from the groin to the knee and its branches ligated. The vein is distended with heparinized saline and excess adventitia removed. The vessel is next reversed and laid on the front of the forearm under slight tension in the form of a loop. A small incision is made at the base of the projected course of the vein, and using artery forceps, subcutaneous tunnels are developed. The vein is then pulled into the tunnel so that its ends lie opposite the brachial artery and the chosen vein.

At this stage the patient is given 5000 U. of heparin intravenously, and the brachial artery is clamped. A longitudinal arteriotomy is made and the vessels are anastomosed end to side using continuous 000000 silk. At the conclusion of this anastomosis the arterial clamp is temporarily released to ensure that the graft is not twisted. The venous end of the vein loop is then completed in the same fashion. The patency of the chosen vein should be checked prior to the anastomosis. This is performed by passing a No. 3 Fogarty embolectomy catheter proximally into the vein. Following the procedure, the patient should be anticoagulated for 24 hours with heparin (5000 U., 6-hourly).

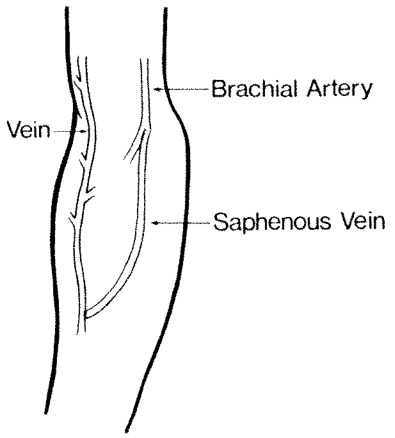

FIG. 2.—Alternative method of insertion of a saphenous vein as a straight segment. This procedure may be modified according to the availability of the venous drainage.

In 2 patients, because of the lack of a suitable vein in the antecubital region, the saphenous vein was sutured from the brachial artery to a small forearm vein in 1 case (C. R.) and to a vein in the upper arm in the second patient (M. McC.) (*Fig.* 2).

RESULTS

The autogenous saphenous vein loops have functioned satisfactorily for up to 18 months (*Table I*) for the purposes of haemodialysis in all except 1 patient (M. McC.). In general, unless the need is urgent the graft should not be used for dialysis purposes for 6 weeks. This interval allows the vessel to become arterialized and minimizes subsequent damage from repeated puncture. Because of this the operation should be planned several weeks prior to use.

The dialysis technique is similar to that employed with internal arteriovenous fistulae, the needles being inserted into the ascending and descending limbs of the loops. Following cannulation, satisfactory flow rates in excess of 300 ml. per minute have been achieved in most patients and blood-urea and creatinine figures confirm that the dialysis is as efficient as when an arteriovenous fistula or shunt is used. Excessive venous back pressure has been a problem in 2 cases and will be discussed later.

COMPLICATIONS

1. Clotting.—None of the loops clotted in the immediate postoperative period, but 3 thrombosed several months after a successful renal transplant. The reason for this phenomenon is not clear but it is known also to occur with conventional arteriovenous fistulae. The vein loop in 1 patient (M. McC.) thrombosed during dialysis.

2. Aneurysm Formation.—Repeated needling for dialysis has resulted in aneurysm formation in 1 patient (A. A.). A saccular aneurysm formed when the loop was needled for blood sampling shortly after its insertion. This aneurysm proved simple to repair under local anaesthesia and did not compromise the future of the use of the loop.

3. High Venous Back Pressure.—This occurred in 2 patients, though it did not decrease the efficiency of the dialysis. Arteriograms in these patients (M. McC. and M. McM.) (*Fig.* 3) show stenosis of the vessels distal to the anastomosis. These areas of narrowing were probably present prior to the creation of the vein loop and an alternative vein should have been used. Both vein loops subsequently clotted, one after transplantation and the other during a dialysis.

4. Dilatation of the Vein Loop.—In 1 patient (M. L.) the saphenous vein was noticed to be moderately varicosed. Several weeks after insertion it began to increase in diameter, eventually reaching a size of 2·5 cm. The cardiac output in this patient was estimated at 13 litres per minute and the patient subsequently died in congestive cardiac failure. The contribution which the loop made to the cardiac failure is difficult to assess.

5. Failure during Dialysis.—Failure during dialysis occurred in 1 patient (M. McC.). This patient had a high venous back pressure and the graft thrombosed after functioning satisfactorily for 1 year. Embolectomy under local anaesthesia restored the patency for a further 4 months, after which it clotted completely. A second loop was therefore performed in the other arm and unfortunately became infected, with subsequent haemorrhage necessitating ligation of the brachial artery above the loop. In this patient, and in 1 other (C. R.) where suitable antecubital veins were not available, the saphenous vein was anastomosed to the brachial artery and to a vein lower in the forearm. Although technically more difficult this procedure had the advantage of allowing other venous channels in the forearm to become arterialized and therefore available for cannulation.

DISCUSSION

The problem of access to the circulation will continue to be a challenge to surgeons who are associated with a regular dialysis programme. Fortunately, the use of arteriovenous fistulae has obviated many of the earlier difficulties with shunts, and they continue to function well in the long term. However, a small percentage of patients (in our series 12 per cent) will require alternative procedures. Autogenous saphenous veins have been used for many years in peripheral vascular surgery, with a 5-year patency of around 60 per cent (De Weese and Rob, 1971). Although we have used the long saphenous vein, arterialized by anastomosis to the brachial artery, the technique is versatile and can be adapted to suit available arteries and veins. Moses and others (1970), for example, used the ulnar artery at the wrist and a vein in the antecubital fossa, and Girardet and others (1970) have described the use of very long grafts, from the ulnar artery to the cephalic vein at the upper third of the arm. In 2 of our patients straight grafts rather than vein loops were required.

In the long term it will be important to know the useful life of these grafts. The longest period reported is 12 months (Girardet and others, 1970), and our own results show that they may be used for periods of up to 18 months. Two factors are probably important in securing long-term patency. First, the graft should not be used for a period of 6–8 weeks until it has become arterialized. This time allows the vein wall to thicken and thus contract when the needle is removed after dialysis. Secondly, care should be taken to ensure that the vein draining the loop is not narrowed by previous thrombophlebitis. Preoperative venography may be used to assess the patency of the venous drainage or, alternatively, a Fogarty embolectomy catheter may be used for direct evaluation at operation.

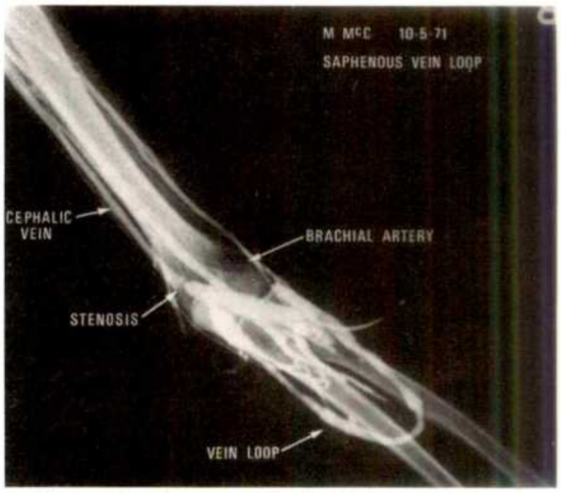

FIG. 3.—Arteriogram via the brachial artery, showing the vein loop and a stenosis at the venous end proximal to the anastomosis.

One patient in this series died in cardiac failure with a functioning graft (M. L.). The vein loop was dilated and a shunt of this size could conceivably have added considerably to the cardiac output. In retrospect the vessel should not have been used in this patient; it was moderately varicose and we would not use such a vessel in the future. Johnston and Blythe (1970) have shown that conventional arteriovenous fistulae normally used for dialysis do result in an increased cardiac output. We are currently assessing the importance of these loops on the haemodynamics of patients on regular dialysis.

Other potential drawbacks such as subacute bacterial endocarditis (Hook, Hainer, McGee, and Fellers, 1957) or ischaemic syndromes of the hand (Storey, George, Stewart, Tiller, May, and Sheil, 1969) have not been observed in our patients.

Although our experience with autogenous saphenous vein loops has been very satisfactory they should be looked upon principally as a method to be used on those patients with no alternative method of gaining access to the circulation. We believe, therefore, that the Cimino-Brescia fistula remains the procedure of choice in patients commencing regular haemodialysis, because of its ease of construction and reliability for long-term use.

FACTORS INFLUENCING PROGNOSIS IN THE SURGERY OF PERIPHERAL VASCULAR DISEASE: PLATELET ADHESIVENESS, PLASMA FIBRINOGEN, AND FIBRINOLYSIS*

BY J. D. HAMER, F. ASHTON, AND M. J. MEYNELL

THE DEPARTMENTS OF SURGERY AND HAEMATOLOGY, QUEEN ELIZABETH HOSPITAL, QUEEN ELIZABETH MEDICAL CENTRE, BIRMINGHAM

SUMMARY

A study of 76 patients having aorto-iliac (46) and femoropopliteal (30) surgery for atherosclerosis has shown a significant correlation between increased platelet adhesiveness, prolonged clot lysis, and failure of the reconstruction between 3 months and 5 years after operation. In addition, a raised plasma-fibrinogen level, persisting 1 year after reconstruction, is often associated with failure. Patients having predominantly femoropopliteal disease show a significantly higher plasma-fibrinogen level than those with localized aorto-iliac disease. This correlation is such that when a high plasma-fibrinogen level is found in a patient with the clinical features of aorto-iliac disease it may be inferred that the femoropopliteal segment is also involved.

ADVANCES in the technical management of occlusive arterial disease are increasingly accompanied by efforts to understand the processes responsible for failure of arterial reconstruction. Failures which occur immediately after operation are usually related to faulty surgical technique (DeBakey, Crawford, Morris, Cooley, and Garrett, 1964) or to an abrupt fall in cardiac output. It is often more difficult to account for failure at a later date.

While our efforts are being directed at the complications, rather than the underlying nature, of atherosclerotic disease, we must expect to encounter failures associated with recurrent disease (Szilagyi, Smith, and Whitney, 1964) and new distal or proximal disease. Lesions resembling atheroma may develop in autogenous vein-grafts (Butzner, 1947), and Walton (1972) has demonstrated lipoprotein deposits in the interstices of prosthetic fabric grafts.

Although long-term results of proximal (aorto-iliac) surgery are better than those of distal (femoropopliteal) surgery (DeBakey and others, 1964), prolonged patency of vein-grafts under conditions of low blood-flow has been described by Mannick, Jackson, Coffman, and Hume (1967). This resistance to thrombosis may be related to the intrinsic fibrinolytic activity of vein tissue (Pandolfi, Nilsson, Robertson, and Isaacson, 1967). We have histochemical evidence of plasminogen activation in a vein-graft removed after several years as a substitute artery.

Blood containing excessively adhesive platelets has been found in patients with atherosclerosis of coronary arteries by McDonald and Edgill (1957) and in patients showing late thrombosis of femoropopliteal by-pass grafts (Evans and Irvine, 1966; Evans and Mustard, 1968).

Nestel (1960) found diminished fibrinolytic activity of the blood in patients with coronary artery and peripheral vascular stigmata of atherosclerosis.

In the context of this study 'early' graft failure is that which occurs during the first 3 postoperative months, subsequent failures being regarded as 'late'. We have studied the blood of patients subjected to aorto-iliac and femoropopliteal surgery, with the intention of seeking a correlation between late graft failure, platelet adhesiveness, plasma fibrinogen, and levels of serum fibrinolytic activity.

PATIENTS AND METHODS

Seventy-six patients were investigated, 46 having aorto-iliac surgery and 30 reconstruction of the femoropopliteal segment. The blood of 68 patients was examined preoperatively, venepuncture of non-congested veins being performed with the patient under basal conditions, including abstinence from smoking. Haematological study of the remaining 8 patients was carried out retrospectively, from 2 to $4\frac{1}{2}$ years after operation.

---

* Based on a paper presented to the Surgical Research Society in July, 1971, and to a symposium on 'Recent Advances in the Surgery of Peripheral Vascular Disease' at the Royal Postgraduate Medical School in November, 1971.

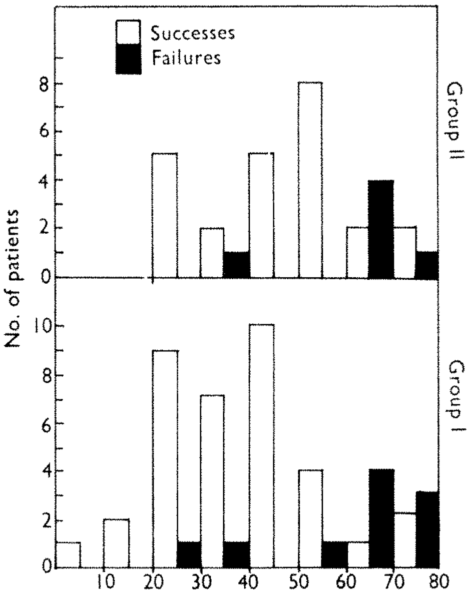

FIG. 1.—Patients having successful and failed grafts in relation to platelet adhesiveness.

Of the 30 femoropopliteal reconstructions, all were autogenous vein by-pass grafts. In the aorto-iliac group, 11 patients had thrombo-endarterectomies performed, and the remaining 35 had by-pass grafts using 'Dacron' or 'Teflon' prostheses.

No patient in whom reconstruction failed during the first 3 postoperative months has been included.

The mean postoperative follow-up period was 28 months, with a range from 6 to 62 months.

Platelet adhesiveness was measured using the rotating glass-bulb technique introduced by Wright (1941). Platelet counts were performed by hand to an accuracy of ±5 per cent. Platelet adhesiveness is defined as the difference in platelet count before and after rotation for 20 minutes expressed as a percentage of the initial count.

Total plasma fibrinogen was measured colorimetrically, as described by Varley (1967), and the heparin-precipitable fraction (H.P.F.) estimated by the method of Smith (1957).

Fibrinolytic activity was estimated by measuring dilute clot lysis times (Fearnley, Balmforth, and Fearnley, 1957) and euglobulin lysis times (von Kaulla, 1963).

RESULTS

The results of surgical treatment and mean ages of patients in group I (femoropopliteal by-pass grafts) and group II (aorto-iliac reconstruction) are summarized in *Table I*. Patients whose grafts were found to have failed during the follow-up period will be described as 'failures' and those with patent reconstructions as 'successes'. The even distribution of patients by age is noteworthy.

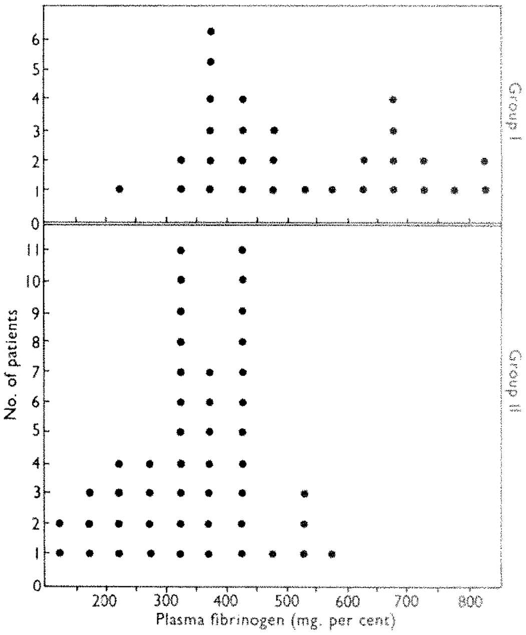

FIG. 2.—Distribution of plasma-fibrinogen level in both groups.

Table I.—NO. OF PATIENTS IN EACH GROUP

GROUP	OVERALL TOTAL		SUCCESSES		FAILURES	
	No. of Patients	Mean Age (yr.)	No. of Patients	Mean Age (yr.)	No. of Patients	Mean Age (yr.)
I	30	59·3	24	58·3	6	63·3
II	46	55·6	36	55·9	10	54·4
Total	76		60		16	

Platelet Adhesiveness.—*Fig.* 1 shows the distribution of patients in groups I and II, and illustrates that in both groups most failures lie in the range of high adhesiveness. Statistical separation of successes and failures is shown in *Table II*, confirming that the platelets of patients whose operations fail lie in a significantly higher adhesive range than those of the successes.

The mean level for all patients in group I was 50·4 per cent, which is significantly higher than the 43·8 per cent found in group II ($P < 0·01$).

Plasma Fibrinogen.—The overall mean level for the population studied was 422·6 mg. per cent. Histograms for both groups (*Fig.* 2) illustrate a group separation, but with considerable overlap. Further analysis of these data (*Table III*) reveals a significant overall difference in plasma fibrinogen between groups I and II ($P < 0·001$).

No difference in the plasma-fibrinogen level was demonstrated between successes and failures in

61 patients followed up from 3 to 12 months postoperatively. However, patients followed up for *more* than 12 months have been studied separately, and of 15 cases in this category, 8 successes showed a mean plasma fibrinogen level of 276 mg. per cent while 7 failures had a significantly higher level of 452·0 mg. per cent ($P < 0{\cdot}01$). It seems possible then that a high level of fibrinogen in the plasma may only prove of prognostic significance when a graft has functioned successfully for at least 12 months.

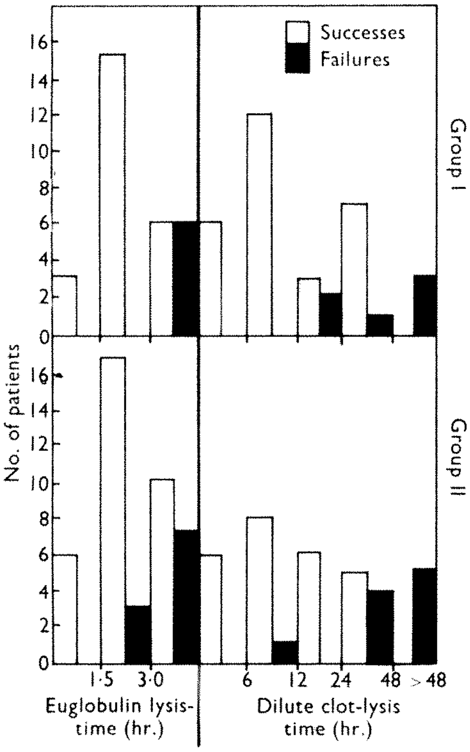

FIG. 3.—Clot-lysis times for patients in group I (above) and group II (below).

Heparin-precipitable Fraction of Fibrinogen (Smith and von Korff, 1957).—While the overall mean values for H.P.F. show no significant separation between groups (*Table IV*) the high value for failures in group II (123·9 mg. per cent) is conspicuous.

Fibrinolysis.—Estimation of clot-lysis times in both groups, using dilute clot lysis and euglobulin lysis methods (*Fig.* 3), shows a clear distribution of patients with 'failed' operations in the slow lysis ranges. While many patients whose operations succeeded showed rapid clot lysis, this was not observed in any patient in the 'failed' category. When the values for the whole series of 76 patients were examined the successes showed significantly more rapid lysis times than the failures ($P < 0{\cdot}01$). There was no apparent overall difference between groups I and II.

Association between Platelet Adhesiveness and Plasma Fibrinogen.—Quadrant analysis of values for these parameters, examining low and high ranges divided at their means, revealed a statistically significant correlation between high levels of adhesiveness and high plasma fibrinogen ($\chi^2 = 12{\cdot}4$; $P < 0{\cdot}001$).

DISCUSSION

The incidence of failure after arterial reconstruction during the late postoperative period in this small series is similar to that previously reported (Szilagyi, Smith, Elliot, and Allen, 1965; Baddeley, Ashton, Slaney, and Barnes, 1970; DeWeese and Rob, 1971) but we should point out a degree of bias in favour of our success rate since not all the patients have been followed for 5 years, and several which have been documented here as successes may subsequently 'fall' into the failure category. As has been pointed out (DeWeese and Rob, 1971), 50 per cent of patients having femoropopliteal vein by-pass grafts are likely to die from sequelae of atherosclerosis before reaching the 5-year follow-up stage, and we may expect a reduced number of 'successes' when assessment is made after 5 years. This reduction in size of each group will, therefore, tend to balance the failures taking place during the 1–5-year period.

Table II.—MEAN VALUES FOR PLATELET ADHESIVENESS AND SIGNIFICANCE OF SEPARATION FOR SUCCESS AND FAILURE

GROUP	PLATELET ADHESIVENESS PERCENTAGE (MEAN)		
	Successes	Failures	*P*
I	47·8	61·0	<0·01
II	39·9	58·0	<0·01

Table III.—PLASMA FIBRINOGEN

GROUP	MEAN PLASMA FIBRINOGEN (mg. per cent)					
	Overall		*Successes*		*Failures*	
	Amount	No. of Cases	Amount	No. of Cases	Amount	No. of Cases
I	532·4	30	523·9	24	566·5	6
II	351·0	46	342·3	36	382·4	10
	$P < 0{\cdot}001$					

Table IV.—HEPARIN-PRECIPITABLE FIBRINOGEN

GROUP	MEAN VALUES FOR HEPARIN PRECIPITABLE FIBRINOGEN (mg. per cent)		
	Overall	*Successes*	*Failures*
I	80·1	84·4	62·8
II	93·2	85·5	123·9
	$P > 25$ (N.S.)		

Our observations showing a correlation between the late failure of femoropopliteal by-pass grafts and increased platelet adhesiveness are complementary to those reported previously concerning aorto-iliac reconstructions (Hamer, 1972) and support the findings of other workers (Evans and Irvine, 1966; Evans and Mustard, 1968). Although we have found an association between high platelet adhesiveness and elevated plasma fibrinogen, the latter parameter appears to be a less reliable prognostic indicator, despite the striking observation that occlusion taking place after 12 months of successful function is frequently associated with high plasma-fibrinogen levels.

Of considerable interest is the observation that patients in group I showed markedly raised levels of plasma fibrinogen. Of the 30 patients in this group, 27 showed no obvious evidence of proximal arterial disease. Conversely, of 4 patients in group II showing plasma-fibrinogen levels exceeding 500 mg. per cent, radiological evidence of tibial atherosclerosis was found in 3 cases. It appears that a high level of plasma fibrinogen is frequently associated with the presence of peripherally situated arterial disease and we suggest that measurement of this parameter is of value in drawing attention to unsuspected distal lesions in patients presenting with predominantly aorto-iliac disease. The source of fibrinogen in patients with peripheral disease has not yet been positively identified, but we have recently reported the early results of an experimental study suggesting that a marked rise in plasma fibrinogen follows deposition of fibrin within *and* outside blood-vessels, there being an associated release of fibrin degradation products (F.D.P.) which may or may not be detectable in the serum (Farrell, Hamer, and Wolf, 1972). We share with Young and Kolmen (1970) the opinion that thrombolysis may provide a stimulus to release of fibrinogen from the liver or platelets, and it is possible that thrombosis and thrombolysis taking place within small peripheral arteries may account for the high plasma fibrinogen observed in patients in group I. The surface area of diseased vessel exposed to circulating blood in patients with small-vessel disease is far greater than that in patients with aorto-iliac disease. This aspect of our work awaits confirmation and is the subject of further study.

Although the results of this investigation suggest that preoperative identification of abnormally adhesive platelets and defective fibrinolytic capability should encourage a guarded long-term prognosis, we would seldom advise against reconstructive surgery in the presence of clear positive clinical indications.

Acknowledgements.—This study was generously supported by a grant from the Endowment Research Fund of the United Birmingham Hospitals. We acknowledge the technical help given by Miss N. Pejhan and Mrs. K. McCann, and wish to thank Mrs. P. Prior for her help with statistical analyses.

GASTRIC ULCER TREATED BY VAGOTOMY, PYLOROPLASTY, AND ULCERECTOMY

BY H. A. DANIELS AND A. W. B. STRACHAN

BARROW AND FURNESS GROUP OF HOSPITALS

SUMMARY

Sixty-two patients with gastric ulcers have been treated by vagotomy, pyloroplasty, and excision of the ulcers from 1963 to 1971. There has been only 1 recurrence.

It is suggested that excision of the ulcer is an important step in conservative surgery for gastric ulcer.

No one really knows why partial gastrectomy prevents the recurrence of gastric ulcers. The operation (1) improves the drainage, (2) reduces the acidity, and (3) usually removes the ulcer. Up to 1962 this was the standard operation for gastric ulcer in Barrow but by that time vagotomy and pyloroplasty had become the operation of choice for duodenal ulcer and we felt that it might be reasonable to use the latter procedure in cases of gastric ulceration. This would improve stomach drainage and reduce acidity. If ulcerectomy were added it would provide the third factor and ensure that a carcinoma was not being missed.

Since then the majority of gastric ulcers have been treated by this method. Partial gastrectomy has been used in some cases of doubt regarding carcinomas and also in some cases of antral ulcers. Vagotomy was sometimes added. In other patients, where the ulcer appeared to be healed or very small, vagotomy and pyloroplasty only were carried out.

TECHNIQUE

The vagotomy has been truncal in most of the cases. Selective vagotomy adds considerably to the difficulty of the operation especially with an indurated lesser-curve ulcer, and we have not been convinced it makes much difference to the incidence of severe diarrhoea.

Table I.—TYPE OF OPERATION FOR 107 GASTRIC ULCERS TREATED SURGICALLY

Type of Operation	*No. of Cases*
Vagotomy, pyloroplasty, and ulcerectomy	62
Vagotomy and pyloroplasty	23
Partial gastrectomy ± vagotomy	22

* 8 per cent overall.

Lesser-curve ulcers are easy to excise and it is often unnecessary to clear the lesser curve of vessels and fat. The stomach is opened close to the ulcer, the crater is inspected, and if benign (apparently) it is excised working from the mucosal surface. In this way it is possible to keep close to the ulcer margin.

The ulcer can sometimes be cored out of the thickness of the stomach wall with a relatively small opening in the stomach. The hole left is, however, surprisingly large. It is closed with catgut in two layers. If there is much fibrous thickening the deep layer takes the mucosa only and the seromuscular layer approximates the thickened wall without inversion.

Large posterior ulcers are more difficult and sometimes it is necessary to make an anterior gastrostomy in order to inspect them. This is most important if any doubt about malignancy exists. It is much easier to spot a benign ulcer with its punched out edges and fibrous floor in this way. The posterior ulcer can then be excised working through the gastrostomy if approach through the lesser sac is difficult.

An ulcer that appears malignant from the outside may well prove benign when seen from the inside. Radical gastrectomies for simple ulcers should be avoided at all costs.

For the past 2 years Ryle's tubes have been removed at the end of the operation and very rarely need to be reinserted.

MATERIAL

The number of gastric ulcers treated from 1963 to 1971 was 107 (*Table I*). Of these, 62 were treated by vagotomy, pyloroplasty, and ulcerectomy, 23 by vagotomy and pyloroplasty, and 22 by partial gastrectomy, sometimes with added vagotomy.

Table IV.—TYPE OF OPERATION COMPARED WITH THE CAUSE AND TIME OF DEATH IN 8 CASES

OPERATION	CAUSE OF DEATH	TIME OF DEATH (Day after Operation)	AGE (yr.)	COMMENT
Vagotomy, pyloroplasty, and ulcerectomy	Pulmonary embolus	5	74	Bleeding gastric ulcer. No postoperative bleeding
Vagotomy, pyloroplasty, and ulcerectomy	Pulmonary embolus	6	56	—
Vagotomy, pyloroplasty, and ulcerectomy	Coronary thrombosis	4	51	—
Vagotomy, pyloroplasty, and ulcerectomy	Diarrhoea	7	56	Staphylococcal enteritis
Vagotomy and pyloroplasty	Persistent bleeding	2	83	Bleeding never stopped
Vagotomy and pyloroplasty	Persistent bleeding	14	67	Ulcer oversewn; bleeding recurred; ulcer excised on the day before death
Partial gastrectomy	Persistent bleeding	1	56	Bleeding splenic artery; 13 pints of blood transfused on the day of operation
Gastrectomy	Oesophageal leak	7	46	Total gastrectomy for a supposed malignant ulcer high up. Leak from oesophagus 1 cm. above suture line

Twenty-two gastric ulcers were associated with duodenal ulcers. This is a minimal figure as it is likely that not every duodenal ulcer scar was mentioned in the notes when the immediate concern was with a gastric ulcer.

Table II shows that 6 of the gastric ulcers presented as acute perforations and were dealt with by vagotomy, pyloroplasty, and ulcerectomy in 5 cases and by vagotomy, pyloroplasty, and suture in 1 case. None of these patients died.

There were 12 bleeding gastric ulcers which did not fare as well as the perforations. Eight were dealt with by vagotomy, pyloroplasty, and ulcerectomy with 1 death, 2 by vagotomy, pyloroplasty, and suture with 1 death, and 2 by partial gastrectomy with 1 death. Details of these deaths will be dealt with later.

The results of the operations are shown in *Table III*, each type of operation showing about a 95 per cent satisfactory result (Visick grades 1 and 2). Three patients were lost to follow-up but none of these was having symptoms when last seen. Only 1 patient of the vagotomy, pyloroplasty, and ulcerectomy series has not been followed up. He was an Indian seaman with a perforated gastric ulcer who returned to India after the operation. One patient developed a recurrence of her gastric ulcer. It was a high lesser-curvature ulcer treated by selective vagotomy, pyloroplasty, and ulcerectomy in 1969. It recurred in 1972 and has been dealt with by a high Billroth-I partial gastrectomy. The recurrence was in the scar where the ulcer had been previously excised.

The causes of death are shown on *Table IV*. Of the vagotomy, pyloroplasty, and ulcerectomy cases, 2 died from emboli and 1 from coronary thrombosis. The fourth patient had diarrhoea, thought to be of staphylococcal origin, and died of bronchopneumonia, probably from excess fluid replacement. Of the vagotomy and pyloroplasty deaths, both were due to persistent bleeding in patients operated on as emergencies for bleeding ulcers.

One of the partial gastrectomy patients who died was also operated on for bleeding, the source being the splenic artery in the floor of a large posterior ulcer.

The second gastrectomy death was the result of misdiagnosing a high posterior gastric ulcer as malignant and carrying out total gastrectomy. The ulcer was in fact benign. Death was from an oesophageal leak about 1 cm. above the suture line, possibly the result of a cut-out suture.

DISCUSSION

There seems to be considerable discrepancy between the reported results of gastric ulcers treated by vagotomy and pyloroplasty. Hendry and Bahrani (1965) treated all types of gastric ulcer by vagotomy and pyloroplasty, and followed their patients carefully until healing, as judged radiologically, was achieved. They reported 98 per cent satisfactory results in patients followed for 6 months to 6 years.

On the other hand, Duthie, Moor, Bardsley, and Clark (1970) and Douglas and Duthie (1971) found that ulcers of the body of the stomach treated by vagotomy and pyloroplasty showed a high recurrence rate, only 79 per cent of cases being satisfactorily cured, while combined duodenal ulcer and gastric ulcer cases showed a 97 per cent satisfactory rate after vagotomy and pyloroplasty.

Clarke, Lewis, and Williams (1972) reported 4 recurrences after vagotomy and pyloroplasty for gastric ulcer, 3 of them being in patients with combined duodenal and gastric ulcers. They concluded that vagotomy and pyloroplasty comprise a sound operation for a high ulcer or a bleeding ulcer but not for combined ulcers.

Kennedy, Kelly, and George (1972) also reported 4 recurrences in 66 patients treated by vagotomy and pyloroplasty, 3 of them being in patients with ulcers of the body or lesser curve of the stomach. They suggested that vagotomy and pyloroplasty are suitable for antral or combined ulcers but not for high ulcers.

In the present series 62 patients had vagotomy, pyloroplasty, and ulcerectomy with 1 recurrence. It is suggested that excision of the ulcer is important in the prevention of recurrence.

A feature of gastric ulcers which is not often stressed is their tendency to inhabit one particular site in the stomach. If the ulcer heals and recurs it is found in the same place each time.

It is unusual at operation to see more than one gastric ulcer or the scars of other gastric ulcers that have healed. If conditions favourable to the formation of gastric ulcers obtain one could expect more than one ulcer to form or if healing occurred recurrence could be expected anywhere in the stomach. This is what happens in the duodenum where it is common to find more than one active ulcer and perhaps the scars of two or three others in the first 3·5 cm. of the duodenum.

It therefore seems likely that there is some local factor at the actual site of the gastric ulcer which causes the ulcer to form repeatedly at the same site. If there is a locus minoris resistentiae, then excision of this area might well be important in the prevention of recurrence of gastric ulcers. When Billroth-I gastrectomy is carried out for gastric ulcer surgeons go to considerable pains to remove the ulcer and only leave it behind if it is situated adjacent to the oesophagus. If the same care was taken to excise the ulcer when vagotomy and pyloroplasty was carried out it is suggested that recurrence would be rare.

A CIRCULATING DEPRESSANT EFFECT FOLLOWING CANINE HAEMORRHAGIC SHOCK

By W. D. FISHER, D. W. HEIMBACH, C. S. McARDLE, M. MADDERN,
MAUREEN M. HUTCHESON, AND I. McA. LEDINGHAM

UNIVERSITY DEPARTMENT OF SURGERY, WESTERN INFIRMARY, AND DEPARTMENT OF PHARMACOLOGY, UNIVERSITY OF STRATHCLYDE, GLASGOW

SUMMARY

Following periods of 1 or 3½ hours of haemorrhagic shock in 12 anaesthetized ventilated greyhounds, ultrafiltrates of plasma taken 4 hours after retransfusion exibited significantly increased depressant activity on guinea-pig atrium *in vitro*. This effect was significantly greater following prolonged hypotension and could not be accounted for by changes in electrolyte composition. It is suggested that this effect may be related to defective myocardial function following haemorrhagic shock.

SEVERAL investigators have described impaired performance of the heart following canine haemorrhagic shock (Gomez and Hamilton, 1964; Siegel and Downing, 1970). Lefer and his colleagues (Brand and Lefer, 1966; Lefer, 1970; Lefer and Martin, 1970) have postulated that this effect is due to a circulating peptide present in the post-shock plasma of cats and dogs following haemorrhagic, endotoxic, and cardiogenic shock. In spite of the potentially important clinical implications this observation has not received independent substantiation. The following study presents the results of a continuing investigation in dogs.

MATERIALS AND METHODS

Twelve greyhounds (weight range 23–32 kg.) were anaesthetized and ventilated and subjected to controlled haemorrhage into a reservoir until the mean arterial blood-pressure was 35–40 mm. Hg. The arterial pressure was maintained at this value for 3½ hours in 6 dogs and for 1 hour in another 6 animals. Following the period of hypotension in both groups of dogs all the remaining shed blood was retransfused. The animals were then observed for a further period of 4 hours. The haemodynamic and metabolic results of these studies are reported in detail elsewhere (Ledingham, Heimbach, Hutton, and McArdle, 1971; Heimbach, Fisher, Hutton, McArdle, and Ledingham, 1972).

Processing of Plasma.—Arterial blood-samples (50 ml.) were removed prior to haemorrhage (control) and at the conclusion of each experiment, i.e., 4 hours after the retransfusion of the shed blood (post-hypotension). The blood samples were placed immediately in ice-cold heparinized centrifuge tubes containing 1 per cent v./v. dextran 70 and spun at 4° C. for 20 minutes at 2000 × *g* and the supernatant plasma was frozen until required. Samples of plasma were filtered at 4° C. through a Diaflo (Amicon Corp., Lexington, U.S.A.) filter UM-10 (cut off M.W. 10,000). The resultant ultrafiltrates were then assayed.

Assay.—Guinea-pigs were killed and the left atrium was removed rapidly and placed in modified Krebs-Henseleit buffer (Lefer, 1966) previously equilibrated with 95 per cent O_2/5 per cent CO_2. The atrium was mounted on the positive electrode in a 5-ml. organ bath at 33° C. and suspended under 600 mg. of tension on a Nihon Kohden (Tokyo, Japan) force-displacement transducer attached to a Devices recorder (Devices Instruments Ltd., Welwyn Garden City). The atrium was stimulated supramaximally with a square-wave stimulator at 2 Hz. Samples for assay were brought to bath temperature and equilibrated with 95 per cent O_2/5 per cent CO_2, following which the *p*H fell to 7·35. When a stable developed tension had been obtained the bath was emptied and the sample added. The activity of the atrium was then followed until a new stable developed

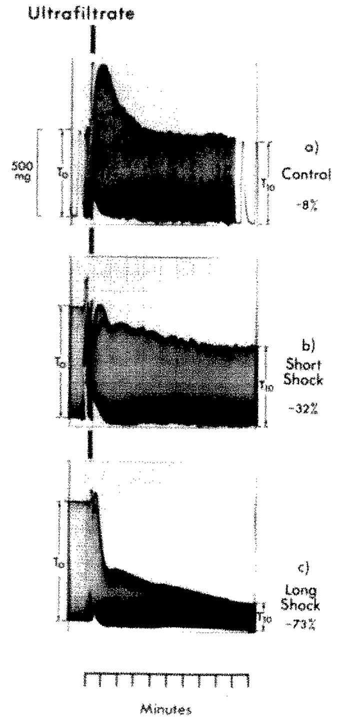

FIG. 1.—Tracings of assays of 3 ultrafiltrates from (a) control sample and post-hypotension samples (b) following 1 hour of hypotension (short shock) and (c) following 3½ hours of hypotension (long shock). The values of developed atrial tension at 10 minutes (T_{10}) were expressed as a percentage of the developed tension in Krebs-Henseleit buffer (T_0). The percentage depressions for each assay are shown.

tension had been achieved and the percentage change in developed tension at 10 minutes was recorded.

Samples of ultrafiltrates of control and post-hypotension blood were also analysed to determine their electrolyte content; sodium and potassium by flame ionization photometry, chloride by titration, calcium and magnesium by atomic absorption spectrometry.

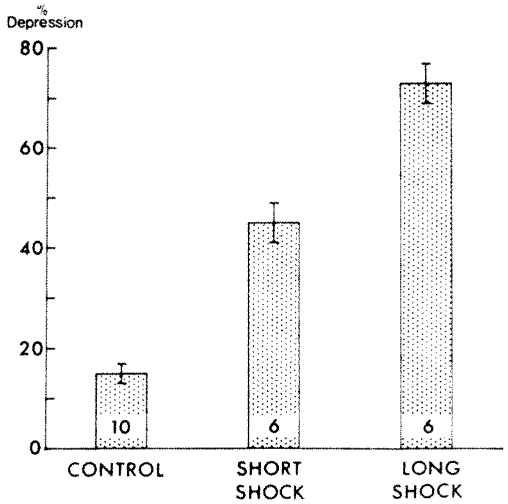

FIG. 2.—Mean percentage depression and standard error of the mean of samples of control ultrafiltrates and post-hypotension ultrafiltrates following 1 hour (short shock) and 3½ hours (long shock) of hypotension. Figures are the number of dogs in each group.

Table I.—ELECTROLYTE COMPOSITION OF THE ULTRAFILTRATE FROM 6 CONTROL AND 6 POST-HYPOTENSION (3½ HOURS' DURATION) DOGS

ELECTROLYTE	CONTROL GROUP (mEq./l.)	POST-HYPOTENSION GROUP (mEq./l.)
Sodium	161 ± 9	151 ± 9
Potassium	4·0 ± 0·2	6·2 ± 0·9
Chloride	104 ± 12	74 ± 3
Calcium	2·1 ± 0·3	1·7 ± 0·2
Magnesium	0·96 ± 0·08	1·74 ± 0·14

RESULTS

Typical tracings of assays of a control ultrafiltrate and of post-hypotension ultrafiltrates from each of the two groups of animals are shown in *Fig.* 1. A variable but consistent initial increase in developed tension occurred after the addition of all the ultrafiltrates but in the shock samples it was masked by the magnitude of the atrial depression. The initial increase in developed tension after addition of the ultrafiltrate is the result of exposure of the atrium on emptying the organ bath. The mean percentage depression of developed tension in the control group and both groups of bled animals is shown in *Fig.* 2. Control samples exerted a depression of 15 ± 2 per cent (mean ± standard error of the mean). Following 1 hour of hypotension the depression had increased to 45 ± 4 per cent ($P < 0{\cdot}001$) and had increased significantly further after 3½ hours' shock to 73 ± 4 per cent ($P < 0{\cdot}005$).

A sample from 1 dog subjected to 3½ hours of hypotension was diluted in varying amounts of Krebs-Henseleit buffer. These dilutions were then assayed. The results are shown in *Fig.* 3. An exponential regression was obtained ($r = 0{\cdot}95$).

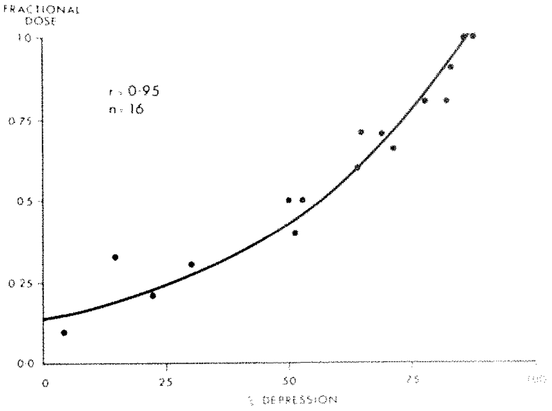

FIG. 3.—Exponential regression analysis of dilutions in Krebs-Henseleit buffer of an ultrafiltrate from an animal subjected to 3½ hours of hypotension against the percentage depression obtained in assays of each dilution.

The electrolyte composition of 6 control and 6 post-hypotension (3½ hours' duration) ultrafiltrates is shown in *Table I*. Sodium concentration did not change (161 ± 9 and 151 ± 9 mEq./l. in control and post-hypotension samples respectively); calcium concentration was also unchanged (2·1 ± 0·3 and 1·7 ± 0·2 mEq./l. respectively). There was a rise after hypotension in both potassium (4·0 ± 0·2 to 6·2 ± 0·9 mEq./l.; $P < 0{\cdot}05$) and magnesium (0·96 ± 0·08 to 1·74 ± 0·14 mEq./l.; $P < 0{\cdot}001$) concentrations and a fall in chloride concentration (104 ± 12 to 74 ± 3 mEq./l.; $P < 0{\cdot}05$).

DISCUSSION

It has been reported that prolongation of hypotension results in diminished myocardial contractility (Regan, LaForce, Teres, Block, and Hellems, 1965). In our experimental model prolongation of hypotension resulted in an increase in the depressant activity of resuscitation plasma. The values following 3½ hours of hypotension corresponded to that found by Wangensteen, DeHoll, Kiechel, Martin, and Lefer (1970), using a different assay system but with a similar degree of hypotension. The possibility of electrolyte changes contributing to this effect was considered. Although there was a rise in potassium concentration the value following hypotension corresponded to that of the Krebs-Henseleit buffer. However, the rise in magnesium concentration did not reach the concentration in the Krebs-Henseleit buffer. As protein-bound calcium is removed by ultrafiltration the ultrafiltrate calcium concentration was lower than plasma total calcium concentration and also Krebs-Henseleit buffer calcium concentration. This might have contributed to the small but consistent depression of developed atrial tension found in the control ultrafiltrate; it is unlikely, however, to have represented more than a minor fraction of the depression observed in the post-hypotension ultrafiltrates. Lefer and his co-workers (Brand, Cowgill, and Lefer, 1969; Lefer, Cowgill, Marshall, Hall, and Brand, 1967) have investigated other substances present in plasma following shock and found no major depressant effects. These results thus support the view that a substance is appearing in increasing quantities in the plasma of dogs subjected to hypotension of increasing duration. Further support was found in the dose–response curve (*Fig.* 3) which showed an exponential relationship between response and dilutions of ultrafiltrate.

These results are consistent with the appearance in plasma of a compound of low molecular weight in increasing quantity with the prolongation of shock. Its *in vitro* effects on myocardial contractility would agree with the finding of defective myocardial performance in the resuscitation phase of experimental haemorrhagic shock.

HYPERBARIC OXYGEN AND WOUND HEALING IN POST-IRRADIATION HEAD AND NECK SURGERY

BY T. W. GREENWOOD AND A. G. GILCHRIST

WESTMINSTER HOSPITAL, LONDON

SUMMARY

Irradiation impairs wound healing owing to reduced vascularity with an increased susceptibility to infection. The case histories of 4 patients with carcinoma of the larynx who have had irradiation and subsequent laryngectomies followed by hyperbaric oxygen therapy are described. It is the authors' clinical impression that skin healing in these patients has been improved by hyperbaric oxygen therapy. The skin changes following ionizing radiation, the rationale of hyperbaric oxygen, and its method of use are described.

MANY patients who undergo head and neck surgery for cancer have previously received radiotherapy. The complications of wound breakdown and infection in such cases are well known. These complications frequently prolong the patient's stay in hospital and may require further reconstructive procedures.

These sequelae are often due to the inability of irradiated tissues to heal normally and to resist infection as a result of reduced vascularity and the resultant tissue hypoxia. If the arterial Po_2 is increased, hypoxia is reduced, encouraging healing and reducing the liability to infection. This may be done by exposing the patient to an atmosphere of hyperbaric oxygen. Hyperbaric oxygen has been used with some success in the treatment of ischaemic skin-flaps (Perrins, 1966; Niinikoski, 1970) and in varicose ulceration (Slack, Thomas, and De Jode, 1966). It has had palliative success in peripheral vascular disease (Illingworth, Smith, Lawson, Ledingham, Sharp, Griffiths, and Henderson, 1961; Schraibman, and Ledingham, 1969; Watt, 1971). Particular success has been noted in the treatment of anaerobic infections, especially gas gangrene (Boerema and Groeneveld, 1970; Cooke, 1971; Watt, 1971). Hyperbaric oxygen also has an inhibiting effect on aerobic organisms (McAllister, 1966).

Hyperbaric oxygen has been used in conjunction with radiotherapy in the treatment of cancer (Van den Brenk, 1961; Wildermuth, 1965; Churchill-Davidson, Foster, Wiernik, Collins, Pizey, Skeggs, and Purser, 1966), but its use in wound healing in irradiated patients has not apparently been reported before.

Four patients who had undergone post-irradiation head and neck surgery and who subsequently developed wound-healing problems have been treated with hyperbaric oxygen.

CASE REPORTS

Case 1.—Mrs. R. C., aged 50 years, presented in November, 1968, with a right supraglottic squamous-cell carcinoma (T2 No Mo). She underwent radiotherapy, receiving 6360 rad. from a cobalt unit. Three months later there was residual disease and she underwent total laryngectomy with standard block dissection in the neck in April, 1970. On the third and fourth postoperative days wound infection became evident with necrosis of the edge of the skin-flaps. A pharyngocutaneous fistula developed. A bacteriological culture grew *Proteus mirabilis* and *Pseudomonas aeruginosa*. The patient underwent hyperbaric oxygen therapy from the twelfth to the twenty-seventh postoperative days, receiving a total treatment time of

48 hours 45 minutes over 15 days at 2 atmospheres absolute (A.T.A.) (15 lb. per in.^{2} or 1·1 kg. per cm.^{2}). During this time there was very rapid improvement in healing although a small fistula remained. This persisted and was excised in August, 1970. She received further hyperbaric oxygen after this excision for 31 hours 50 minutes over 7 days at 2 A.T.A. Healing was complete and she has remained well since.

Case 2.—Mr. R. F., aged 55 years, presented at another hospital in January, 1970, with a poorly differentiated squamous-cell carcinoma in the region of the left aryteno-epiglottic fold extending into the pyriform fossa. He was treated with a course of radiotherapy, receiving a total of 4500 rad which was intended as a preoperative course in a combined régime. Operation was, however, delayed and the patient was transferred to the Westminster Hospital where he underwent total laryngectomy and standard block dissection of the neck in May, 1970. During the first postoperative week he developed a wound infection with fluctuation under the skin-flaps. A culture grew anaerobic streptococci. He was treated with hyperbaric oxygen, receiving a total treatment time of 52 hours 15 minutes over 16 days at 2 A.T.A. The infection resolved rapidly. The patient died over a year later of systemic metastases.

Case 3.—Mr. A. U., a Turkish patient aged 50 years, presented in 1965 with a squamous-cell carcinoma of the left vocal cord extending to the anterior commissure and to the subglottic region (T3 N1 M0). In a course of radiotheraphy he received 6714 rad from a cobalt-60 unit. Two years later the disease recurred. The patient refused surgery and received a further course of 4800 rad. Following this he received intravenous methotrexate. In 1971 the patient agreed to surgery and underwent palliative total laryngectomy in June. He then developed a wound infection with wound breakdown. Healing was slow and a fistula persisted. During the eighth postoperative week the fistula was curetted but failed to heal. Curettage was repeated 3 weeks later and on this occasion the patient was exposed to hyperbaric oxygen for a total of 54 hours over 14 days at 3 A.T.A. At the end of this time the wound was healed and dry and remained so until the patient's discharge from hospital. No further follow-up is available.

Case 4.—Mrs. M. C., aged 52 years, presented in 1969 with a squamous-cell carcinoma of the right vallecular region extending to the right pharyngeal wall. She received a course of radiotherapy of 7200 rad from a cobalt-60 unit. She underwent total laryngectomy with removal of the posterior one-third of the tongue in 1971 for recurrent disease, and developed wound breakdown and a pharyngocutaneous fistula postoperatively. She underwent a course of hyperbaric oxygen for 46 hours from the twentieth postoperative day over 12 days at 3 A.T.A. At the completion of treatment the wound and fistula had completely healed.

All the patients received full supportive treatment and appropriate antibiotics.

DISCUSSION

Pathology of Radiation Changes.—Therapeutic doses of radiation may produce a mild erythema of the skin with degeneration of the sweat-glands and hair follicles. The initial reaction settles within 6–8 weeks. Subsequently the epithelium becomes atrophic, epilation persists, and there is pigmentation or depigmentation and telangiectasia.

In the blood-vessels the endothelium becomes oedematous, and there may be arrest of circulation in small vessels and a narrowing of the lumen in those of moderate size. There is atrophy of the muscular coat, fibrosis, and a thickening of the vessel walls, the end-result being an obliterative endarteritis (Gillies and McIndoe, 1933; McIndoe, 1947; Cade, 1948). Such changes have been considered to be changes in the vessels themselves (Ackerman and Del Regato, 1970), although there is evidence to suggest that they may be secondary to those in the surrounding connective tissue (Rhoades, 1948). The changes in the skin and blood-vessels are progressive (Cade, 1948). Their effect, associated with the direct effect of radiation on the viability of individual cells, is to reduce the regenerative and recuperative powers of the tissues; they are less able to sustain infection and trauma and their healing powers are impaired (McIndoe, 1947).

There is experimental evidence to confirm the delaying effect of radiation on wound healing (Ritchie, 1933; Grillo and Potsaid, 1961).

Effect on Subsequent Surgery.—The surgical problems encountered during operation and in the healing of wounds in patients who have been previously irradiated are within the experience of most surgeons. Work (1959) reviewed these problems. He considered that the majority of patients operated on within 12 months of radiation have few problems although occasional cases may present difficulties during surgery or healing. However, he stated: 'Surgery of the neck in patients who have been irradiated 12 months or more previously for cancer of the larynx is fraught with many difficulties. The surgeon experiences these during the performance of the surgery and during the postoperative care of the patient. This is true whether there is persistent cancer or not in these patients.'

Whilst up-to-date, supervoltage radiotherapy may have gone some way to reduce these problems they nevertheless still exist.

Theories and Methods of Hyperbaric Oxygenation.—It has been noted by several users of hyperbaric oxygen that a beneficial effect is obtained in the healing of ischaemic skin-flaps (Perrins, 1966), infected varicose ulcers (Slack and others, 1966), and to a lesser extent in limbs with ischaemic trophic changes and ulcers (Kidokoro, Sakakibara, Takao, Nihei, Hibi, Sakakibara, Washizu, Takahashi, Koike, Kawamura, Kobayashi, and Konishi, 1970). In view of the fact that irradiation to the skin causes local hypoxia, it would therefore seem logical to assess the effect of hyperbaric oxygenation in patients who are awaiting healing of irradiated skin areas which may or may not be infected. It has also been noted in dogs that the healing of traumatized skin is improved in hyperbaric oxygen. This has been assessed by measuring the tensile strength of the wound and it has been found that an increase as great as 43 per cent in the tensile strength of the wound has been achieved (Beckham and Hitchcock, 1965).

Hyperbaric oxygenation has been used for some time for the therapy of resistant infections with considerable success. Its effect on anaerobic organisms is well known, particularly on *Clostridium welchii* (Boerema and Groeneveld, 1970). However, it may also be used with good effect in aerobic infections (Goulon, Rapin, Letournel, and Barois, 1966; Ollodart, 1966). It exerts its effect in two ways: by reducing hypoxia in infected tissues, thereby increasing the host's own active resistance to infection and by a direct toxic effect on the micro-organism (McAllister, Stark, Norman, and Ross, 1965). It has been shown by Winter and Perrins (1970) that in healthy pigs whose skin has been traumatized the acceleration of epithelial cells across a wound is increased in hyperbaric oxygen as also is the number of mitotic figures in these cells. The rate of epithelization is proportional to the level of oxygen. At 1·1 kg. per sq. cm. (15 lb. per sq. in., 2 A.T.A.) the rate is almost double that at 1 A.T.A. In tissue culture it has been demonstrated that mitosis and cell movement are dependent on the oxygen tension (Medawar, 1948).

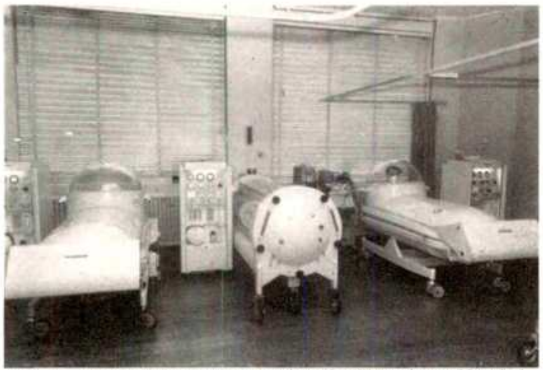

FIG. 1.—The hyperbaric oxygen unit at the Westminster Hospital.

The most satisfactory way of administering the oxygen is by the use of a one-person, hyperbaric chamber (*Fig.* 1). For the patients reported here the Vickers hyperbaric bed and cylinder have been used which are capable of administering oxygen at pressures of 1·1 kg. per sq. cm. (15 lb. per sq. in., 2 A.T.A.) or 2·2 kg. per sq. cm. (30 lb. per sq. in., 3 A.T.A.) respectively. As the patient is totally immersed in oxygen, the oxygen reaches the tissues directly by solution in the tissue fluids and via the lungs and thence via the systemic circulation. The oxygen is conditioned for humidity and temperature. Carbon-dioxide levels are controlled by use of soda-lime filters. Cardiac monitoring and artificial ventilation can be carried out, if necessary, within the chamber. During the course of therapy a patient receives 2 hours' hyperbaric oxygen twice a day at 2 or preferably 3 A.T.A.

At normal temperature and pressure the atmosphere has a partial pressure of oxygen of about 150 mm. Hg but the partial pressure of oxygen in the alveoli is only about 105 mm. Hg. This difference is accounted for by the presence of water vapour and expired carbon dioxide. However, there is also a loss of oxygen across the alveolar–capillary membrane, leaving a figure of 98–100 mm. Hg in the arterial blood. In normal people breathing air at normal temperature and pressure 19·4 ml. of oxygen per 100 ml. of blood are carried combined with haemoglobin and 0·3 ml. is dissolved in simple solution in the plasma. Estimates based on physiological principles of the partial pressure of oxygen in the arterial blood of patients breathing pure oxygen at 1, 2, and 3 A.T.A. are 650, 1400, and 2000 mm. Hg respectively. This constitutes a very considerable increase in the oxygen tension. If, however, the patient is anaemic the anaemia will not interfere with oxygenation at hyperbaric pressures. This is explained as follows: at pressures of 1, 2, and 3 A.T.A. of pure oxygen 2, 4·3, and 6·5 ml. of oxygen per 100 ml. of blood respectively are dissolved in simple solution. At rest the tissues of a patient extract 6·0 ml. of oxygen per 100 ml. of blood passing through. It can therefore be seen that at 3 A.T.A. the patient could survive without any haemoglobin (Boerema, Meijne, Brummelkamp, Bouma, Mensh, Kamermans, Sternhane, and Van Aalderen, 1960).

It has also been shown that high levels of Po_2 result in a reduction of blood-flow through tissues (Bird and Telfer, 1965). This is more than compensated for by the increase in Po_2, so that the oxygen delivery to the tissues is still increased and in the one-person chamber the skin will also be receiving increased oxygen directly from the ambient atmosphere.

There is no standardized period of treatment as this depends on the rate of healing. Treatment is stopped when healing is complete. Nevertheless, a course of treatment should not last for more than 3 weeks because of the potential toxic effects of oxygen therapy. Provided that these limits are enforced toxic effects are very rare, but the individual patient may have a lower threshold than average for these effects so that each patient must be observed carefully and treatment stopped if there is any suspicion of toxicity. The commonest manifestations are mild confusion and tingling of the extremities. Middle-ear pressure problems are occasionally encountered but are seldom severe. Pain can generally be relieved by a temporary decompression.

The favourable clinical impression in the case histories presented here suggests that the practice of using hyperbaric oxygen in head and neck surgery after irradiation is rational. Statistically significant clinical trials are impracticable, so that animal experiments are being conducted to test this hypothesis.

THE AETIOLOGY OF CYSTIC ARTERIAL DISEASE

By K. SHUTE and N. G. ROTHNIE

ROYAL BERKSHIRE HOSPITAL, READING

SUMMARY

Two cases of cystic arterial disease of the popliteal artery are described in which a communication with the capsule of the knee-joint was demonstrated. The importance of this finding in the aetiology of the condition is discussed.

Cystic adventitial disease is a condition characterized by the presence in the adventitial coat of the artery of multiple cystic spaces containing a viscid gel with surrounding fibrosis. About 40 cases have been documented (Haid, Conn, and Bergan, 1970) since it was first described in 1946. The majority of these have involved the midpopliteal artery and it is a rare cause of unilateral calf claudication. The other arteries that have been affected are the common iliac artery (Atkins and Key, 1946; Jaquet and Meyer-Burgdorff, 1960) and the radial and ulnar arteries (Parkes, 1961; Bäckström, Linell, and Ostberg, 1965).

The aetiology of the condition has been much discussed and, as stressed by Little and Goodman (1970) in their review of the literature, no conclusive evidence has been presented to support any of the theories postulated. We report 2 cases of cystic arterial disease of the popliteal artery in which the findings suggest the possible aetiology of the condition.

CASE REPORTS

Case 1.—Mr. J. S., a storeman aged 43, presented with a history of exercise pain (intermittent claudication) in the right calf for 8 months. The onset had been sudden and the symptoms gradually progressive. His walking distance was about 400 yards. He had no other symptoms of peripheral ischaemia and was otherwise well. He was a non-smoker and there was no relevant family or past history.

On examination he was a fit-looking man of normal build. There was no abnormality to be found in his chest or abdomen. He was normotensive. In his legs the pulse state was normal before and after exercise and no bruits were detected. The circulatory and nutritional states of his feet and his toes were satisfactory.

In view of the definite and persistent history of exercise pain right femoral arteriography was carried out and this showed a smooth indentation in the upper part of the popliteal artery (*Fig.* 1) with a normal lumen above and below. There was no evidence of atherosclerosis and a provisional diagnosis of cystic adventitial disease was made.

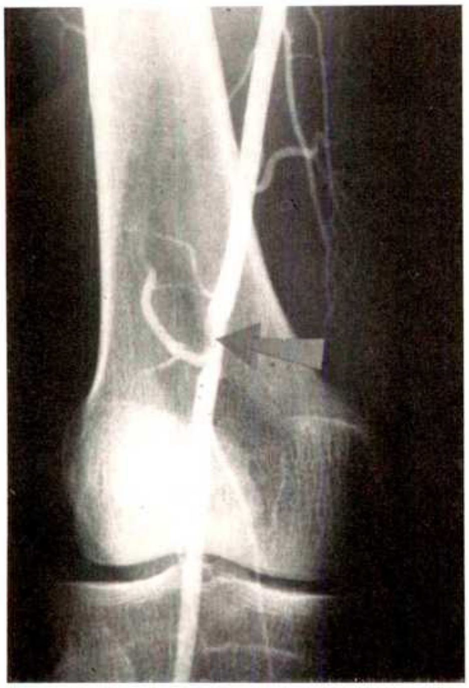

FIG. 1.—*Case* 1. Arteriogram showing indentation of the popliteal artery (arrowed).

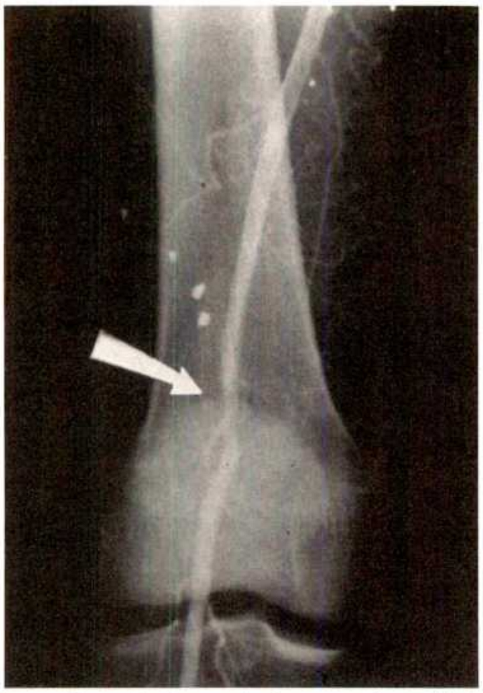

FIG. 3.—*Case* 2. Arteriogram showing compression and deviation of the popliteal artery (arrowed).

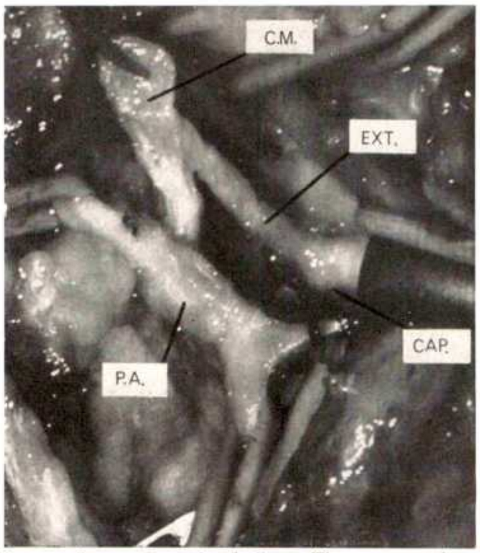

FIG. 2.—*Case* 1. Operative findings. The empty cystic mass (**C.M.**) enucleated from the popliteal artery (**P.A.**) with the extension (**EXT.**) passing from it to the capsule of the knee-joint (**CAP.**).

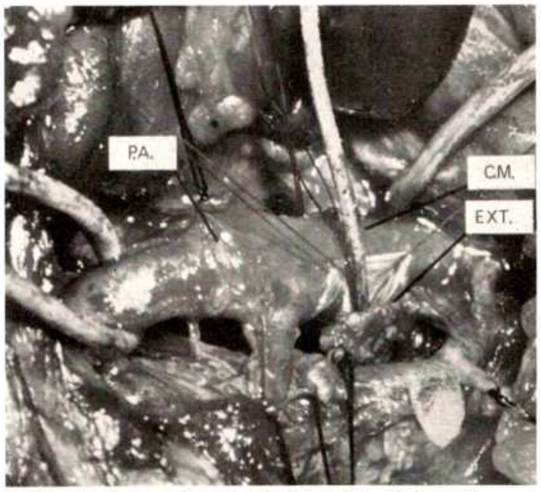

FIG. 4.—*Case* 2. Operative findings. Part of the cystic mass (**C.M.**) in and around the popliteal artery (**P.A.**) with a probe in the extension (**EXT.**) passing to the capsule of the knee-joint.

At operation a posterior approach revealed marked fibrosis and adhesions around the artery in the popliteal fossa. Careful dissection showed a collection of cysts around the artery, especially on its deep surface, involving about 3 cm. of its length. On further dissection an extension from the cystic segment was found to pass to the posterior capsule of the knee-joint to which it was firmly attached. The extension contained a viscid gel similar to that found in the cystic segment. The cysts were carefully peeled off the artery and removed, together with the extension, without damaging the artery (*Fig*. 2). The popliteal artery expanded to a normal calibre with improvement of the pulse distally.

Postoperatively his recovery was uneventful until the sixth day when he suffered a minor pulmonary embolus which was confirmed by lung scan. This was treated by anticoagulants. He recovered well and was discharged on the seventeenth day. He was soon able to resume normal activities and return to his work symptom-free. At follow-up 1 year after operation he was completely free of exercise pain with satisfactory peripheral pulses.

Histological examination of the periarterial cysts showed that the wall consisted of thick fibrous tissue lined in parts by a layer of flattened epithelial cells. Cross-sections of the extension to the knee-joint showed a normal genicular artery with, on one side, a layer of fibrous tissue in which there was a cleft lined by a layer of flattened cells similar to that seen in the cysts surrounding the popliteal artery. There was no elastic tissue to be seen in the cysts or extension.

Case 2.—Mr. L. P., a market gardener aged 55, gradually over a period of 8 months developed exercise pain in the right calf muscles. The pain had become troublesome at his work, which was an active outdoor job, and he had noted coldness in his right foot. There were no other symptoms of peripheral ischaemia and he was otherwise well. He was a moderate smoker and drinker and had been in good health previously.

On examination he was generally fit and of a normal build. He had mild hypertension. There was no abnormality to be found in his chest or abdomen. At rest he had normal pulses in both legs with a faint bruit in the right popliteal fossa. After limited exercise there was diminution of the right pedal pulses and a harsher popliteal bruit. The skin circulation and nutrition of his foot and toes were satisfactory. Routine blood screening revealed no abnormality.

A provisional diagnosis of popliteal stenosis due to cystic adventitial disease was made and arteriography carried out. A right femoral arteriogram showed kinking and compression of the midpopliteal artery with normal-looking vessels above and below (*Fig.* 3).

At operation the popliteal artery was exposed through a posterior approach. Fibrosis and multiple cysts were found around a segment of the artery, especially on its medial and deep aspects, for about 2·5 cm. of its length. A small pressure gradient was found across the segment. From the posterior aspect of the affected segment an extension about 5 mm. across was found to pass to the posterior capsule of the knee-joint to which it was firmly adherent (*Fig.* 4). The extension contained viscid gel similar to that in the cysts around the artery.

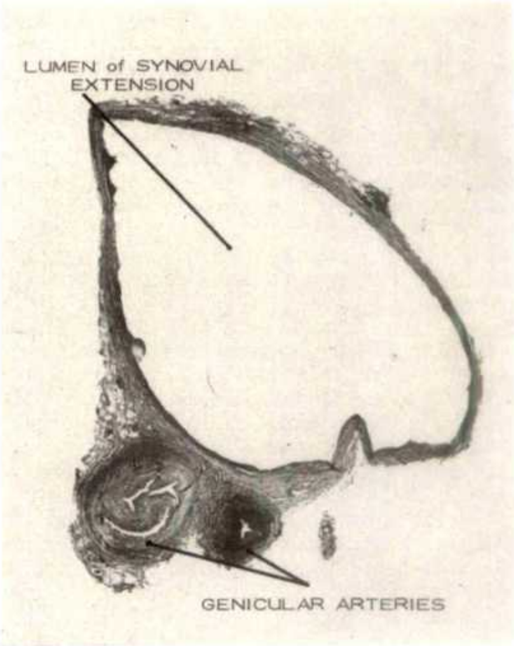

FIG. 5.—*Case* 2. Cross-section of the extension from the cystic popliteal artery to the capsule of the knee-joint.

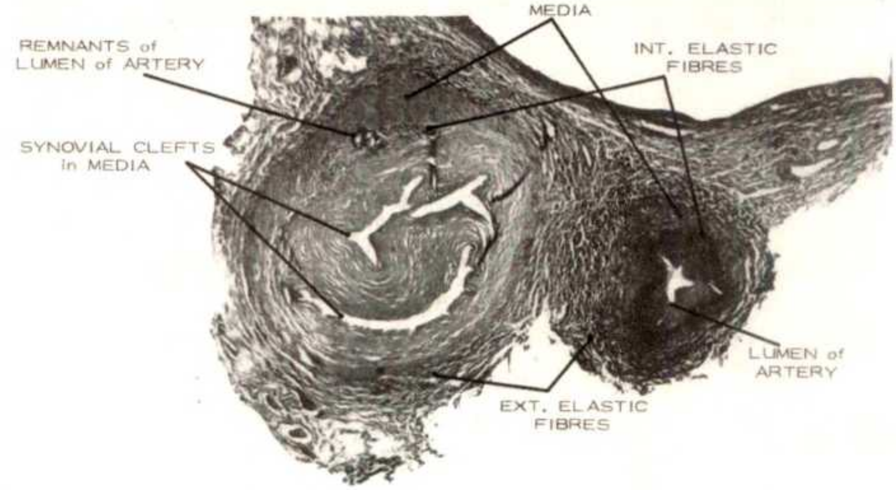

FIG. 6.—*Case* 2. Magnified cross-section of the genicular arteries shown in *Fig.* 5.

The involvement of the arterial wall by the cystic disease was such that enucleation was not possible. After systemic heparinization the affected segment was resected together with the extension and its attachment to the capsule of the knee-joint. No communication with the cavity of the knee-joint was demonstrated. The arterial defect was repaired by a graft from the long saphenous vein. A satisfactory restoration of the distal circulation was obtained with good pedal pulses.

Postoperatively the patient's progress was uneventful and he was discharged on the tenth day. He soon returned to his work and at follow-up 6 months after operation he was fully active and symptom-free with normal peripheral pulses. His hypertension was controlled by Aldomet.

Histological examination was similar to that seen in *Case* 1. The fibrous-walled cystic spaces, with a patchy inner lining of flattened epithelial-like cells and a mucinous content, had the features of a ganglion. The cystic extension to the knee-joint showed in its fibrous wall small arteries and remnants of elastic and plain muscle-tissue. One section showed expansion of part of an artery by cystic spaces lying in its muscular coats and pushing the lumen and internal elastic lamina to one side (*Figs.* 5, 6).

DISCUSSION

The clinical picture of cystic adventitial disease of the popliteal artery is of the sudden onset of unilateral intermittent calf claudication in a 30–40-year-old man, usually with a progressive course (Lewis, Douglas, Reid, and Kennedy Watt, 1967; Haid and others, 1970; Little and Goodman, 1970). On examination there is no clinical evidence of generalized cardiovascular disease. The femoral pulses are always normal whilst the popliteal and pedal pulses may be diminished at rest and may disappear after exercise, though these are not constant features (Ishikawa, Mishima, and Kobayashi, 1961). Our cases illustrate the variable clinical signs that may be encountered.

Arteriography is essential in establishing the diagnosis. A limited segment of the artery is involved by a smooth filling defect with a normal lumen above and below. The clinical and radiographic appearances are such that a differential diagnosis of the popliteal entrapment syndrome must be borne in mind (Leading Article, 1970).

Exploration is indicated in order to establish the diagnosis and to correct the defect. The only effective long-term treatment is either complete stripping of the adventitial coat and its cysts from the vessel wall or resection of the affected segment and graft replacement. Histological examination of the cysts shows them to be lined by fibrous tissue sometimes with an epithelial synovial-like lining. The cysts contain a gelatinous fluid similar both physically and chemically to that found in the common ganglion. These facts were demonstrated in our cases.

The current concepts of aetiology have recently been reviewed by Haid and others (1970) and are:—

1. Repeated minor trauma from stretching and distortion of the artery, owing to its proximity to the knee-joint, producing cystic degeneration of the adventitia.
2. Myxomatous degeneration in the adventitial coat of the artery as part of a generalized disorder of connective tissue. This theory is unlikely.
3. Developmental inclusion of mucin-secreting cells in the arterial wall. McEvedy (1962) in his thesis on simple ganglia advocated that these lesions arose as extensions of so-called 'capsular cysts' in the capsule of the neighbouring joint. These cysts were lined by synovial membrane and enlarge as a result of repeated minor trauma to form simple ganglia. Histological and biochemical comparisons between ganglia and adventitial cysts are similar (Leaf, 1967; Lewis and others, 1967).

It has been postulated that these two conditions might be similar in origin (Lewis and others, 1967). Richards (1963) suggested that more definite evidence of such an origin would be the demonstration of a communication between the cysts and the neighbouring joint. Such a connexion has been demonstrated in both our cases. This has not been reported before in relation to the popliteal artery, although Parkes (1961) noted connexions between cysts of the radial and ulnar arteries and the carpal joints.

The operative and histological findings in our cases support the synovial cellular inclusion theory and that the pathogenesis is similar to that of a simple ganglion. Either capsular synovial cysts enlarge and probably track along a genicular artery to involve the adventitia of the popliteal artery or synovial rests are sequestrated during development into the arterial wall, there to secrete, enlarge, and extend over many years. The interesting histological findings in our second case in which synovial clefts were found within the media of the genicular artery suggests sequestration rather than tracking along such a resistant layer.

In the first patient the cysts were entirely adventitial and were readily removed, leaving an intact popliteal artery. In the second patient enucleation was impossible because the cysts were both adventitial and in the media of the artery. Resection of the affected segment of artery was therefore required. These operative findings confirm the probable dual aetiological mechanism of tracking and sequestration from a common synovial source. Anatomically the cystic condition is not entirely adventitial in its distribution but also involves the media. It would therefore be more correct to call it 'cystic arterial disease'.

Careful dissection in other cases may reveal similar communications between the popliteal artery and the adjacent capsule of the knee-joint. Removal of the cysts and their connexion is probably important in the eradication of the condition and the prevention of a recurrence.

Acknowledgements.—We are grateful to Dr. E. H. Hemsted for his detailed histological studies and advice and to Mr. L. Williams of the Photographic Department of the Royal Berkshire Hospital for the illustrations.

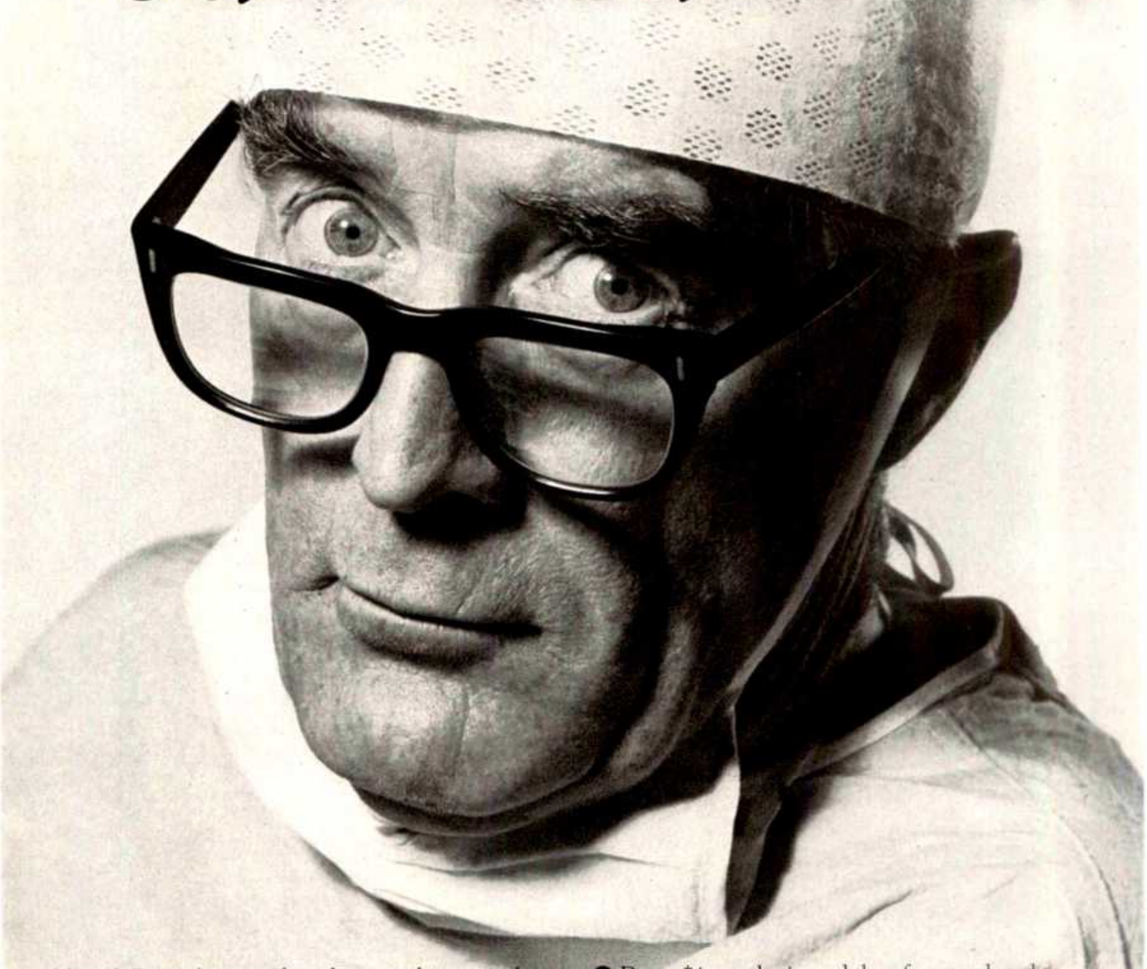
Dexon* is the suture that superseded catgut-but

don't take our word for it!



Although Dexon* sutures have been used extensively in British hospitals for the past three years and throughout the world, not every surgeon has yet used them and so demonstrated their advantages for himself.

● Dexon* is a synthetic absorbable suture that causes minimum tissue reaction and inflammation.

● Although it is totally absorbable it is consistently stronger than catgut for the critical first 7–10 days of healing.

● The braided construction means that every knot holds securely.

● Dexon* is synthetic, and therefore produced to exact, predictable specifications – and this includes predictable absorption.

● Cost savings can be made when Dexon* is used in place of a variety of other suture materials.

We will be happy to tell you more about Dexon sutures but*

Why not prove Dexon* for yourself ?

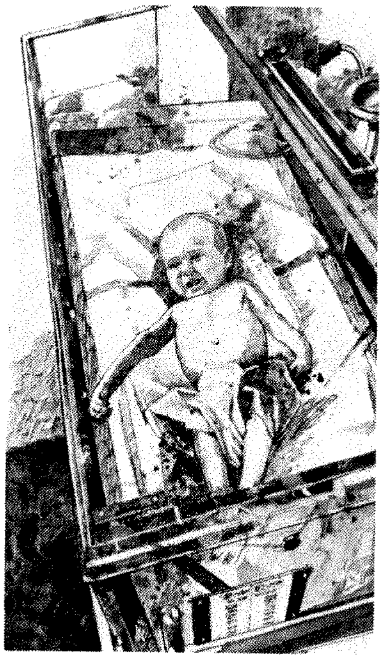
First
and for all.



In severe neo-natal infections

In septicaemias

In serious post-operative situations

G-DAY-those first vital 24 hours in serious bacterial infections:

- ● when effective therapy must be initiated to prevent rapid deterioration in the patient's condition
- ● when the causative organism is unknown or uncertain
- ● when there is no time for trial and error

When these situations occur in acute or acute on chronic infections, Genticin Injectable, the antibiotic with the broadest bactericidal spectrum of all, has proved eminently successful as first-line therapy in a wide range of conditions.

"It therefore follows that on sensitivity testing alone, gentamicin (Genticin) would be the best single antibiotic for blind chemotherapy."[1]

[1] Reference: J Irish med Ass, 65, No 20, 514, 1972.

Genticin Injectable is available in 2 ml multidose vials and snap-off ampoules. Each 2 ml contains 80 mg gentamicin base as gentamicin sulphate.

Further details are available on request from:
Genticin Technical Service, Slough 23971

MOUSSEAU-BARBIN TUBES FOR THE TREATMENT OF CARCINOMA OF THE LOWER TWO-THIRDS OF THE OESOPHAGUS

RESULTS AND OPERATIVE TECHNIQUES

By M. P. HOLDEN, G. H. WOOLER, and M. I. IONESCU

DEPARTMENT OF CARDIOTHORACIC SURGERY, UNIVERSITY OF LEEDS AND THE GENERAL INFIRMARY, LEEDS

SUMMARY

Twenty-three patients have undergone insertion of a Mousseau-Barbin tube for the correction of dysphagia due to inoperable carcinoma of the stomach or the oesophagus. All the patients obtained relief of their symptoms and there was no postoperative mortality or infection.

Technical details are discussed which are designed to reduce the occurrence of obstruction of the tube and erosion of the mucosa of stomach and oesophagus, and to facilitate insertion of the tube in difficult cases.

MOUSSEAU, Le Forrestier, Barbin, and Hardy (1956) first described their tube 17 years ago. Since then a technique has been evolved in the Department of Cardiothoracic Surgery, University of Leeds, which during the past 4 years has produced very successful results without postoperative mortality.

MATERIALS AND METHODS

During the past 4 years (Feb., 1968, to Feb., 1972) 23 patients have undergone insertion of Mousseau-Barbin tubes in an attempt to relieve dysphagia caused by inoperable carcinoma of the gastro-oesophageal junction and the lower and middle thirds of the oesophagus.

The indication for insertion of the tube was the presence of a growth which could not be removed or by-passed satisfactorily, or if the patient was too ill to withstand major surgery when there was no hope of a cure, particularly if secondary deposits were present.

Oesophagoscopy should always be performed immediately prior to performing the laparotomy to assess the size and state of the oesophagus and the extent of the growth. A nasogastric tube can then be passed through the obstructed lumen under direct vision into the stomach. This procedure should never be performed blindly because the oesophagus adjacent to the growth is very friable and is easily perforated.

1. Carcinoma of the Lower Third of the Oesophagus and Gastro-oesophageal Junction.—Packs are placed around the stomach to absorb any overspill of the gastric contents. The stomach is opened through a longitudinal incision with diathermy, between supporting stay-sutures, sufficient to allow entry of the whole hand. When a large, craggy growth is present at the gastro-oesophageal junction it may be almost impossible to define the entrance to the oesophagus which is necessary if a nasogastric tube could not be passed successfully from above. In such cases the index finger is inserted into the oesophagus and a gum-elastic bougie is passed along the groove between the index and second (middle) fingers and thus more easily into the oesophagus.

If the gastrostomy requires extension in difficult cases it should be made paradoxically towards the pylorus. This facilitates closure ultimately without undue retraction being necessary both on the stomach and the laparotomy; it also reduces efflux of gastric contents into the subphrenic spaces.

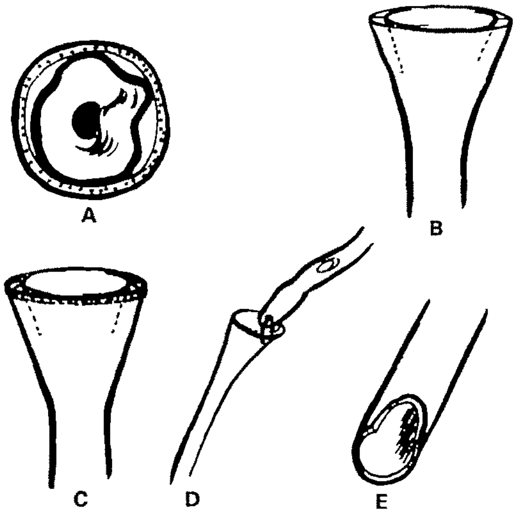

FIG. 1.—A, View of proximal, funnel end of the tube demonstrating the disparity between its circumference and that of the oesophagus. B, C, Demonstrating the rounded edges of the funnel end after it has been cut to fit the oesophagus. D, Suture of the tail end of the tube to the end of 'rail-roading' vehicle. E, Distal end of the tube tailored to increase opening area and reduce possibility of obstruction.

Before the Mousseau-Barbin tube is given to the anaesthetist the surgeon should trim its funnel end in order to provide a snug fit in the oesophagus. If the diameter of the funnel is greater than that of the oesophageal lumen then folds will occur in the funnel (*Fig.* 1 A) in which food will collect, producing oesophagitis, ulceration, and infection. This scalloping of the funnel margin also reduces the area of entrance to the tube. When the funnel is trimmed to size the sharp edge (*Fig.* 1 B) should be rounded with scissors (*Fig.* 1 C) in an attempt to reduce trauma to the mucosa.

The thin end of the Mousseau-Barbin tube is attached to the end of the nasogastric tube or gum-elastic bougie with a suture placed by the anaesthetist. The suture should be placed as near to the end of both tubes as possible in order to minimize trauma in transit (*Fig.* 1 D).

When pulling the tube into place it should be pulled slowly and firmly by holding a long swab in the hand in an attempt to keep the operating field clean.

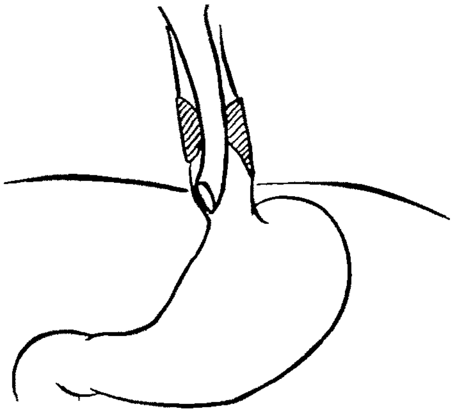

FIG. 2.—Malposition of the distal end of the tube in the lower oesophagus causing obstruction. The tube has slipped upwards out of the stomach.

Occasionally slight difficulty will be experienced at the cricopharyngeal level. The anaesthetist can check with a laryngscope that all is well, but we have not found it necessary to trim the tube for this reason as suggested by Dean (1969).

When the tube rests firmly on the growth excess length is removed using angled bone-cutters. Three cm. is sufficient length of tube to remain in the stomach. If more remains the tube will impinge upon the greater curvature of the stomach, producing ulceration, haemorrhage, or perforation, and also obstruction to the downward passage of food through the tube.

To reduce the possibility of obstruction a flap should be cut out of the end of the tube as shown in *Fig.* 1 E. This also doubles the area of outlet. Again any sharp edges should be rounded with bone-cutters.

It is not necessary to suture the tube in place or to perform temporary gastrostomy, as suggested by Dave (1971).

2. Carcinoma of the Middle Third of the Oesophagus.—The same methods apply here except that the tube is pulled into place through a longitudinal oesophagotomy. The distal end of the tube is cut so that it is 3 cm. above the cardia in order to prevent it becoming misplaced as shown in *Fig.* 2 with the likelihood that it will become obstructed.

DISCUSSION

The age range of the 23 patients was 42–87 years (mean 67 years). They all obtained complete relief of their symptoms and surprisingly none of them experienced unpleasant symptoms due to the presence of this tubular splint.

Reflux oesophagitis results if the patients lie flat and this can have severe consequences (Holden and Wooler, 1971) if acid reflux is not controlled. All the patients are advised to eat liquidized food and to avoid fish and bread. However, many of them disregard this advice and some admit to having no dietary restrictions.

Postoperatively antibiotics (Ampiclox 500 mg., 6-hourly i.m.) are prescribed for 2 days and with this régime no infection has followed this very unsterile operation.

Three of the patients were in the 'middle third' category. One of them had the tube pulled into place via a gastrotomy. The tube slipped up into the oesophagus and became malpositioned (*Fig.* 2) and irremediable blockage followed, requiring removal of the tube. This was easily performed by making four longitudinal slits down the funnel using endoscopic scissors. The collapsed tube could then be removed without trauma to the upper alimentary tract.

The tube is not suitable for tumours above the level of the aortic arch because the proximity of the funnel to the pharynx causes the tube to be displaced upwards owing to the longitudinal shortening of the oesophagus during swallowing.

CONCLUSIONS

The Mousseau-Barbin tube is of great benefit to patients who have dysphagia caused by inoperable carcinoma of the stomach or the oesophagus or who are too ill to undergo major surgery. It can be introduced safely in all patients by any surgeon whose training permits them to perform a laparotomy, particularly if the above suggestions are employed.

OESOPHAGEAL INTUBATION IN OBSTRUCTIVE LESIONS OF THE OESOPHAGUS

By SUMAN KUMAR DAS* AND H. T. JOHN
ROYAL UNITED HOSPITAL, BATH

SUMMARY

In a study of the relative merits of the Mousseau-Barbin and Celestin tubes used for palliation in 60 patients with dysphagia due to mechanical obstruction of the oesophagus by cancer or stricture, the Celestin tube emerged as a better palliative measure than the Mousseau-Barbin tube in so far as operative morbidity and mortality are concerned. In the assessment of the quality of life after intubation the Celestin tube again appears to be the better tube in the early postoperative period but in the later stages there appears to be no significant difference in the quality of life between the two tubes.

The quality of life as defined in this paper appears to have little relation to the duration of survival.

OESOPHAGEAL intubation has become a common palliative procedure for patients with inoperable lesions of the oesophagus and cardia of the stomach. It is usually indicated where the lesion has been shown to be incurable or the general state of the patient is too poor for major surgery. In general the expectation of life of these patients is limited and the primary objective of intubation is therefore the restoration of trouble-free swallowing.

In this survey of 60 patients intubated at the Royal United Hospital, Bath, the majority had a carcinoma of the oesophagus or stomach (91·6 per cent) and the remainder had benign strictures associated with peptic oesophagitis. Most of the patients in the series had oesophageal lesions, but those with high gastric lesions have also been included where tubes have been used to overcome the obstruction to swallowing.

Two types of tubes have been used in this group of patients, the Mousseau-Barbin and Celestin tubes, and all the operations were performed by one consultant surgeon over a period of 7 years from 1966 to 1972. The objectives of this study were twofold: to compare the effectiveness of these two types of tube and to evaluate the quality of life experienced by these patients after intubation.

HISTORICAL BACKGROUND

The first but unsuccessful attempt at oesophageal intubation was made in the year 1845 by Leroy d'Etiolles of France who used decalcified ivory as the material for his tube (Celestin, 1959). The first successful intubation was reported by Sir Charles Symmonds in 1885; initially he used an oesophageal tube fixed to a boxwood funnel, but later he improved the tube by using ivory, silver, and finally gum-elastic, fixing the tube in place by threads brought out through the mouth and tied to the ear. About this time Hill (Souttar, 1924) introduced a probe, made of silver wire covered by a fine rubber tube which was left in situ and around which some food was able to pass. In 1914 Guisez, using a De-Pezzer-like catheter, introduced a tube for the first time under direct vision with the help of an oesophagoscope. After the introduction by Sir Henry Souttar in 1924 of a tube made of German silver wire with an expanded top, inserted through the oesophagoscope (Souttar, 1924, 1927) interest in the field died down until 1949 when Brown produced an improved tube made of silver. Plastic materials were used for the first time by Coyas (1955) in Athens and by Triboulet-Piton in France in 1954 (Lortat-Jacob and Triboulet-Piton, 1955) in the form of a tube made with a radio-opaque ring at both ends. In the same year Kropff designed a tube made of polythene which was inserted through a cervical oesophagotomy. These tubes had disadvantages and a major advance was made in 1956 when Mousseau and Barbin introduced the Mousseau-Barbin tube made of Neoplex, and Barbin first described the 'pull-through' method of inserting the tube through a high gastrotomy. The final development occurred in 1959 when Celestin described a tube based on the Mousseau-Barbin tube but made in two parts: a hollow oesophageal tube and a detachable pilot bougie made of solid polythene. The upper end of the Celestin tube was formed into a barrel shape so that the tube fitted the oesophagus better and was therefore less likely to pass through the stricture or to become obstructed. This particular tube was also less liable to produce pressure necrosis of the oesophageal wall, and at a later stage Celestin incorporated a radio-opaque strip in the tube.

METHOD OF SURVEY

The information used in this survey has been obtained in three main ways. First, by examination of the clinical history, clinical findings, investigations, operations, and postoperative complications from the hospital records. Secondly, the patient's general practitioner was contacted and asked for his observations on the patient's condition after intubation. Thirdly, in the case of surviving patients, direct interviews were sought with both the patient and relatives, or where the patient had subsequently died the close relatives were interviewed in order to obtain information and opinions about the success of the procedure.

PATIENTS

Sixty patients are included in this series, 55 of whom had carcinomas and 5 had benign strictures of the oesophagus. Of the malignant lesions, 58 per cent were in males and 42 per cent in females. The eldest patient was a 97-year-old female and the youngest a 48-year-old female. The highest incidence of carcinoma was in the age-group 60–90 years. The lesions have been classified into four groups: the first three according to the level of the oesophagus involved, i.e., upper third, middle third, and lower third, and the fourth group includes lesions of the cardia and other gastric cancers causing obstruction of the oesophagus.

---

*Present address: Department of Surgery and Gastroenterology, Frenchay Hospital, Bristol.

The investigations used for diagnosis and localization of the lesion in this series have been barium-swallow examination, oesophagoscopy, and biopsy. The highest incidence of carcinoma of the oesophagus was in the lower-third region. In all the patients the state of operability of the lesion was established and the extent of the disease delineated before intubation was undertaken. The age and sex distributions of the patients are shown in *Table I* and the sites of the lesions are shown in detail in *Table II*.

Table I.—AGE AND SEX DISTRIBUTIONS OF PATIENTS WITH MALIGNANT LESIONS

Table II.—SITE OF THE MALIGNANT LESIONS

SITE OF LESION	NO	PERCENTAGE
Upper third of the oesophagus	1	1·8
Middle third of the oesophagus	17	30 8
Lower third of the oesophagus	23	41 8
Cardia, fundal (high gastric)	14	25 4

OPERATIVE PROCEDURES

The operations were performed by one consultant surgeon over a period of 7 years, using the 'pull-through' method of intubation. All the patients had a preliminary oesophagoscopy and biopsy except 2 patients, both more than 90 years of age, where intubation was done in one stage. In 6 patients the inoperability of the lesion was established after exploratory thoracotomy and in a further 8 patients after exploratory laparotomy.

Two methods of intubation have been used in this study. In the more usual of these methods a small-bore gum-elastic bougie is passed through the narrowed area under direct vision using the oesophagoscope. The tip of the bougie is recovered from the stomach through a high gastrotomy made through a small, left upper paramedian incision. The distal end of the Mousseau-Barbin tube, or in the case of the Celestin tube the distal end of the pilot bougie, is tied to the gum-elastic bougie at the mouth end and the main oesophageal tube is guided through the oesophageal stenosis to the stomach. The tube is then drawn through and impacted at the proximal end of the obstructing lesion and the tube is cut off at a suitable length in the stomach.

In the second method retrograde bouginage is undertaken via the gastrotomy incision in cases where the stricture is difficult to pass from above or where a laparotomy has been undertaken for assessment of operability. Once the bougie is in position through the obstruction the procedure is the same as with the first method. A small corrugated rubber drain is usually used to guard against leakage from the closed gastrotomy wound. The tube has not been fixed to the stomach in this series and in no patient has a pyloroplasty been done as has been suggested by Celestin. On the day following operation a radiograph of the chest is obtained and if there is no evidence of oesophageal perforation the patient is allowed fluids by mouth; from the second day a gradual return to a normal diet has been usual and most patients are eating solid food by the third postoperative day. All the patients were instructed about taking an effervescent drink, such as Enos or Andrews Salts, should the tube become blocked by solid food impacted in it.

COMPLICATIONS

Of the 60 patients, 36 had a Mousseau-Barbin tube inserted and 24 a Celestin tube, the Mousseau-Barbin tube being used from 1966 to 1969 and the Celestin tube from 1970 to 1972 (*Table III*). The patients in general were in the older age-groups and were usually in a poor general condition presenting a considerable anaesthetic and surgical risk. Although many of the complications could be attributed to anaesthesia they have all been grouped as postoperative complications associated with oesophageal intubation. It has proved difficult to distinguish between anaesthetic and operative complications in this group of patients.

Table III.—TYPE OF TUBES USED

TYPE OF TUBE	NO	PERCENTAGE	PERIOD
Mousseau–Barbin	36	60	1965–69
Celestin	24	40	1970–71

The commonest complication was bronchopneumonia. This is particularly significant because the incidence was notably higher in our patients than in postoperative patients of the same sex and age distribution undergoing other surgical procedures. The overall incidence of bronchopneumonia in this series was 30 per cent; in the Mousseau-Barbin group it was 32·7 per cent and in the Celestin tube group 29·1 per cent.

The other immediate postoperative complications were pulmonary collapse, pleural effusion, haemorrhage from the oesophagus, perforation of the oesophagus and mediastinitis, coronary thrombosis, and peritonitis. The late complications were wound infection, a persistent gastric fistula, oesophageal haemorrhage, and, in the long-term, frequent episodes of blocking of the tube. The details of these complications are shown in *Table IV*.

MORTALITY

As in the differentiation of the cause of the complications it was difficult to distinguish between the mortality due to operation and that due to anaesthesia. We have accepted that all the patients who died in the immediate postoperative period died from the operation irrespective of whether they died from operative or anaesthetic complications. We have arbitrarily defined a postoperative death as one which occurred within 7 days of the operation as we estimate that most of the patients who had complications due to surgery died within this period. The overall operative mortality was 20 per cent. However, in the Mousseau-Barbin tube series it was 25 per cent but was only 12·5 per cent in the Celestin tube patients. As would be expected from the incidence of post-operative complications, the commonest cause o death was bronchopneumonia. Other causes of death were haemorrhage from the oesophagus or stomach, perforation of the oesophagus with mediastinitis, and coronary thrombosis (*Table V*).

Table IV.—COMPLICATIONS

THE QUALITY OF LIFE OF INTUBATED PATIENTS

The stimulus for this survey was a curiosity about the quality of life of patients after intubation because the purpose of intubation was the relief of dysphagia. We were interested in how these patients lived with their tube and how their post-intubation existence compared with their preoperative state. We have attempted to review their day-to-day life from both the physical and mental aspects, particularly with regard to their ability to enjoy life to some degree. In order to evaluate this degree of palliation we had first to find a standard against which the quality of life in individual patients could be compared. It proved to be difficult because so many factors were involved, i.e., different types of patients with different types of lesions at different stages and treated with two different types of tube. Since treatment was palliative in all the cases with the objective of relief of dysphagia, relief of preoperative symptoms seemed to us to be the best criterion. The commonest presenting symptoms were dysphagia and loss of weight, so that our criteria were based on the postoperative ability to swallow and the maintenance or gain of body-weight. We also added the incidence of blockage of the tube.

Table VI.—GRADES USED FOR ASSESSING QUALITY OF LIFE IN THIS SERIES

GRADE	SWALLOWING	BLOCKAGE OF TUBE	WEIGHT
I (very good)	Solid	Nil or minimum	Gain
II (good)	Solid	Occasional	Steady
III (fair)	Semi-solid	Occasional	Steady
IV (bad)	Liquid	Often	Loss

Table VII.—QUALITY OF LIFE COMPARED WITH THE TYPE OF TUBE USED

GRADE	CELESTIN TYPE		MOUSSEAU-BARBIN TYPE	
	No of Cases	Percentage of Total	No. of Cases	Percentage of Total
I	5	20·8	2	5·5
II	10	41·6	4	11·1
III	3	12·5	15	41·6
IV	3	12·5	6	16·6

As far as swallowing was concerned, we divided foods into three types (solid, semi-solid, and liquid) in order to compare the patient's ability to swallow. We have used meat, such as steak, and salad and apple as our examples of solid food, mincemeat, rice pudding, soft-boiled egg, or bread softened in milk for semi-solid food. Because loss of weight is such a common presenting symptom, the surviving patients were weighed routinely as a measure of their ability to maintain their body-weight or even to gain weight.

Blockage of the tube proved to be a very common postoperative incident in the lives of these patients and we regarded a blockage as significant when the patient or his relatives were worried, the patient had to abandon the meal, the attentions of the patient's doctor were required, or the patient needed admission to hospital. On admission, the tube quite frequently spontaneously unblocked itself, but if it failed to do so the tube was unblocked either by the passage of a Levin's tube or by oesophagoscopy and endoscopic removal of the food mass.

Accordingly the quality of life for these patients in the postoperative period was judged as one of four grades (*Tables VI, VII*).

Table VIII.—LENGTH OF SURVIVAL AFTER INTUBATION COMPARED WITH THE TYPE OF TUBE USED

TIME AFTER INTUBATION (mth)	MORTALITY (per cent)	
	Mousseau-Barbin Tube	Celestin Tube
0–3	47	25
4–6	11	21
7–9	2 8	8 3
10–12	5 6	—
13–15	2 8	—
16–18	—	—
19–30	5 6	—

Grade I (very good): Able to swallow solid food without blockage of the tube, associated with a steady weight-gain.

Grade II (good): Initially able to swallow solid food but later able to swallow semi-solids only with occasional blockage of the tube although maintaining a steady body-weight.

Grade III (fair): Able to swallow semi-solids onl with occasional blockage of tube, but with maintenanc of body-weight.

Grade IV (bad): Able to swallow liquids only wit frequent blocking of the tube and a steady loss o body-weight.

We found that the quality of life was related to som degree with the period of survival (*Table VIII*) bu the relationship was by no means a direct one.

The patients in grade I did not survive for th longest periods and only in grade IV patients was ther a direct relation between the quality of life and th survival period. All the patients in this group di uniformly badly and died within a month or so o intubation. On the other hand, grade I and I patients tended to die within 3 or 4 months o intubation whereas patients in grade III survived fo longer periods. As might be expected, as time o survival increased the patients in grades I and I tended to descend into grade III or IV.

In Memoriam

Charles F. M. Saint, C.B.E., F.R.C.S.

(1886–1973)

BORN on 14 August, 1886, at Bedlington, Northumberland, Charles F. M. Saint was educated at King Edward VI Grammar School, Morpeth, and the University of Durham, Newcastle upon Tyne. His academic record as a student was absolutely brilliant. After graduating M.B., B.S. in 1908 Charles Saint became intimately associated with Professor Rutherford Morison, first as house-surgeon and later as surgical registrar and private assistant. He spent much of his time preparing Morison's later work for publication, in particular that well-known book, *An Introduction to Surgery*. In 1912 he obtained the M.D., M.S. with first-class honours, and in 1913 he became a Fellow of the Royal College of Surgeons of England.

Soon after the outbreak of World War I he joined the Royal Army Medical Corps and was drafted to France, where he distinguished himself as a surgeon in charge of various forward surgical units. For his military work he was awarded the C.B.E. and the Médaille d'Honneur in gold. In 1919 he returned with the rank of Major and resumed his pre-war appointments.

Such was the man who came to Cape Town in March, 1920, at the age of 33 years as the first Professor of Surgery in the first School of Medicine in South Africa. The principles of surgery formed the basis of Professor Saint's approach to the practice and teaching of surgery, and when he retired in 1946 he had moulded and inspired the surgical ideas which, developing in the Cape Town School, permeated far through Southern Africa and spread beyond the seas. Indeed, his dynamic influence has continued to live and flourish through his students, for what was once said of Morison can equally well be said of him: 'Because he was a great man as well as a great surgeon, he handed on the spirit as well as the letter of his creed and became one of the greatest disseminators of surgical thought and makers of surgeons.'

Charlie Saint, as he was known to his students, gave top priority to teaching, but he was also a superb clinician, a master surgeon, and a widely respected man who possessed those unique qualities found only in truly great men: leadership and the ability to inspire. Although he moved to Sark in 1960 he continued to take a keen interest in medical schools and to offer wise counsel to many, and as he grew older we saw more of Saint the philosopher and classical scholar. His aphorisms—all pearls of wisdom—have become the by-words of many and in 1967, aged 81 years, he delivered a stirring address entitled 'Another Look Around' in which he reiterated his lifelong philosophy of looking outwards, forwards, and upwards and through this achieving 'happiness which is the most important thing in life'.

SHORT NOTES OF RARE OR OBSCURE CASES

DUODENO-URETERIC FISTULA*

BY E. M. HOARE†
ROYAL FREE HOSPITAL, LONDON

SUMMARY

A case of a duodeno-ureteric fistula in a man of 46 years is described. This is a rare condition, only 2 previous cases having been reported. The patient did not agree to operation and no tissue is available for histological examination. However, reasons are given for believing this to be the first case in which the primary pathology is in the duodenum.

CASE REPORT

Mr. W. M., a fitter, first began to get attacks of abdominal pain in 1961 at the age of 35 years. He had no significant previous medical history. The patient described his initial attacks as 'gastric' in type. On his first admission to New End Hospital in July, 1967, the character of the pain had changed and suggested a right renal colic. He had been investigated for pain in the right hypochondrium between 1965 and 1967 at another hospital. In 1966 an intravenous pyelogram and cholecystogram had been normal and a further intravenous pyelogram in June, 1967, was also normal (*Fig.* 1). After 1967 his attacks of pain remained predominantly in the right abdomen. Sometimes his symptoms suggested a peptic ulcer, the pain being aggravated by food and relieved by milk. The pain occasionally woke him at night and was sometimes associated with the vomiting of food. He had no disturbance of bowel habit. His symptoms were exacerbated by a high alcohol intake. At other times his symptoms were more characteristic of a renal colic with pain in the right loin radiating to the right groin. Usually he had no urinary symptoms, but occasionally he had frequency and dysuria.

---

* Paper presented to the Clinical Section of the Royal Society of Medicine on 12 Nov., 1971.

† Present address: Manchester Royal Infirmary.

In April, 1969, he had a severe exacerbation of his symptoms which required admission to hospital. He had pain in the right side of his abdomen which radiated to his right loin and right testicle. He had no urinary symptoms, but his right testicle was mildly swollen and tender. An intravenous pyelogram on this occasion was abnormal, showing a mild hydronephrosis of the right kidney. A barium-meal examination showed that the second part of the duodenum was narrowed. A combined liver and pancreatic scan was normal, which made a diagnosis of carcinoma of the head of the pancreas unlikely, but primary carcinoma of the duodenum could not be excluded. This and the severity and duration of his symptoms were indications for operation, but on the day of the proposed operation the patient discharged himself. Since that time the patient has had many admissions with attacks of pain. On each occasion he steadfastly refused operation and was given symptomatic treatment only. Despite this, however, the patient put on over 6½ kg. in weight and the frequency and severity of the attacks diminished.

In September, 1969, a further intravenous pyelogram again showed a hydronephrosis, but for the first time a

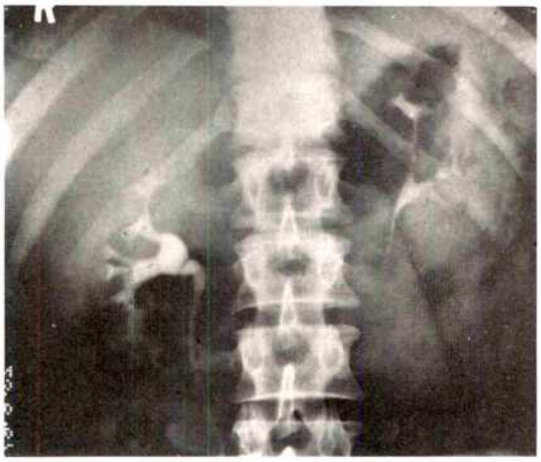

FIG. 1.—Normal intravenous pyelogram in June, 1967.

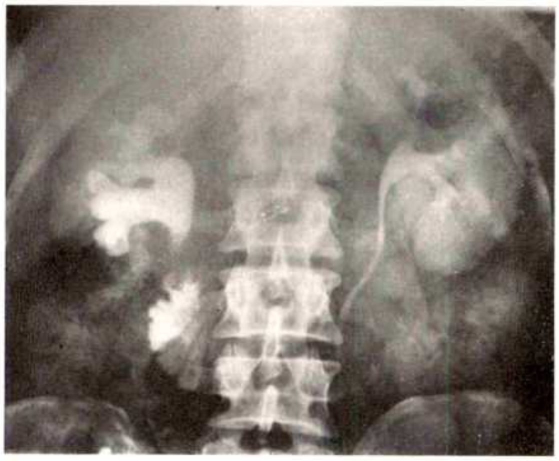

FIG. 2.—Intravenous pyelogram in September, 1969, showing hydronephrosis of the right kidney and passage of contrast into the second part of the duodenum.

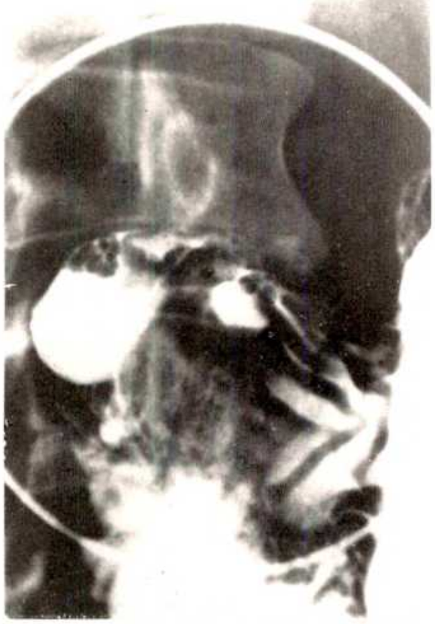

FIG. 3.—Barium-meal examination in September, 1969. Coned view of the duodenum showing narrowing of the second part of the duodenum with a small ulcer crater. A further ulcer crater is seen in the prepyloric area.

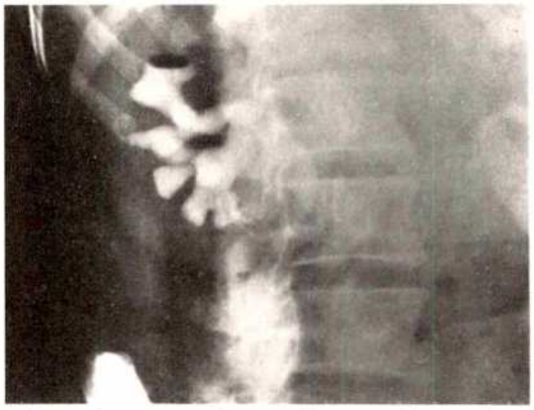

FIG. 4.—Intravenous pyelogram in May, 1971. Oblique view of the right kidney showing an air-bubble in the superior calix.

fistula was shown between the upper ureter, 1 cm. below the pelvi-ureteric junction, and the second part of the duodenum (*Fig.* 2).

A barium-meal examination showed a small ulcer crater at the lower end of the narrowed duodenal segment and in addition a prepyloric ulcer (*Fig.* 3). A combined intravenous pyelogram and barium-meal examination showed the fistula to be related to the lower part of the narrowed duodenal segment. The ureter distal to the fistula could not be demonstrated. On questioning the patient after this investigation it was established that he had had pneumaturia intermittently for some time, but had paid little attention to it.

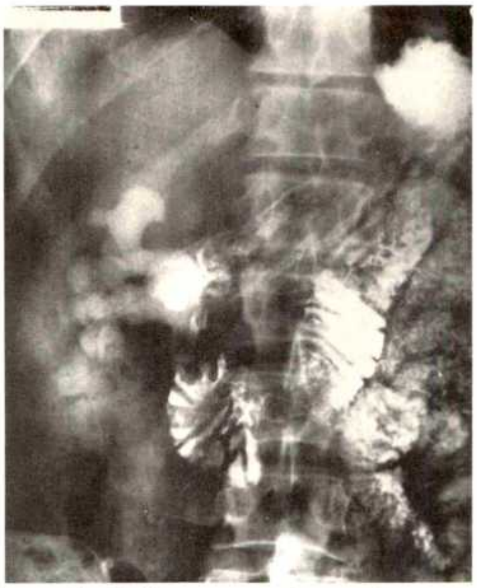

FIG. 5.—Combined intravenous pyelogram and barium-meal examination in May, 1971, showing the ureter related to the lower end of the narrowed duodenal segment. Note the bubble of air in the ureter.

Further barium-meal and intravenous pyelogram examinations in May, 1971, showed little change from 1969. Air-bubbles were clearly seen in the urinary tract (*Figs.* 4, 5). In addition, a further cholecystogram was normal.

In the absence of biopsy material obtained by operation, attempts were made to obtain this endoscopically. It was possible to visualize the stomach and a small prepyloric ulcer was seen, but the patient did not tolerate passage of the instrument into the duodenum. An attempt to biopsy the duodenum using a Crosby capsule was thwarted by the patient discharging himself yet again. However, duodenal intubation revealed the intriguing information that the duodenal content had a urea concentration of 14 mg. per 100 ml.

At the present time the patient is still getting attacks of pain and occasionally requires admission to hospital. He is well nourished and his weight remains steady. He still refuses to consider operation.

A summary of his other investigations are as follows:—

Normal values for: haemoglobin, white-blood count, erythrocyte-sedimentation rate, vitamin B_{12}, folate, urea, electrolytes, sugar, alkaline phosphatase, aspartate transaminase, bilirubin, amylase, plasma proteins, calcium, and phosphate.

Urine contained no blood, protein, sugar, or bile; specific gravity 1010–1020; *p*H 5·5–9·0.

Midstream urine, occasional growth of *Escherichia coli*, *Streptococcus faecalis*, *Proteus*, or *Klebsiella*. Early morning specimens of urine (× 6), negative cultures for tubercle bacilli. Urine calcium (24 hours), normal. Endogenous creatinine clearance, normal.

Stools, occult blood was occasionally positive.

Mantoux test, weakly positive.

Wassermann reaction, negative.

Pentagastrin test: before pentagastrin, 1·5 mEq. acid per hour; after pentagastrin, 23·22 mEq. acid per hour. Fasting plasma gastrin, 107 pg. per ml. (normal).

DISCUSSION

There have been only 2 previous reports of duodeno-ureteric fistula. Davis (1918), in the days before the use of the intravenous pyelogram, demonstrated a fistula by retrograde catheterization of the right ureter. Bile-like fluid was seen discharging from the right ureteric orifice and retrograde injections of contrast showed the fistula to be at the pelvi-ureteric junction. The second case was reported by Deslesaver (1969). An intravenous pyelogram showed a functioning right kidney, but the contrast passed into the second part of the duodenum through a fistula 3 cm. below the pelvi-ureteric junction. Both cases were treated by nephrectomy and suturing of the duodenum and the histology in both cases was chronic renal infection.

Pyelo- or nephroduodenal fistula is more common, and is almost always between the second part of the duodenum and the right kidney, although at least 1 case involved the left kidney and the terminal duodenum (Arendt and Brockmann, 1934). About 30 cases have been recorded and without exception the pathological process has always begun in the kidney. In a recent review McEwan (1968) recorded 23 cases. Biondi (1935) described a case which he thought was secondary to a duodenal ulcer, but the tuberculous right kidney removed at operation was almost certainly the primary pathology (King, 1950). Prior to effective chemotherapy tuberculosis was a common cause of pyeloduodenal fistula, but now chronic renal infection with or without stones is the commonest pathology. The renal infection causes a perinephritis, which involves the duodenal wall with subsequent fistula formation. This is analogous to the cholecystoduodenal fistula associated with cholecystitis and stones, which may occasionally lead to gall-stone ileus. However, there has as yet been no recorded case of renal stone ileus.

The present case is interesting in that the symptoms preceded the demonstration of the fistula by 7 years. In fact in 1961 the initial symptoms were described by the patient as 'gastric' in type with nothing to suggest a renal pathology. In 1967 after symptoms had been present for 6 years the intravenous pyelogram was still normal. Even when the fistula was demonstrated in 1969 the kidney was still shown on the intravenous pyelogram to function normally, and, apart from the mild hydronephrosis, appeared to have a normal anatomy. No evidence of renal tuberculosis has been found and the occasional urinary infection can be explained by the passage of small amounts of duodenal content into the urine, as is evidenced by the pneumaturia. No renal stones were seen on the intravenous pyelogram in 1967 and this makes unlikely the possibility of a stone becoming arrested in the upper ureter and ulcerating through into the duodenum. Therefore, although no histological proof is at present available it would seem that the primary pathology was in the duodenum.

The exact duodenal pathology, however, must be a matter for speculation. The commonest duodenal lesion is a duodenal ulcer. This patient's gastric secretion of 23 mEq. acid per hour after pentagastrin stimulation is within normal limits although it would be compatible with the diagnosis of duodenal ulcer. A prepyloric ulcer was demonstrated radiologically and visualized endoscopically and it is known that these may be associated with ulcers in the duodenum. However, the duodenal ulcer demonstrated by barium-meal examination was located in the second part of the duodenum which is an unusual location. A diagnosis of Zollinger-Ellison syndrome was considered, but this was ruled out by the low resting acid output and the normal fasting plasma-gastrin level. It is conceivable that the patient may have had a sealed-off perforation of a posterior duodenal ulcer causing a localized abscess. Its subsequent rupture into the upper ureter and duodenum could result in the formation of a fistula. The 'ulcer' seen in the second part of the duodenum may not be an ulcer in the accepted sense but may simply represent the mucosal defect at the entry point of the fistula.

A primary malignant tumour of the duodenum is unlikely in view of the length of history and the lack of progression of the disease, while a benign tumour is unlikely to ulcerate the duodenal wall.

Any inflammatory lesion which could cause a periduodenitis with adherence of the duodenum to the ureter could theoretically cause a fistula.

Perforated diverticula of the duodenum have been recorded causing fistula into the gall-bladder and colon (Munnell and Preston, 1966). Swallowed sharp foreign bodies have caused pyeloduodenal fistula (Abeshouse, 1949) and pancreatitis may occur in an annular pancreas (Hope and Gibbons, 1954). All these conditions are uncommon and no evidence can be produced for any of these diagnoses in this patient.

Retroperitoneal fibrosis often causes ureteric obstruction, but usually at the level of the fourth lumbar vertebra. It has also been reported causing duodenal obstruction (Schneider, 1964). However, the fibrosis constricts but does not infiltrate and fistula formation is unlikely.

Crohn's disease is well known for its tendency to form fistulae. It occurs in the duodenum in less than 5 per cent of cases and is almost always associated with disease elsewhere in the bowel (Fielding, Toye, Beton, and Cooke, 1970). The present patient had no evidence of disease on follow-through examination of the small intestine and no diarrhoea or evidence of malabsorption. Crohn's disease has been diagnosed by per-oral duodenal biopsy techniques (Hermos, Cooper, Kramer, and Trier, 1970).

This case still presents a diagnostic problem, but it is felt that its unique nature justifies this report. An exact diagnosis can probably only be obtained by laparotomy which is at present not possible and, since the patient is maintaining reasonable health, perhaps not even justifiable.

Acknowledgements.—I should like to thank Mr. M. J. Lange for his permission to publish this case, and Dr. C. E. Mackintosh who undertook the most recent radiological studies. Professor C. G. Clark kindly arranged for the plasma-gastrin assay to be done in the Department of Surgery at University College Hospital, London.

AN UNUSUAL THYROID GLAND

BY B. A. LEATHERDALE*

THE CLINICAL RESEARCH CENTRE, NORTHWICK PARK HOSPITAL

SUMMARY

A patient is described in whom the only thyroid tissue present was a mass approximately 4 cm. in diameter situated high up in the neck and just lateral to the laryngeal prominence of the thyroid cartilage. Degenerative changes in this ectopic gland were marked. An ectopic gland in such a position has not previously been described in euthyroid adults. The embryological development, functional activity, and pathology of ectopic thyroid glands are discussed.

ABNORMALITIES of the thyroid gland and its embryological remnants are not uncommon. Cysts along the track of the thyroglossal duct can for various reasons require surgical treatment. A case is presented in which the thyroid gland was represented solely by a small area of functioning thyroid tissue in an ectopic position. Originally a tentative diagnosis of thyroglossal cyst had been entertained. However, careful clinical assessment in association with detailed thyroid-function tests revealed the true nature of the cervical swelling preoperatively.

---

* Present address: Senior Medical Registrar, King's College Hospital, London.

CASE REPORT

HISTORY.—M. L., a 17-year-old schoolgirl, presented in September, 1970, with a painless swelling in the neck, which had first been noted a month previously. She had no dysphagia, dysphonia, cough, or dyspnoea, and direct questioning revealed no symptoms of systemic thyroid dysfunction. Past history and family history were unremarkable.

EXAMINATION.—The patient was clinically euthyroid and general examination was normal. She had a firm, roughly circular swelling approximately 4 cm. in diameter in the left anterior triangle of the neck just lateral to the upper border of the laryngeal prominence of the thyroid cartilage. It moved with swallowing but not with protrusion of the tongue and was freely mobile. There was no thyroid tissue palpable in the normal position.

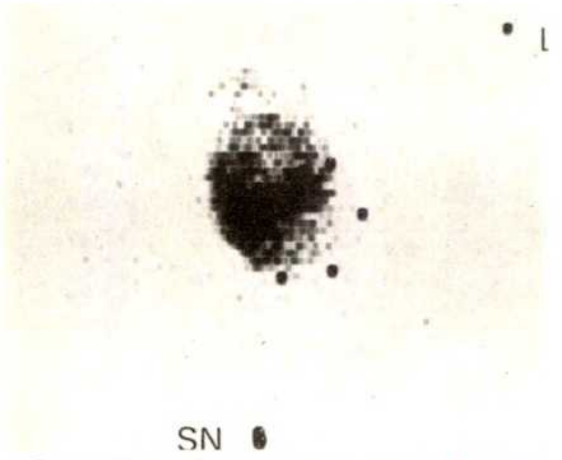

FIG. 1.—^{131}I scan of the neck, showing uptake by the ectopic thyroid with an area of diminished uptake superiorly. S.N., Sternal notch.

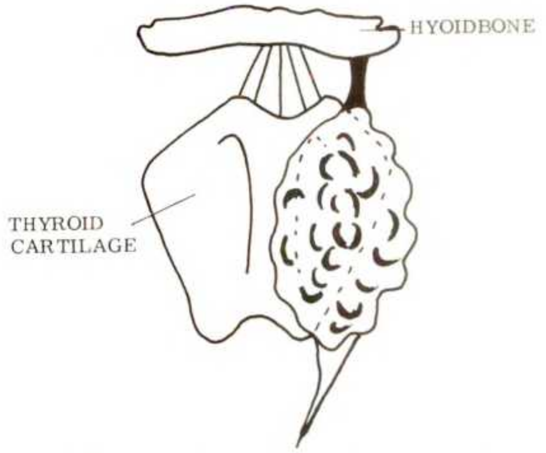

FIG. 2.—Diagram showing the anatomical relationships of the ectopic gland.

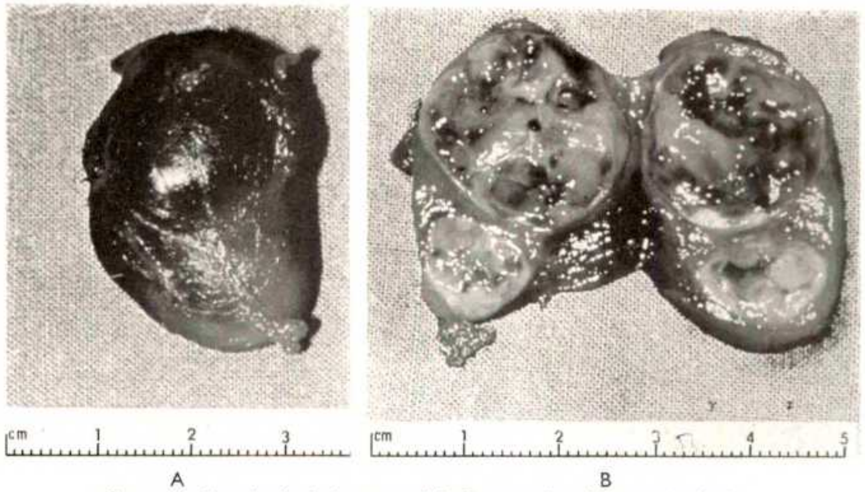

FIG. 3.—A, Ectopic gland after removal. B, Cross-section of the ectopic gland.

INVESTIGATION.—A chest radiograph and a full blood-count and erythrocyte-sedimentation rate were normal. No abnormality was found on measurement of the serum electrolytes (including calcium and phosphorus), and no antibodies to thyroid tissue were present.

A ^{131}I scan showed a single area concentrating ^{131}I which corresponded accurately with the swelling felt on examination; within the scan there was a 'cold' area superiorly (*Fig.* 1). ^{131}I uptake was not present in the normal thyroid position.

Base-line serum-thyroxine concentration was 83 nmol. per litre, T_3 uptake 113 per cent of normal, and thyroid-stimulating hormone 1·5 μU. per ml., confirming the euthyroid status. Uptake of ^{99m}Tc at 15 minutes was slightly elevated at 8 per cent. After giving thyroid-stimulating hormone, 10 U. i.m. daily for 2 consecutive days, the serum thyroxine level rose to 115 nmol. per litre and ^{99m}Tc uptake rose to 12 per cent. The neck was rescanned and no additional areas of ^{131}I uptake could be demonstrated. Tri-iodothyronine, 40 μg. t.d.s., was given orally for 7 days, at the end of which the serum-thyroxine concentration had decreased to 62 nmol. per litre and the uptake of ^{99m}Tc had been abolished.

From these results (*Table I*) it was concluded that the cervical swelling represented the patient's only functioning thyroid tissue which behaved physiologically in its responses to thyroid-stimulating hormone and T_3 suppression.

PROGRESS.—In view of the suppressibility of the ectopic thyroid gland, thyroxine, 0·3 mg. daily, was prescribed to try to reduce its size. After approximately 10 months no significant reduction in size had been achieved. Because the gland had become an embarrassment from the cosmetic point of view and also because the 'cold' area on the ^{131}I scan was viewed as possibly malignant, exploration of the neck and removal of the gland were recommended.

Table I.—RESPONSES OF SERUM T_4 AND ^{99m}Tc UPTAKE TO THYROID-STIMULATING HORMONE AND T_3 SUPPRESSION

	SERUM T_4* (nmol. per litre)	^{99m}Tc UPTAKE (Percentage at 15 min.)
Base-line	92	8
After thyroid-stimulating hormone, 10 U. 1 m. daily for 2 days	115	12
After T_3, 40 µg. t.d.s. for 7 days	62	0

* Normal serum T_4 = 60–150 nmol per litre.

At the operation the thyroid gland was laterally placed on the left wing of the thyroid cartilage (*Fig.* 2). It was supplied by a lease of blood-vessels entering inferiorly, and remnants, presumably of the lingual duct, extended up as a fibrous band behind the hyoid bone. No thyroid tissue was present in the normal position. The gland was removed *in toto*; histologically it consisted of two degenerate cysts lined externally by a narrow rim of normal thyroid tissue. This almost complete investment with normal thyroid tissue might have accounted for the relatively normal scanning appearances in such an obviously abnormal gland (*Fig.* 3).

The patient was not given immediate replacement therapy postoperatively, but approximately 6 weeks following surgery she complained of tiredness, general malaise, and weight-gain. Thyroid function tests indicated hypothyroidism (*Table II*). Thyroxine, 0·2 mg. daily, was given and she has remained euthyroid on this dose.

DISCUSSION

There are several points of interest about ectopic thyroid glands in general and the present case in particular. First, the embryological aspects should be considered. The potential thyroid gland is initially recognizable as a midline thickening on the endoderm of the floor of the pharynx at about 1 month of foetal life. From this thickening the thyroglossal duct develops; with development of the neck and descent of the heart this becomes elongated, thinned, and eventually it fragments to separate the now bilobed distal end which will form the thyroid gland proper. The primitive thyroid gland is at this stage a close relation of the third and fourth pharyngeal pouches, each of which divides into a dorsal and ventral portion. The third pouches give rise to the thymus and inferior parathyroid glands. The dorsal portions of the fourth pouches form the superior parathyroids and the ventral portions receive contributions from the rudimentary fifth pouches to form the 'ultimo-branchial bodies'. It seems that the ultimo-branchial portion, although incorporated into the thyroid gland, does not give rise to thyroxine-producing tissue but to the clear cells of the thyroid which produce calcitonin (Pearce and Carvalheira, 1967). Before this was demonstrated it had been debated whether there was any contribution to the thyroid from the fourth pouches (Boyd, 1964). The fact that removal of the lingual thyroids nearly always resulted in hypothyroidism had suggested to some workers that the fourth pouch derivatives (which presumably would be undisturbed by such surgery) made little contribution to thyroxine-producing tissue. The concept of 'lateral aberrant thyroids' had long since been discredited as such tissue could always be explained on the basis of secondary deposits from primary thyroid tumours (Dalgaard and Wetteland, 1956).

Clinically the following abnormalities of thyroid gland development are well recognized:—

Group A: Aplasia.
  1. Total.
  2. Unilateral.
  3. Isthmic.

Group B: Abnormal descent.
  1. Lingual.
  2. Sublingual.
  3. Intrathoracic.

The relative prevalence of the various abnormalities is difficult to determine with accuracy. In group A 9·5 per cent of cases of non-goitrous hypothyroidism are due to total aplasia (Niemann, Pierson, and Martin, 1961). In a series of 708 patients who had thyroid scans isthmic asplasia was judged to be present in 5·5 per cent of cases and unilateral aplasia in 0·98 per cent (Andreew, 1968). In group B thyroid tissue may be found anywhere along the line of descent of the embryonic thyroid gland. Of 46 cases of abnormal thyroid descent in hypothyroid children, 22 were lingual, 12 were between the hyoid bone and maxilla, and 12 were infrahyoid in position. Such glands were never palpable and were always situated in the midline (Niemann and others, 1961). In adults Lahey (1923) reported only 2 lingual thyroids among 8500 patients attending his goitre clinic.

In the patient described here the ectopic thyroid gland fell into group B, but was very unusual because it was laterally placed. Because it was infrahyoid in position it might have been more liable to lateral displacement in a purely mechanical fashion by the development of the laryngeal prominence of the thyroid cartilage.

The cause of maldescent of the thyroid gland is not known. It is of interest that a lingual thyroid has been reported in siblings (Orti, Castells, Qazi, and Inadar, 1971), and in view of the rarity of this abnormality (*see above*) this suggests the possibility that genetic factors may be involved in the descent of the thyroid gland.

The functional state of ectopic thyroid glands has not been adequately studied. It would seem, in paediatric practice at least, that functional underactivity of ectopically placed thyroid glands is a common cause of non-goitrous hypothyroidism. Niemann and others (1961) reviewed 74 non-goitrous hypothyroid children 62 per cent of whom had ectopic thyroid glands. Lingual thyroid glands usually present with pressure symptoms or haemorrhage; Montgomery (1936), however, reported clinical hypothyroidism in 15 per cent of cases. It is possible that many ectopic glands are symptomless and never detected clinically; if this is so the estimated prevalence of hypothyroidism in such cases is likely to be too large.

The pathology of ectopic thyroid glands has not received much attention probably because their rarity makes adequate data collection difficult. Cystic degeneration in this patient was marked, a finding which would appear to be most unusual. Hendrick (1956) reported that his cases of lingual thyroid showed no remarkable pathological changes but he gives no histological details.

The risk of malignancy developing in ectopic thyroid glands seems to be small. Akbari, Richter, and Papadakis (1967) reviewed the development of malignancy in thyroglossal duct remnants and put the risk at less than 1 per cent if neoplasms of thyroid tissue only were considered; others (Keeling and Ochsner, 1959) report similar findings. However, this does not mean that ectopic glands are not subject to the same pathological processes as normally situated glands and the presence of an apparent solitary 'cold area' on scanning was one of the indications for removal in the present case.

This case is also unusual in that the very small, histologically degenerate, thyroid gland was able to produce sufficient thyroxine to maintain a euthyroid state. After its removal the patient rapidly became hypothyroid and required replacement thyroxine therapy.

REVERSED ROTATION OF THE GUT INCIDENTAL TO CHOLECYSTITIS IN A LEFT-SIDED GALL-BLADDER

BY L. H. STAGG
SIR CHARLES GAIRDNER HOSPITAL, SHENTON PARK, WESTERN AUSTRALIA

AND H. J. SHEINER
UNIVERSITY OF WESTERN AUSTRALIA

SUMMARY

A patient with reversed rotation of the midgut loop of the retro-arterial colon type is reported. She is unique in being the first case recorded in the literature with a right-sided colon and a left-sided liver without situs inversus of the abdominal viscera. An explanation of the findings is suggested, based on known embryological facts.

Previous reports indicate that patients with reversed rotation all present with obstructive symptoms secondary to the altered anatomy. This patient is unusual in that her symptoms and pathology were unrelated to the anatomical abnormality.

EXPERIENCE in treating adult patients with anomalies of intestinal rotation is limited. This is particularly true of one of the rarest abnormalities of rotation, that of reversal of the midgut loop, two variants of which are now recognized. The first is the retro-arterial colon type where the superior mesenteric vessels and duodenum cross anterior to the transverse colon. In the second type the liver and the entire colon are ipsilateral (Estrada, 1958).

The case described here is one of reversed rotation of the retro-arterial colon type but with the unique finding of a left-sided liver and right-sided descending colon. In addition the patient presented with jaundice due to gall-stones, making this the first reported case to present because of associated pathology and not with the clinical features of bowel obstruction.

CASE REPORT

The patient, a female aged 59 years, was admitted in April, 1970, complaining of severe lower retrosternal chest pain for 1 week. In the past she had been treated for angina, and a transient episode of jaundice 1 year previously was thought to be due to chlorpromazine therapy.

On examination only epigastric tenderness was noted and a provisional diagnosis of either myocardial or pulmonary infarction was made. However, subsequent chest radiographs, electrocardiograms, and enzyme studies did not confirm the diagnosis. Two days after admission the patient had a further severe attack of pain and the following day she was noticed to be jaundiced with a discrete mass in the upper abdomen and was transferred to a surgical ward. A diagnosis of acute cholecystitis with secondary pancreatitis and a possible collection in the lesser sac was made, despite a serum amylase of 84 Somogyi units. The relevant investigations confirmed an obstructive jaundice as evidenced by bile in the urine, bilirubin of 8·5 mg. per 100 ml., alkaline phosphatase of 23 K.A. units, and normal liver enzymes. On barium-meal examination the only abnormality was a widened duodenal loop, and a rounded filling defect was noted in the descending portion of the duodenum in the vicinity of the ampulla of Vater (*Fig.* 1).

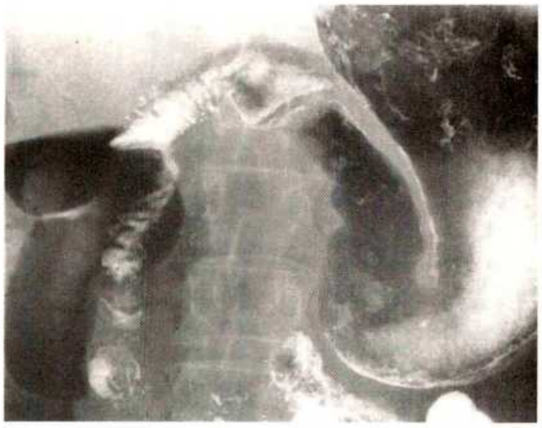

FIG. 1.—Barium-meal film, showing the widened duodenal loop. The filling defect can be seen in the second part and below this there is a duodenal diverticulum.

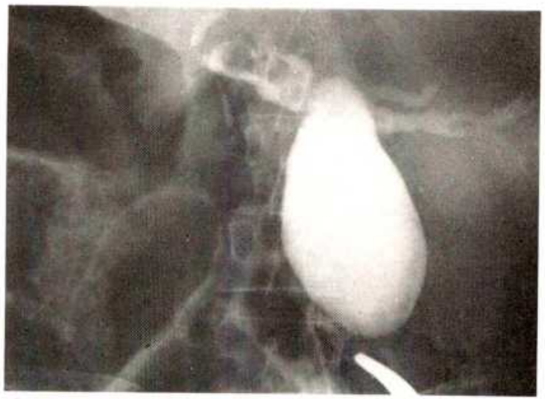

FIG. 3.—Operative choledochogram via the gall-bladder. The filling defects can be clearly seen in the duct system.

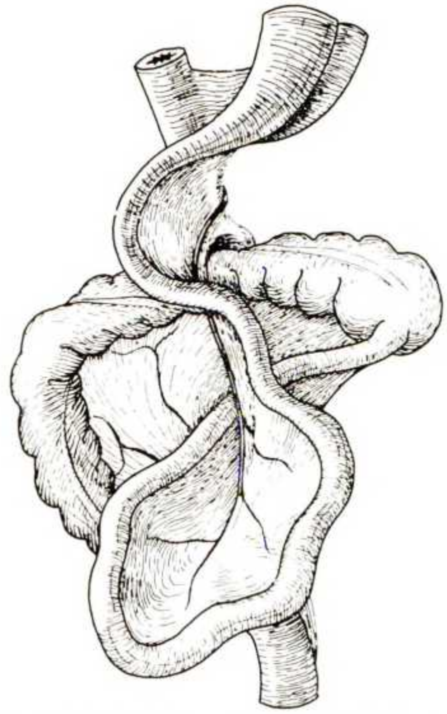

FIG. 2.—Line drawing of the anatomy described in the text.

The patient's symptoms rapidly settled within a week and prior to discharge an intravenous cholangiogram demonstrated biliary calculi. The patient remained well and was readmitted for surgery 6 weeks later.

OPERATIVE FINDINGS.—Laparotomy was performed via a right upper paramedian incision. The stomach and first and second parts of the duodenum were normal in position. The third part of the duodenum was elongated and narrowed and, together with the fourth part, took a straight course passing over the underlying transverse colon. The superior mesenteric artery was to the left of the duodenum passing across the transverse colon (*Fig.* 2). Two thin-walled diverticula were noted on the left side in the region of the duodenojejunal junction.

The gall-bladder was located in a fossa on the undersurface of a large left lobe of the liver. Later dissection revealed that the cystic duct joined the left hepatic duct by passing from left to right. The common bile-duct also passed to the right across the midline and entered the duodenum from the left. The spleen was palpable beneath the left dome of the diaphragm and the pancreas lay in its normal position across the posterior abdominal wall.

The small intestine had no mesentery, its attachment to the posterior abdominal wall being a short segment just above the region where the duodenum crossed over the transverse colon. The terminal ileum also passed through a 'tunnel'-like opening beneath the duodenum and immediately below the transverse colon to join the caecum in the left iliac fossa. The base of the appendix was situated on the right of the caecum near the entrance of the terminal ileum.

The mobile ascending colon on becoming the transverse colon under the left lobe of the liver passed to the right in the retro-arterial 'tunnel', where it was noted to be constricted. The transverse colon had no attached omentum. The descending and sigmoid colons passed down the right side of the abdomen to the rectum.

variants have been described by Estrada (1958), who 'demonstrated that both types have the same embryological basis, namely, reversal of rotation of the midgut loop during the stage of realinement' when elongation of the midgut loop occurs within the physiological hernia. In the normal embryological sequence there is a total of 270° of anticlockwise rotation (*Fig*. 4 A).

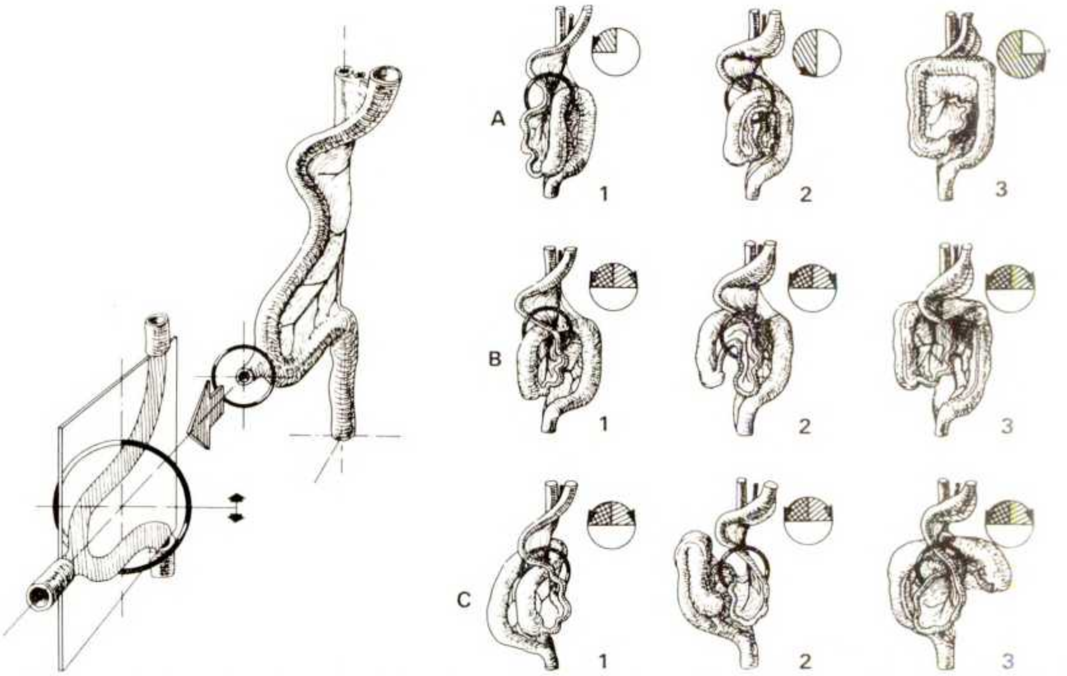

FIG. 4.—Normal and reversed rotation seen from the front. The dark ring represents the physiological hernial opening. The shaded circles represent the degree and direction of rotation at each stage. A, Normal sequence: 1, The first 90° of anticlockwise rotation has occurred. 2, Realinement of the physiological hernia with a further 90° of anticlockwise rotation. 3, Reduction and final appearance. There has been a total anticlockwise rotation of 270°. B, Reversed rotation: 1, The initial anticlockwise rotation of 90° has been reversed with a clockwise rotation of 180° following realinement in the physiological hernia. The net result is a 90° anticlockwise rotation. 2, The postarterial segment has been reduced first. No further rotation occurs. 3, Final appearance. C, Right-sided retro-arterial colon type: 1, Same stage as B1 but showing the hindgut deflected to the right. 2, Further deflexion of the hindgut as the reducing postarterial segment comes back to the left side of the dorsal mesentery. 3, The caecum has 'descended' to the left beneath the omphalomesenteric vascular axis.

In an attempt to correct the malrotation the caecum was pulled to the right from beneath the overlying duodenum and vascular pedicle but it was soon obvious that this only compounded the problem, because the terminal ileum followed the caecum through the tunnel and created a possible 'closed-loop situation' as well as a kink at its junction with the caecum. The caecum was therefore returned to the left side.

After dissection, an operative choledochogram via the gall-bladder outlined multiple filling defects in the common bile-duct as well as the anomalous anatomy (*Fig*. 3). A cholecystectomy was performed, the common duct was explored, and four calculi were removed. The duodenum was opened at the junction of the third and fourth parts and the duodenal 'tumour' was shown to be an oedematous papilla of Vater. An appendicectomy was performed and the abdomen was closed.

The patient's postoperative course was uneventful and when reviewed 3 months and 12 months later she had no complaints.

DISCUSSION

Reversed rotation is a rare anomaly, 45 cases having been reported up to 1969 (Scobie, 1969). The two

In reversed rotation 90° of anticlockwise deviation occurs normally, then during realinement a reversal of rotation of 180° in a clockwise direction occurs (*Fig*. 4 B), followed by the stage of reduction without further rotation. If the pre-arterial segment returns first the entire colon comes to be on the right side of the abdomen, producing the colon and liver ipsilateral variant. If, as is more usual, the postarterial segment returns first the retro-arterial colon variant is produced (*Fig*. 4 B). The conversion to a 'tunnel' is now believed to be a secondary phenomenon of fixation of a small intestinal mesentery which is avascular. This has been confirmed by the description of cases without the retro-arterial tunnel, and by the observation that the avascular mesentery, when present, can be divided and the anomaly totally corrected (Estrada and Gurd, 1962).

The patient described in this article is the first recorded with a left-sided liver and a right-sided colon. The explanation for these findings is difficult, but we believe that the sequence of events follows that described for the retro-arterial colon type and that the displacement of the hindgut to the right side occurred because the reducing postarterial segment returned on the left side of the hindgut dorsal mesentery, thus deflecting it into the right flank, a situation which came about because of the bulk of the developing mass of liver in the left side of the abdominal cavity (*Fig.* 4 C). Subsequently, with the enlargement of the peritoneal cavity and the 'descent' of the caecum into the left iliac fossa, the final adult disposition of the colon resulted (*Fig.* 5).

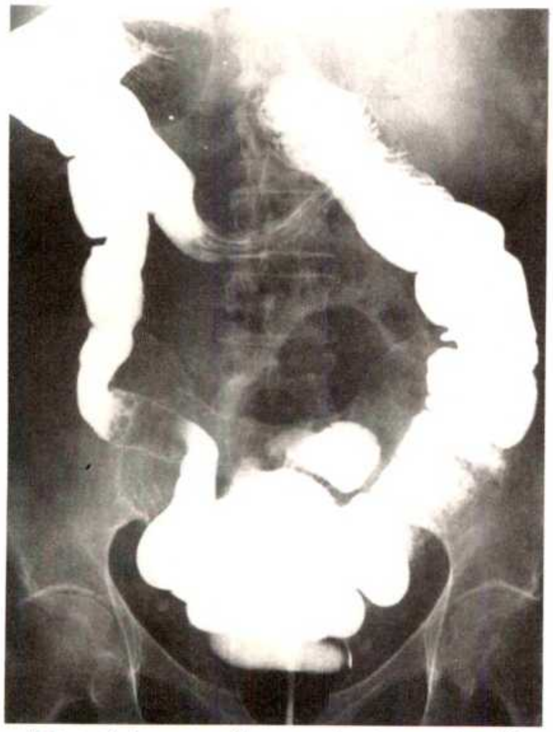

FIG. 5.—Barium-enema film 12 months after operation. The narrowed retro-arterial segment of the transverse colon is clearly seen. Note the sigmoid colon on the right side and the small bowel filling on the left.

Only 2 cases of reversed rotation in association with a left-sided liver have been reported (McIntosh and Donovan, 1939; Van Meurs, 1946), but Estrada (1958) classifies these as reversed rotation with the liver and colon ipsilateral and in which there existed situs inversus of the abdominal organs. The present patient does not have situs inversus of the abdominal organs, as evidenced by the normal positions of the spleen and stomach. Similarly this patient cannot be classified as one of non-rotation with a retro-arterial colon, a situation which Rose (1941) has suggested may easily be mistaken for reversed rotation, because of the finding that there was no attachment of omentum to the transverse colon (volvulus neonatorum excepted).

The clinical presentation of these patients is invariably with the symptoms of bowel obstruction (Estrada and Gurd, 1962). Associated pathology in the presence of reversed rotation has been reported on two occasions and these were only noted at operation (Grant, 1940; Scobie, 1969). The patient reported here is notable in that she underwent surgery for jaundice due to gall-stones and not for bowel obstruction.

At laparotomy the anatomy was not recognized and understood and no definitive repositioning procedure was done. In order to restore the anatomy in this patient a technique similar to that described by Estrada and Gurd (1962) could be employed although the descending colon would remain on the right side. In this method the avascular mesentery joining the retro-arterial tunnel is divided and the entire bowel is then rotated anticlockwise through 360° on its vascular pedicle. It remains to be seen whether further surgery will be necessary in this patient.

REVIEWS AND NOTICES OF BOOKS

The Metabolic Basis of Surgical Care. By WILLIAM F. WALKER, Ch.M., F.R.C.S. (Edin.), F.R.C.S. (Eng.), Dundee, and IVAN D. A. JOHNSTON, M.Ch., F.R.C.S. (Eng.), Newcastle upon Tyne. 8½ × 5½ in. Pp. 251 + x. Illustrated. 1971. London: William Heinemann Medical Books Ltd. £3.

THIS book has been written to give a concise account of the composition and metabolism of the human body in health and in disease. It is both didactic and simplified in its treatment of the subject-matter and is aimed widely at clinicians who look after patients, undergraduate clinical students facing their final examinations in those schools which still adhere to this convention, postgraduates who are going to sit the primary examination for the higher diplomas, and senior members of hospital staff who are trying to care for ill patients. Both authors are well known for their original work on many of the aspects of surgical care on which they write and perhaps their own deep familiarity with their subject has made them assume a basic knowledge which some of their readers will lack; nevertheless there is a vast amount of factual information. Perhaps it is because this book attempts so much in a limited compass that it may fail to please and satisfy at least some of those for whom it was written. Yet at the price of £3 it is within the reach of many more than some current books of its kind. The index is not always accurate, for example, the four references to dextran refer to dextrose and the actual references to dextran are not indexed.

Apart from these comments this book provides a concentrated account of many aspects of a difficult area of surgical treatment and deserves to be widely read.

Essays on Future Trends in Anaesthesia. By A. BOBA, Mount Vernon, Illinois. 9 × 6 in. Pp. 93 + x. Illustrated. 1972. Berlin: Springer-Verlag. DM.28.

'PATIENTS . . . see the anaesthetist in the light of the man who puts them to sleep . . . our surgical colleagues also share this image. . . .' The phrases from the opening page of Dr. Boba's book reflect the image which he is hoping to destroy and which should be extinct in the next generation. However, he also aims to educate anaesthetists, of whom he says: 'unfortunately . . . too frequently this is also the image which he has of himself'. He does not underestimate the task since he concedes: 'The true nature of administering an anaesthetic requires a smaller number of manual skills than any equivalent procedure in medicine'.

This little book consists of four main chapters, in the first of which Dr. Boba analyses and rationalizes processes which the trained anaesthetist performs 'automatically', dealing with monitoring, messages received from the patient, and decisions taken as the result of these messages. The administration of an anaesthetic is likened to a sequential decision-taking process of the intellectual type. No doubt this applies to all of medicine, but nevertheless this is a very thought-provoking chapter. This same type of reasoning is applied to anaesthetic equipment and in Chapter 3 the author deals at length with the 'anaesthetic module' concept. Such things as an independent record of vapour concentration during anaesthesia (analogous to a flight recorder) or a more complete automatic recorder of the entire course of anaesthesia ('black box') are discussed in depth and provide much food for thought. 'Knowledge is the by-product of abstract or intellectual activity and the development of new tools leads to new knowledge.' However, he warns: 'One should avoid the pitfall of building aggregations of gadgets with functional characteristics of great white elephants.'

Next follows a section on first-hand experience which shatters all the concepts of anaesthesia being an art rather than a science and yet even the most unscientific clinician could not fail to benefit from reading this. Although the reviewer does not agree with all the views put forward in this chapter, or in the following one on the future of anaesthesia, he finds those on the value of much of our current monitoring practice challenging and are worth reading by anyone who has the future of the specialty at heart or who considers the routine administration of anaesthesia to be a boring process.

One is left with the thought that the anaesthetist–patient contact will be reduced even more if anaesthesia develops along the lines suggested by Dr. Boba. He recommends us to devote time and energy to 'programmed anaesthesia', but nowhere advises us to be 'good doctors'.

This is not an easy book to read; it is particularly difficult to get started but becomes fascinating as one proceeds. It leaves one with two big unanswered questions: Who pays for the equipment? Has the author ever heard of the millions of people who cannot get the basic necessities of medical care?

Management of Neglected Trauma. Edited by J. FRANCIS SILVA, F.R.C.S., F.R.A.C.S., F.A.C.S., Kuala Lumpur. 9¼ × 6 in. Pp. 323 + xvi. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $19.50.

THIS volume has a seductive title and amongst its nine contributors one recognizes several orthopaedic surgeons who have carried out noble work under often difficult circumstances. However, its promise is unhappily not fulfilled. With one or two exceptions, the book consists of a digest of well-known facts in everyday orthopaedic practice. Many of the techniques described can hardly be considered suitable for countries which—to use the editor's introductory words—'have hardly more than a few scattered orthopaedic centres, all with a heavy work load'. In such conditions it is difficult to understand the free use of metal prostheses for the late effects of trauma to the shoulder, elbow, knee, or hip.

In this context it is also surprising to note that time is seemingly available to follow the advice, for example, that 'small tears of the rotator cuff have to be operated upon'.

The book also suffers from some rather cursory proofreading which adds to the general impression of a lack of direction. A few examples may suffice: ulna used as ap adjective, the mis-spelling of 'Jowett' for 'Jewett', 'Nuefeld' for 'Neufeld', 'straighten' for 'strengthen' the quadriceps, and a transposition of legends to figures, e.g. 108 and 109.

Nevertheless, on more careful perusal, one finds several worth-while and occasionally highly instructive concepts. It is not surprising to find in the chapters by Professor Huckstep, with his vast experience in this field, a careful and highly informative essay on the treatment of the late traumatic dislocations of the hip which might well be read to advantage by all surgeons in metropolitan countries. 'Neglected trauma' is unfortunately not confined to any particular parts of the world! Professor P. T. Kotani of Osaka, whose treatment of brachial plexus injuries is now receiving increasing attention, gives a very interesting and modest account of his attempts to restore sensibility and occasionally some motor power to a totally paralysed upper limb. Such a challenging endeavour from one of the newer orthopaedic centres should stimulate us to re-examine many of our established (if not yet fossilized) ideas. It is very much to be hoped that serious revision of a future edition of this book will enable it to fulfil more satisfactorily the obvious need for a book on this subject.

The Anesthesiologists Handbook. By Donald G. Catron, M.D., Tennessee. 7 × 4½ in. Pp. 158. Illustrated. 1972. Baltimore: University Park Press. $7.50.

In his preface the author states that he has aimed to compile a collection of reference material in the form of a convenient handbook; he says 'few memories would fail to benefit from an occasional on the spot review of a problem situation'. Although many facts are presented in this book, explanation is scanty; Chapter 4, which is entitled 'Anaesthesia for Thoracic Surgery', is especially deficient.

The names of many of the drugs mentioned differ from the terminology used in the United Kingdom. There are very few figures, and these are very small; a mere 25 references are offered at the very end of the book and do not represent a particularly valuable selection. In the main, however, the book is to be criticized for the intense degree of condensation rather than for inaccuracy.

One is tempted to compare it with Alfred Lee's magnificent *Synopsis of Anaesthesia* which is available in the same price range; in this perspective Dr. Catron's book seems to be inadequate and cannot be recommended to British students or practitioners of anaesthesia.

Progress in Pediatric Surgery, Volume 3. Edited by P. P. Rickham, M.D., M.S., F.R.C.S., D.C.H., Liverpool, Professor W. Ch. Hecker, München, and Professor J. Prévot, Nancy. 8½ × 5½ in. Pp. 167. Illustrated. 1972. Baltimore: University Park Press. No price given.

This is the third volume of an annual review of various aspects of paediatric surgery. In this volume there are two chapters on deformities of the chest. The first by Ravitch is the Simpson-Smith Memorial Lecture of 1970, and it gives a good account, particularly, of funnel chest and advocates radical treatment. The second article discusses the aetiology and pathogenesis of funnel chest and the experimental production of it in rabbits, and suggests that the most important causal factor is probably a dysplastic anterior chest wall. Bughaigis and Emery discuss functional obstruction of the intestine in the newly born on the basis of immaturity of the nerve-supply of the bowel, and this is followed by a discussion of the effects of subvesical disturbances of urinary drainage on the upper urinary tract in childhood. There is an interesting paper on preduodenal portal vein which discusses at some length the embryology, and another section discusses the function of the cardia in childhood and reports the results of measurements of intracardial pressure in 152 children. The remainder of the book is a report of a symposium on extensive therapy in newly born babies submitted to surgical operations. It covers the administration and design of an intensive-therapy unit, the indications for intermittent positive-pressure ventilation, the features and design of ventilators, and the results of long-term positive-pressure ventilation in newly born surgical patients. It is inevitable that there should be differences of opinion about the indications for and value of positive-pressure ventilation and these two sections will well repay close study by paediatric and other surgeons and their anaesthetists who are concerned with the surgical care of the newly born.

There is much of interest in this book which really consists of a number of papers which are too long to be accepted by surgical journals and are here conveniently put together in an annual package for the specialist reader.

Scientific Basis of Surgery. Second edition. Edited by W. T. Irvine, B.Sc., M.D., Ch.M., F.R.C.S. (Eng.), F.R.C.S. (Edin.), St. Mary's Hospital, London. 9¾ × 7¼ in. Pp. 677 + x. Illustrated. 1972. Edinburgh: Churchill Livingstone. £9·50.

The merits of the scientific approach to surgery are accepted by all who take part in the training of surgeons. Craftsmanship on its own is no longer enough. Among so many distinguished Scottish academic surgeons none had a broader outlook or was more ready to contribute massively to surgical science than Professor Irvine, who in the early 1960's prepared the first edition of this accepted standard work and who has now revised and added to his material in a second edition. His modest preface could conceal the vast amount of work that he and his contributors have undertaken to maintain the leading position that this book enjoys. A perusal of the list of references (now greatly improved in interest and usefulness by the addition of titles) soon shows how much new material has been added. With the exception of the chapters on peripheral circulation (lacks ultrasound), repair process of nerves (no mention of limb replantation), urology (little on renography), hyperbaric oxygen (gas gangrene, the chief application, still eclipsed by other, less useful ones), the advances since 1965 are well covered, particularly in the sections dealing with gastric function (by the editor), shock, and surgical infection, as well as that on the biochemistry of the cancer cell. This elegant, simple, comprehensive book will clearly maintain its deservedly superior position.

Radiology in Renal Disease. Edited by Thomas Sherwood, Royal Postgraduate Medical School, London. 11 × 8½ in. Pp. 75. Illustrated. 1972. London: British Medical Bulletin. £2·25.

In no sector of clinical medicine has radiology made greater contributions in recent years than in that of urology, mainly but not exclusively because of the work of Hodson, formerly of University College Hospital, London. The tendency to think that this contribution is solely in the improved application of a diagnostic method to clinical problems is corrected in this well-produced issue which presents the whole spectrum of urological radiology. The use of newer methods is amply demonstrated in papers by Joekes and Rhys Davies on isotopes, and Barnett and Morley on ultra-sound.

Urological radiology leans heavily on the employment of contrast media which have now been elaborated to greater degrees of safety and a higher radiographic pictorial quality. The toxicity to the kidney of all types of such agents is discussed by Grainger, paying particular attention to the peculiar risks in renal and hepatic failure.

The great research potential of radiological techniques in anatomy and physiology is reflected in the work of Kelsey Fry and Cattell on nephrography, that of Lavender and Sherwood on the fine detail of circulatory patterns in hypotension which is most beautifully illustrated, and that of Sidaway using macro-angiography *in vivo* in the study of clinically common problems.

The Guy's Hospital research team record their experience with and assess the value of needle nephrostomy mainly in difficult problems of acute upper urinary-tract obstruction; this technique at once offers a means of decompressing the kidney and appraising its function. To be able to record pressure and flow recordings simultaneously and also to see the dynamic radiographic picture of the bladder by videocystography promises much in the investigation of disorders of vesical function. Whiteside has contributed an excellent and concise paper on the work done by Turner-Warwick and himself using a development of Miller's technique which is likely to lead to a much clearer appreciation of the hitherto obscure mechanisms of micturition, perhaps particularly in the neurogenic bladder.

The purely clinical aspects of urinary-tract radiology are selectively described in articles on medullary necrosis in infancy (Chrispin), tropical disease (Middlemiss), and spinal dysraphism (J. E. Williams) and in an informative contribution by Hodson on post-obstructive atrophy of the kidney which includes a correlation between the radiological picture and the pathological condition.

A high standard of illustration has been achieved in this work and is nowhere better seen than in the two articles by Doyle and his colleagues describing the patterns and pathogenesis of bone disease in renal failure.

The editor, Thomas Sherwood, in combining established findings with work in progress has produced a well-balanced issue of the *British Medical Bulletin* which will interest and inform the growing body of people in all disciplines concerned with the elucidation and treatment of urinary-tract problems.

Medicine and Public Health in the People's Republic of China. Edited by Joseph R. Quinn, Ph.D. 9 × 6 in. Pp. 305 + xii. Illustrated. 1972. United States Department of Health, Education and Welfare. No price given.

With China readmitted to the world's councils and a thaw in the long restrictions in cultural and economic exchanges the appearance of this report on one of the first medical visits to China in modern times is of certain value and interest. It is a successful outcome of much sincere goodwill on both sides and a great deal of hard work and frank discussion. In particular, the role of Chinese traditional medicine—a subject on which most Chinese are sensitive—and its special pharmacology are both faithfully reported, with a selection of English references. Although most of the book is given over to broad subjects of collective rather than individual interest (much of it in the genre of the Cultural Revolution with many faithful citations from Chairman Mao) there are other special features of great interest to Western readers; in particular, there is quite a long section on acupuncture, with many interesting examples, clinical photographs, and diagrams of puncture sites. The figures and charts that have been permitted to be reproduced are of surprising frankness and interest. This is a paperback that should not be missed by anyone with an interest in this topical subject.

Operative Anatomy of Thorax. By Edward A. Edwards, M.D., Paul D. Malone, A. B., and John J. Collins, jun., M.D., Harvard Medical School. 11 × 8¼ in. Pp. 246 + xvii, with 134 illustrations. 1972. London: Henry Kimpton. £7·90.

This is the first of a series of volumes designed to cover the 'operative anatomy' of every region of the body. By the term 'operative anatomy' the authors mean to include specific operative approaches, views seen at operation, anatomical anomalies to be expected, and operative dangers. This is a formidable list to cover in a mere 200 pages. There is a considerable amount of text, but about a third of the book consists of illustrations. Curiously, most of these are taken from classic papers on the subject, so that many are 20 or 30 years old. One has only to look at these figures to realize the enormous strides that have been made in medical illustration in the past 25 years. Many of the drawings are, therefore, quite inadequate for present-day purposes, although they may be of great historical interest.

The original illustrations (in black and white) are clear and useful. The previously published ones are often obscure. Thus, figures 3 and 9 are said to illustrate extrafascial apicolysis. There is, however, no mention of Sébileau's bands, even though they are just visible in the drawing taken from Sébileau's paper and dated 1891.

Some of the illustrations are of little value. It is difficult to see the purpose of 2 whole pages devoted to poor drawings of the standard views of the mediastinum and root of the lung which are known to every medical student. These figures are repeated on pp. 174 and 175.

The text follows the illustrations in often being of greater historical interest than practical value. Surgery would have no right to be called a profession if, indeed, all operations were still carried out exactly as described by their originators. For example, an illustration shows Blalock's operation with the original anterior thoracotomy which left an ugly scar across the front of the chest. There is no mention of Potts's or Waterston's operations. The only description of the operation for coarctation of the aorta is that of Gross (1953). The incision advised is a posterolateral T-shaped one through the fourth intercostal space, dividing the posterior ends of two ribs above and three below this level!

It is disappointing to find that the anatomy illustrated is that of the normal structures, whereas the surgeon is interested in the abnormalities and distortions caused by pathological processes. The surgeon operating on, for example, a case of Fallot's tetralogy would get little guidance in the anatomical variations within the right ventricle from the brief account given here. There are useful sections on the variations in the anatomy of the coronary arteries and on the cardiac conduction system. It is difficult to understand how the authors determined what material to include and what to exclude. This unbalanced approach is seen in a full description of the Vineberg operation but none of aorto-coronary by-pass grafting. Similarly, although there is a chapter on cardiac transplantation, there is no mention of the surgery of total anomalous pulmonary venous drainage or of transposition of the great arteries.

The book as a whole suffers from indecision, hovering between an anatomical descriptive approach and a detailed account of surgical technique. Lingulectomy is illustrated in detail as an example of segmental resection, but this would be of little help to the surgeon seeking information on how to perform a resection of the anterior segment of the right upper lobe of the lung.

The description of the antireflux mechanism at the cardia is outdated and indeed must be so, since there is no reference to oesophageal manometry. The Allison repair is described as the only transthoracic procedure and the Lucius Hill technique as the only abdominal operation, without any attempt to appraise them critically. There is no mention of the Belsey and Nissen procedures.

The book leans far too heavily on somewhat outdated published material and not at all on the authors' experience. For these reasons it will be of much less assistance to the trainee surgeon than a more personal and up-to-date approach would have been.

Atlas of Improved Surgical Procedures for Common Foot Disorders: Ingrown Toenail and Hammertoe. By George C. Wee, M.D., F.A.C.S., F.I.C.S., St. Louis. 9 × 6 in. Pp. 58 + xv. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $6.

This is an extraordinary monograph describing 'phenolic [*sic*] cauterisation . . . of ingrown toenail' (13 single line drawings including sports shoes, a beaker of phenol solution, and a tube of ointment) and 'excision of the proximal phalangeal head for . . . hammertoe' (10 single line drawings), the latter deformity being described as the most common congenital [*sic*] disorder of the foot!

There is more text in the preface and introduction than in the main body of the book. Even at $6.00 it is difficult to recommend it for serious consideration by medical students or chiropodists in training.

Spezielle Chirurgie für die Praxis. Vol. 11, Part 2, **Digestive System 11.** Edited by F. BAUMGARTLE, Augsburg, K. KREMER, Düsseldorf, and H. W. SCHREIBER, Hamburg. 10¼ × 7¼ in. Pp. 892, with 470 illustrations. 1972. Stuttgart: Georg Thieme Verlag. DM.458.

THIS major textbook of practical surgery has 22 contributors who are all actively engaged in surgery at 10 different West German clinics. The book is beautifully produced and has over 1000 diagrams, figures, and tables with clear line drawings of operative procedures. The book covers the surgery of the small and large intestines, including the appendix, and is essentially a working handbook for the operating surgeon. Each subject is fully described under the main headings of Diagnosis, Indications for Surgery (absolute and relative), Contra-indications, Operative Techniques, covering the various alternative procedures, and finally Complications. Very complete lists of references are given with the full titles of all the papers mentioned; for example, those for the jejunum and ileum number 669, including many from the English literature. The various sections are clearly and concisely written and the indexing is good.

This book is too big to allow detailed review of any special chapters but it has been well edited and must be regarded as an excellent exposition of present-day surgical practice in West Germany with the typical characteristics of German care, thoroughness, and attention to detail. It is essentially a practical book designed for the practising surgeon.

Gastrointestinal Hormones. International Symposium at Erlangen, August, 1971. Edited by Professor Dr. L. DEMLING, Erlangen. 9 × 6⅛ in. Pp. 118, with 100 illustrations. 1972. Stuttgart: Georg Thieme Verlag. DM.29.70.

OUR knowledge of gastro-intestinal hormones has notably increased during recent years and their importance has been more fully recognized both in health and disease. This book presents an excellent review of the subject, being a most expertly edited account of an international symposium held at Erlangen in August, 1971. Many of the papers are concerned with new work and the names of those contributing are sufficient guarantee of their scientific value. Professor Demling has shown great editorial skill in the way in which he has produced such a uniform pattern of reports with a clear and concise presentation by authors from seven different countries. Most of the work reported is experimental and, as would be expected, is largely concerned with the action of gastrin, secretin, cholecystokinin, and caerulein. Grossman's brilliant paper gives a fine review of much fundamental work and makes clear how it is the length of intestine exposed to hydrogen ions which ultimately controls the release of secretin and so the output of bicarbonate. There are interesting reports from the Texas school upon the way in which oral calcium raises the gastric acid without there being any increase in the serum-calcium level, and a number of other stimulating and valuable contributions. In all there are 16 papers in this small book of only 117 pages, but it is well illustrated with diagrams and tables and, in spite of its rather high price, is an important contribution to gastro-enterology. The editor and contributors are to be warmly congratulated.

Air Instrument Surgery, Vol. 2. **Orthopedics.** Edited by R. M. HALL, Santa Barbara, California. Pp. 509, with 356 illustrations. 1972. Berlin: Springer-Verlag. DM.140.

THIS is a 'textbook' or rather a technical handbook in which every conceivable operation upon almost every bone or every joint of the human body using the Hall air-driven instrument is shown. Fourteen orthopaedic surgeons and two neurosurgeons have described how their particular operation can be carried out utilizing this powered instrument. They have even managed to design an air driver for knocking in a femoral prosthesis (instead of a hammer) and an air extractor for pulling it out.

The line drawings are very well done, with the attachments of this machine being greatly in evidence. An interesting although unusual use of a rib graft is illustrated in the Addendum on Thoracic Surgery. A section of an entire rib is screwed into position across the inlet of the pelvis in the line of the superficial perineal membrane, but with no mention of the underlying pathology or of any reason for such a grafting procedure.

The most important section of this book is that entitled 'An Equipment Guide'. This describes the physical properties, the repair, and maintenance of the air drill and its attachments.

In the preface the editor quite rightly points out in describing his instrument that 'possible application and adaptations are as unlimited as the surgeon's skill and imagination'. The real limitation comes in who has DM.140 for this book.

Human Sterilization. Edited by RALPH M. RICHART, M.D., New York, and DENIS J. PRAGER, Ph.D., Seattle, 8¾ × 6 in. Pp. 402 + xx. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $21.

THIS book recording the proceedings of a conference held in October, 1969, to discuss the international problems of human sterilization contains details of the different methods of sterilization in both males and females and it provides information on the evaluation of the different techniques in different communities. The book is principally of interest to the specialist in this field for whom it provides a wealth of information, but it is of less interest to the general reader, except perhaps in selected passages, particularly the reports of the discussions.

Applied Surgical Anatomy. By CHARLES MARKS, M.D., M.B., Ch.B., M.S., F.R.C.P., F.R.C.S., F.A.C.S., New Orleans. 9 × 6 in. Pp. 598 + x. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $22.50.

A SAD feature of medical education in many schools in the United States is the downgrading of anatomy in the curriculum. The author of this book, a professor of surgery at the Louisiana State University School of Medicine, has attempted to review the fundamentals of anatomy and to relate them to clinical conditions. He has aimed this volume at both students and graduates in speciality training. Considerable space, both in the text and illustrations, is given to clinical surgery but, unfortunately for students in this country, the anatomical details are insufficient for examination requirements. Modern anatomical nomenclature is not used, many of the photographs are not of high quality and several are upside down, and a number of important structures (including the heart and coronary vessels) are not illustrated anatomically. The aim of this book is praiseworthy but it is unlikely to meet the needs of British medical schools.

Post-prostatectomy EPSIKAPRON® is better than post-prostatectomy bleeding*

**This observation has a high degree of clinical significance.*

Post-prostatectomy blood loss may be a litre or more[1,2]. Use of EPSIKAPRON can reduce this loss by 80-90%[3,4]. "The control of blood loss has proved to be not only statistically but also clinically significant"[2]. Blood transfusion, which is costly and not without risk, ". . . can be avoided and draining catheters kept patent without difficulty and removed earlier, which makes the post-operative course smoother and shorter"[3].

MERCER'S ORTHOPAEDIC SURGERY

Seventh Edition

Robert B. Duthie and Albert B. Ferguson Jr.

It is over forty years since the first edition of this world-famous textbook on Orthopaedic Surgery appeared. In this Seventh Edition the authors have taken the opportunity to completely revise the text. Much of it has been either reorganised or rewritten; many illustrations have been added and outdated ones replaced. Great care has been taken to select material of proven value to ensure that the book's reputation for providing essential, relevant knowledge for both postgraduates and undergraduates is maintained. The scope of the book has been widened to include the important developments and significant advances in orthopaedic surgery.

The authors have purposely avoided making this a manual of surgical practice. The clinical presentation of the various diseases and disorders of the musculoskeletal systems and their basic sciences of anatomy, physiology and pathology are stressed.

Review of the previous edition

"Mercer's Orthopaedic Surgery has not aged with the passage of the years, and the present edition has a vigour and a freshness that will ensure its survival for a long time to come. Its authors are not only to be congratulated they are to be thanked for a notable contribution to the literature of an important field of surgical endeavour."

FRACTURES AND DISLOCATIONS IN CHILDREN

ANDREW G. POLLEN

1973 *244 pages* *205 illustrations* £5·50

Despite the large number of children who attend fracture clinics many textbooks pay scant attention to this important subject. This book has been written as a practical guide to the treatment of fractures and dislocations in children. It is intended to be a reference book for day to day use by Casualty Officers, Orthopaedic Registrars and other doctors who may be responsible for the primary treatment of children's injuries.

SURGERY OF REPAIR AS APPLIED TO HAND INJURIES

B. K. RANK, Kt.
A. R. WAKEFIELD
J. T. HUESTON

1973 Fourth Edition *408 pages* *310 illustrations* £4·00

Some reviews of previous editions
'This is without doubt the most outstanding thesis on the surgery of acute hand injury. In addition it is a very considerable contribution to the principles of the surgery of repair outside the hand.'—*British Medical Journal.*

'It has had a great impact on surgeons, general, plastic and orthopaedic, all over the English-speaking world. To it must certainly go some of the credit for the improved standard of care and the improved results seen today in the treatment of injuries of the hand.'—*Practitioner.*

CHURCHILL LIVINGSTONE

Although medical science has leapt ahead....
no one has produced a finer surgical blade than Swann-Morton!
22

Swann-Morton, the world's largest producers of surgical blades have kept abreast of the extremely high demands in surgical fields. Safe, stable and economical, their blades are sterilized by gamma radiation packed in quick peel foil envelopes and of a superb quality yet to be beaten.

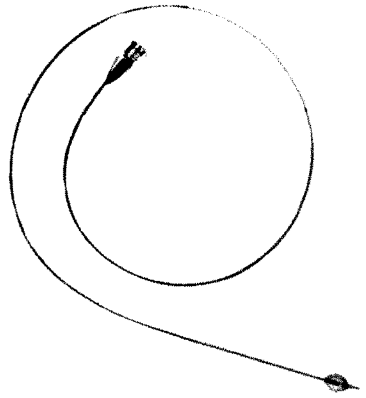
FOGARTY CATHETERS FOR ACUTE VASCULAR OCCLUSION



FOR: Venous Thrombectomy

Occlusion/Emergency Tamponade

Arterial Embolectomy

Dilation/Creation of Atrial Septal Defects in Infants

Double Lumen Balloon Catheter/Creation of Atrial Septal Defects in Infants

Biliary Balloon Probe/Exploration and Removal of Debris and Stones

Irrigation

Rugged Universal Hub Fits All Luer-Lok Type Syringes

BALLOON CATHETER CONCEPT

Each catheter has a specially constructed balloon at the distal tip (except Irrigation Catheter). In thrombectomy and embolectomy, when the catheter is introduced into a vein or artery, the instrument follows the path of least resistance and the tip threads itself past the thrombus or plaque. The balloon is then inflated with sterile fluid and the catheter withdrawn, bringing the clot with it. As an emergency tamponade, for dilation, or as a biliary probe, the balloon is similarly inflated.

GENERAL DESIGN FEATURES

1. Tips on the various types are specially designed for the particular procedure; all are soft and atraumatic.
2. Controlled symmetrical balloon geometry.
3. Secure balloon attachment by epoxied suture.
4. Length marked catheter bodies.

Explanation of Model Numbers in the following table; i.e.; 32-6F

Type	*32*	*Venous*
	62	*Occlusion*

Anorectal Surgery

E. S. R. Hughes and A. M. Cuthbertson
Staff surgeons at the Royal Melbourne Hospital
January 1973: 241 × 178mm: 332pp: half-tone and line illus: 85878 008 9: **£4.50**

The purpose of this book is to set out current practice in the field of anorectal surgery. Special emphasis has been placed on common conditions and the authors' own approach to these has been described.

Contents: Surgical Anatomy of the Anal Canal and Rectum; Rectal Continence and Defaecation; The Symptoms of Anorectal Disease; Investigation of Anorectal Disease; Surgical Wounds of the Anal Region; Anaesthesia for Anorectal Surgery; Anorectal Suppuration (Abscess); Anorectal Suppuration (Anal Fistula); Sinuses Related to the Anus; Anal Fissure; Haemorrhoids; Prolapse of the Rectum; Pruritus Ani; Anorectal Pain of Uncertain Origin; Proctitis (Non-Specific); Benign Ulcers of the Rectum; Irradiation Damage of the Bowel; Benign Tumours of the Rectum; Carcinoma of the Rectum; Squamous Cell Carcinoma of the Anus and Anal Canal; Index.

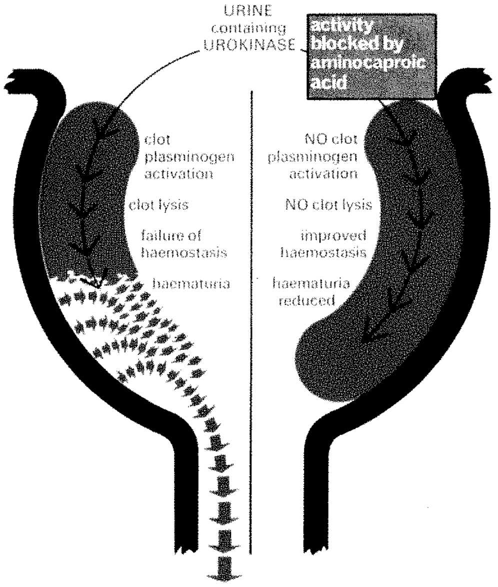
The mechanism of post-prostatectomy bleeding and EPSIKAPRON® control



Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing:

the need for post-operative blood transfusion
clot retention
catheterization
the risk of infection
the period of hospitalization

Presentation
Epsikapron Solution for Injection 0.4 g/ml Box of 6 ampoules of 10 ml, each containing 4.0g aminocaproic acid (0022/5003) Epsikapron Effervescent Powder 50% Box of 30 sachets, each containing 3.0g aminocaproic acid (0022/5004) Epsikapron Syrup 0.3g/ml Bottle of 250ml (0022/5005)

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·83	£3·70	£4·27	£5·70	£5·69	£6·32	£7·74	£8·99
4	3·58	5·19	6·09	7·12	8·07	9·09	10·97	12·97
6/8	5·94	7·62	9·27	10·84	12·59	14·09	17·47	20·72
10/12	9·32	12·72	15·09	17·72	20·34	22·97	28·40	33·05
14/16	10·37	14·34	17·47	20·59	23·72	27·03	33·18	39·55
18/20	14·62	19·47	23·47	27·47	31·78	35·93	44·05	50·89
COVERS	1·94	2·75	3·57	4·38	5·19	6·00	7·63	9·25

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House,* 159 *Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

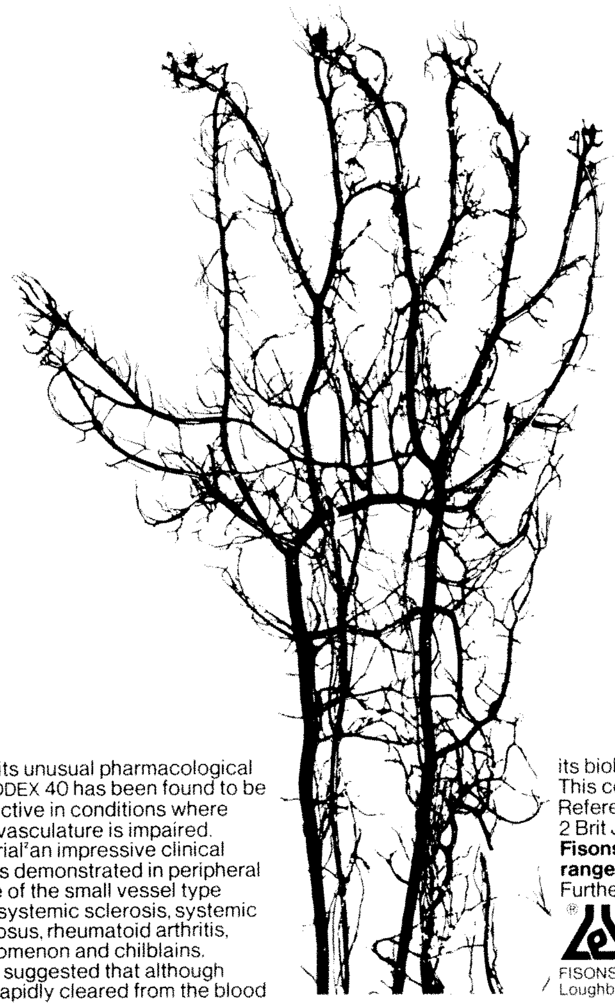
TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

> "By reducing intravascular "sludging" – the aggregation of erythrocytes into clumps – it (low molecular weight dextran) improves the flow of blood through small vessels.[1]"



Because of its unusual pharmacological properties, LOMODEX 40 has been found to be dramatically effective in conditions where flow in the microvasculature is impaired.

In a recent trial[2] an impressive clinical improvement was demonstrated in peripheral vascular disease of the small vessel type associated with systemic sclerosis, systemic lupus erythematosus, rheumatoid arthritis, Raynaud's phenomenon and chilblains.

The authors suggested that although LOMODEX 40 is rapidly cleared from the blood its biological effect may persist for 10-12 weeks. This could explain the prolonged improvement.

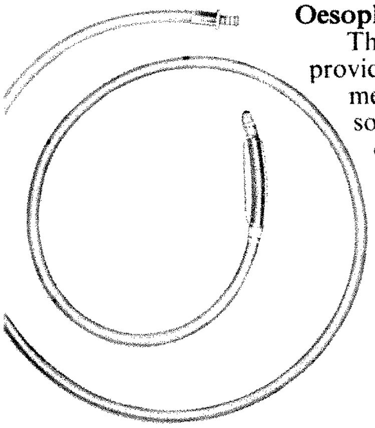
Add your experience to ours and you have the beginning of a successfu operation.

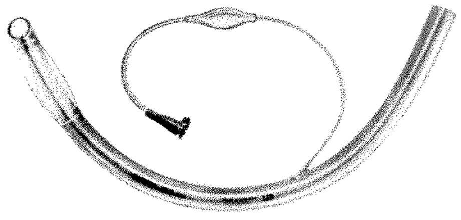
Our 30 years experience have been ledicated to the advancement of surgical ınd medical practice throughout the vorld. And although our contribution nay be small, we take great pains to nake it important.

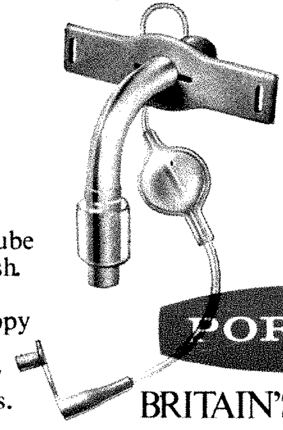
We maintain the highest tandards of quality. Which is why our products need no modification to meet the regulations of the most demanding public health bodies.

But we are never satisfied with past and present achievements. Our continuing programme of research seeks to develop new products. The products you'll want tomorrow.



Oesophageal Stethoscope This is a new product which provides a simple, yet highly efficient method of monitoring heart sounds. It is particularly useful during paediatric and neurosurgical procedures. Available in three sizes, all double wrapped and sterile.





Cuffed Blue Line Endotracheal Tube Designed with a new thin wall to give up to ½ mm larger lumen than before and with even better slip properties. The cuff is inflated symmetrically via the airline which is incorporated into the wall without reduction of lumen.

Blue Line Tracheostomy Tube The new Portex tracheostomy tube as an extra smooth non-irritant finish. lesigned to allow easier suction atheterisation. The strong inert floppy uff allows lower inflation pressures. ach tube is supplied with a one way alve and its own spool of neck tapes.

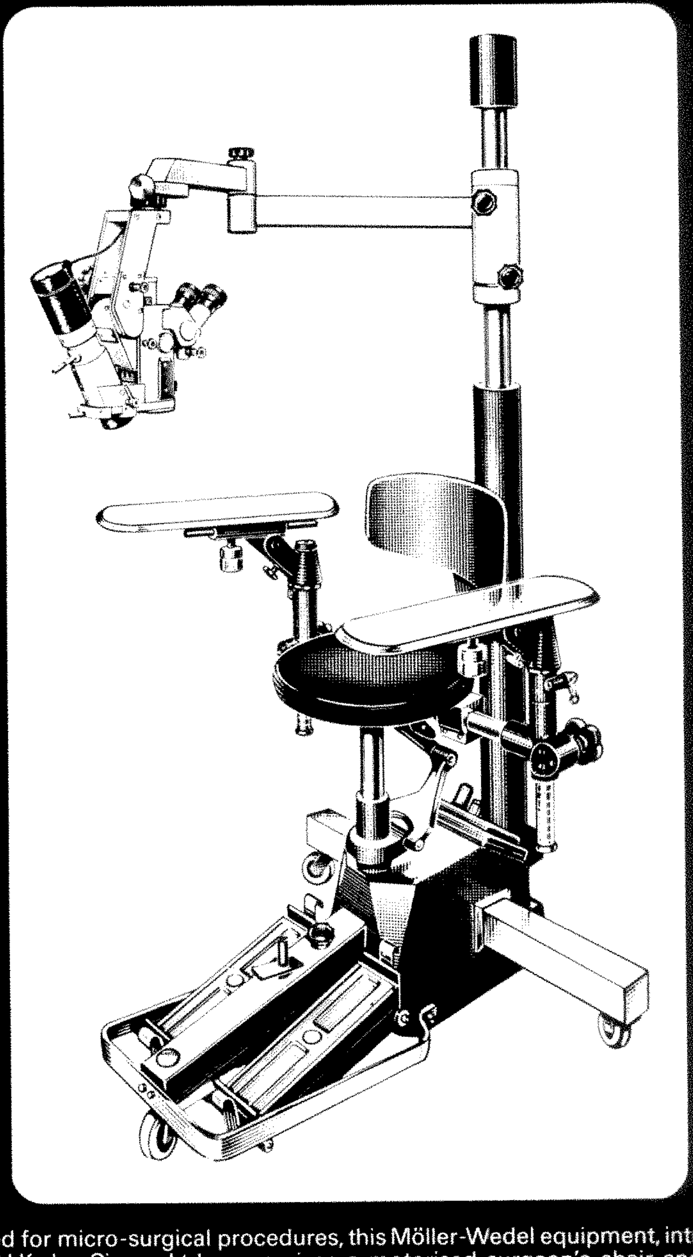
Down Bros and Mayer & Phelps Ltd
CHURCH PATH MITCHAM SURREY CR4 3UE ENGLAND

Sit down with Sierex



Designed for micro-surgical procedures, this Möller-Wedel equipment, introduced to the U.K. by Sierex Ltd., comprises a motorised surgeon's chair and Möller microscope. Footswitches control the height of the chair, raise and lower the microscope, adjust the magnification, activate surgical diathermy and cryo-surgical units, operate still, cine and television cameras . . . and control the operating table too.
Sierex will be pleased to tell you all about it.

Surgical Gut

absorbable by nature
dependable by Ethicon*

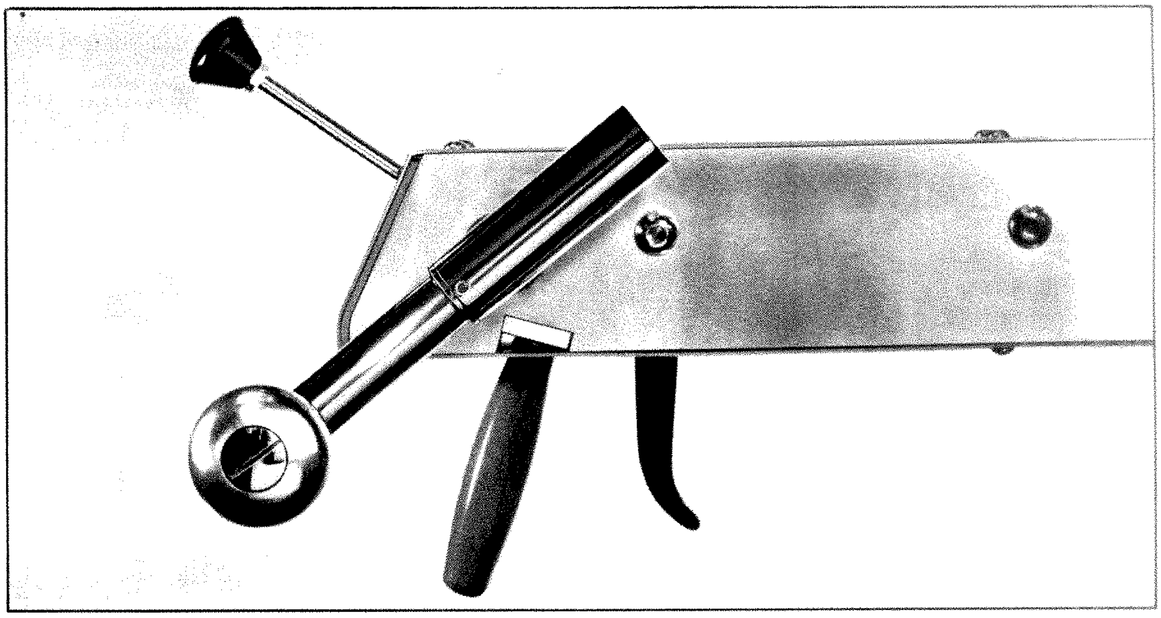
When the need is for an absorbable suture ETHICON surgical gut is the natural choice.

The natural advantages of surgical gut are enhanced at Ethicon by the use of the most modern technology available.

The result is a suture of unsurpassed purity and uniformity upon which the surgeon can rely.

ETHICON*

. . . leadership in wound repair



Our head of table is unique.

The Matburn MS is a dramatic addition to our M table series, which are used in more countries throughout the world than any other operating tables.

The MS controls are grouped on a moveable selector arm at the head end to enable all major table movements to be made without disturbing the surgical team or the sterile area.

It's the most advanced table of its kind.

For further details and demonstration, please use the coupon.

Are you sitting comfortably?

Then we'll begin.

When an organisation like Carl Zeiss turn their attention to the problem of designing an apparently simple thing like an operating chair you can be sure the result will be rather superior.

And it is.

Two models are available as illustrated with a different base if the foot switching facility is not needed. Both are very stable working platforms.

1
Three foot operated cross-switches for 12 functions. (For motorized control of Operating Microscopes with ceiling unit, motorized stands etc.)
2
Seat adjustable for height with foot plate.
3
Arm rests adjustable for width, height, inclination, 360° rotatable, side tilt ±70°, and can be moved forwards or backwards ±180 mm.
4
All cables neatly routed away outside field of work activity with automatic reeling.
5
Back rest adjustable for height and rotatable.
6
All body contact surfaces padded, removable and washable. Arm rests can be sterilized.
7
Easily movable on braked rollers.
8
Superbly comfortable.

TRAUMA SURGERY: EXCEPTING BONES AND JOINTS

P. Powley, M.B., B.S., F.R.C.S., *Consultant Surgeon, Swindon and District Hospital Group.*

This book is designed for hospital staff involved with the reception and initial treatment of the victims of accidents—either road or industrial. It explains in detail the various injuries to the parts of the body other than the main bones and stresses which injuries require specialist treatment from the onset.

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

ORIGINAL PAPERS

METABOLISM AFTER INJURY: 2. EFFECT OF A DRYISH AND WARM ENVIRONMENT ON SKIN TEMPERATURES AND ELECTROLYTE RESPONSES

By D. P. CUTHBERTSON and A. G. RAHIMI*
UNIVERSITY DEPARTMENT OF PATHOLOGICAL BIOCHEMISTRY, ROYAL INFIRMARY, GLASGOW

SUMMARY

Patients with moderate to severe fractures of the major long bones of the lower limb had generally warmer extremities if nursed in cubicles with a dryish (35–45 per cent relative humidity) and warm (29–30° C.) environment than if maintained at a normal temperature of 20–24° C. The additional heat was applied soon after the period of shock was over and was then provided for a further 10–12 days thereafter. The effect of a higher temperature in reducing the protein catabolic response to injury—which seems mainly to involve an increase in the catabolism of some muscle proteins accompanied by increased urinary excretions of potassium, creatine, and zinc—has already been described (Cuthbertson, Fell, Smith, and Tilstone, 1972). The effects of a warmer atmosphere on oral and skin temperatures over various surfaces are described in the present paper and these effects are compared with those found when extra bed coverings are applied under normal ward environmental conditions (20–22° C.). By the application of such heat the skin temperature of the extremities can be raised several degrees; that of the large toes by as much as 12° C. By the use of extra bed coverings conductive losses can undoubtedly be diminished, particularly at normal temperatures.

Oral, axillary, and frontal and mastoid process temperatures are not apparently influenced by a higher environmental temperature but appear to be mainly related to the degree of traumatic fever.

The advantage of the higher environmental temperature over extra bed coverings is presumed to be mainly in reducing total resting heat production from resting to basal values by providing thermoneutral conditions.

Apart from a significant reduction in the rise in serum potassium around the fifth day after injury and a reduction in the normal increased urinary excretion of potassium previously noted, there were no significant changes in the concentration of other serum electrolytes as a result of the higher environmental temperature, nor were the other characteristic electrolyte patterns of urinary excretion altered by the change in the ambient temperature. There were also no distinctive differences in the pattern of urinary amino-acids at the two temperatures.

THE influence of a dryish (35–45 per cent relative humidity) and warm (28–30° C.) environment on the protein, potassium, creatine, and zinc metabolic response to moderate to severe injury of the lower limbs of man has been described in a previous paper (Cuthbertson and others, 1972). The present paper provides additional data on the effect of this thermoneutral environment on smaller groups of male patients with fractures, in respect of their skin temperatures, electrolytes, and certain other metabolic responses. The skin temperatures of a few patients were studied at both temperature levels.

MATERIALS AND METHODS

Patients.—The patients were all otherwise healthy males aged 18–67 years. Two groups were studied: in the first group 11 patients were investigated intensively, some at the two temperature levels; in the second group 18 patients (9 at each temperature) were studied less intensively but with particular regard to the electrolyte responses. A few patients in the first group fitted into the second series.

The patients with long bone injury were studied for 9–12 days after injury in the same cubicles as described previously (Cuthbertson and others, 1972). The

dietary régime was similar for the patients at the normal ward temperature (20–24° C.) and for those at 29–30° C. The total energy intake was around 2500 Cal per day and protein accounted for 13–14 per cent of the total calories. The amino-acid pattern of the intake corresponded to that of muscle protein.

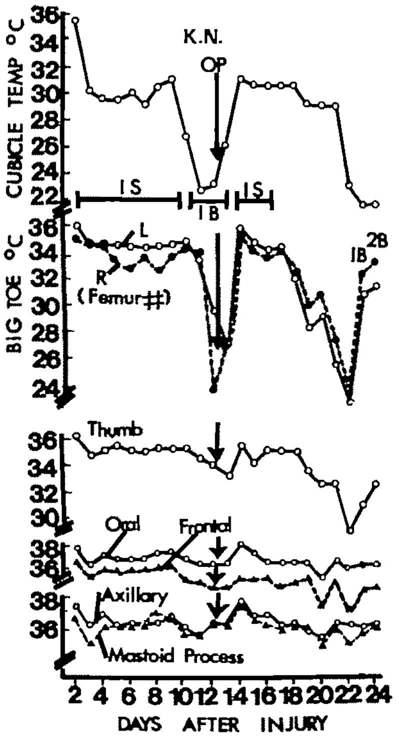

FIG. 1.—*Case* 1. The cubicle was maintained at 30° C. except for a few days at 23° C A Kunchner nail (K.N.) was inserted on the twelfth day and the temperature was raised again At the low temperature one blanket (1B) was substituted for the extra sheet (1S). L, Left. R, Right.

Urine Analysis.—Measurement of the total nitrogen in the urine and food was based on Fleck's (1967) semi-micro modification of the Kjeldahl method. Sodium and potassium were estimated by flame-emission photometry, chloride by an EEL chloride meter (Evans Electrostenum Ltd.) with coulometric titration, and calcium and magnesium by atomic absorption spectrophotometry (SP 90, Unicam Ltd.). These five electrolytes are expressed as mmol per 24 hours. The osmolality was measured by freezing-point depression (Advanced Scientific Company osmometer), glycosuria and ketonuria by the Clinstix test and the acetoacetic acid test (Ames Co.), and amino-acids by paper chromatography (Smith, 1965). Blood *p*H, base excess, and pCO_2 were determined by the Astrup method.

Skin Temperatures.—For this study a Universal Thermometer (Electrolaboratoriet, Copenhagen) with four probes was used. As it was occasionally desirable to determine skin temperatures below bed coverings, the patients were encouraged to co-operate in recording their own temperatures. The effect of the application of additional covering in contrast to the effect of the higher environmental temperature was also studied. Throughout the period of study all the patients had a basic covering of a nightgown and a half-sheet to the waist. Anterior surfaces were selected for ease of access and multiple recordings were made near the nail beds of the big toes and thumbs, and over the mid or upper thighs, the bellies of the biceps, the abdomen, the forehead, and the mastoid processes in addition to taking the oral and/or axillary temperatures. In the first group temperature recordings were made in the middle of the morning, and in the second group approximately 1 hour after lunch. There were two objectives:—

1. By daily multiple measurements to determine the effects of changing and maintaining the cubicle at normal (20–24° C.) and warm (28–30° C.) temperatures. At the latter temperature the humidity was controlled at between 35 and 45 per cent. The effects of additional bed coverings were also studied in these patients at fluctuating temperatures.

2. To determine the continuous effect of the higher ambient temperature on the skin temperature of the injured and non-injured distal extremities of the lower leg, namely, on the dorsum of the big toe proximal to the nail bed, since only injuries to the lower limbs were studied in this investigation, and to compare these areas with the respective axillary temperatures.

Having regard to Benzinger's (1969) criticism of the uselessness of rectal temperature as an index of core temperature owing to pelvic circulatory changes, and to the difficulty of access in such fracture cases, oral and/or axillary temperatures have been used in the series.

RESULTS

1. Intensively Studied Series.—Eleven patients with one or more fractures of the major long bones of the lower limbs were studied daily; some at normal temperatures, some at the higher ambient temperature of 30° C., one for 16 hours daily at the higher temperature with 8 hours at the lower temperature each night, and several at both low and high temperatures but the temperatures were imposed in differing order. The oral and/or axillary temperatures and the temperatures over several parts of the body were recorded for each patient. Details of these cases indicate the variability of individual response to injury and the warmer environment, and also the effect of extra bed coverings.

CASE REPORTS

Case 1.—A. McC., a male aged 17 years, suffered a fracture of his right femur as the result of a traffic accident. On the second day after injury he was placed in a warm cubicle which registered a temperature of 35·5° C. for the first day, and thereafter it settled at around 30° C. for 7 days when it was dropped over a period of 2–3 days to 22·5–23° C. On the third day of the reduced temperature a Küntchner nail was inserted in the femur and the temperature was again raised to around 30° C. for a further 8 days, and then it was allowed to fall to the normal ward level of around 22° C. (*Fig.* 1).

During the first 9 days the patient was covered by an extra sheet of bed clothing which was replaced by a blanket during the first period of a lower cubicle temperature. On return to the higher temperature the blanket was replaced by a sheet for 3 days. This was removed and was not replaced by a blanket until the cubicle temperature had again fallen to just below 22° C., when first one blanket and then two blankets were provided.

The temperature changes over several areas together with the oral and axillary temperature were followed.

It was evident that the degree of traumatic fever was slight after each traumatic event and was shown equally by the temperatures in the mouth, axilla, frontal, and mastoid areas.

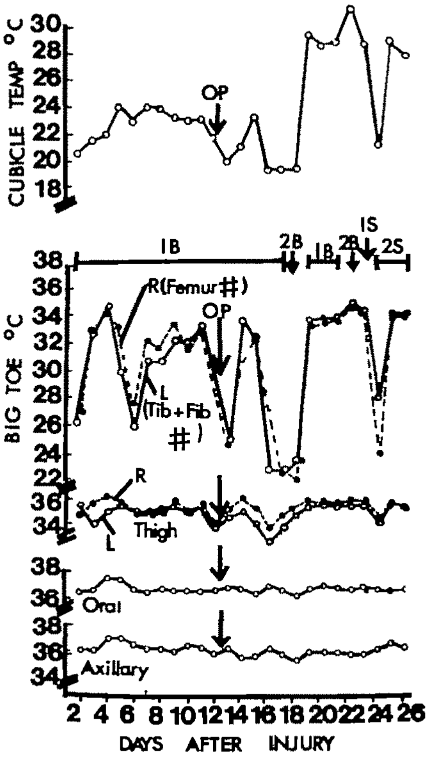

FIG. 2.—*Case* 2. The temperature was kept around 20–24° C. for 17 days, then was raised to around 29° C. for 5 days, and was intermittently low and high for 3 further days. On the thirteenth day there was exploration and resuturing of the wrist. For the first 17 days the patient was covered with one blanket in addition to his basic sheet, then intermittently with one or two blankets or sheets.

The temperatures of both big toes moved in parallel to that of the cubicle, the temperature of the right injured leg being lower by about 1–5° C. over the first 9 days but thereafter there was not much difference although the positions were marginally reversed during the last week. The big toe temperatures were very sensitive to the temperature of the cubicle and when the latter fell the provision of an extra blanket did not prevent a fall of 9–10° C. in the temperatures of the toes. The effect of operation was to cause a slight rise in the temperatures of the toes but the rise in the temperature of the cubicle induced a rapid increase to the plateau level which had been established during the earlier period of high temperature. When, however, the extra sheet was removed the temperatures of the toes could not be sustained by the remaining half-sheet and their temperatures fell by about 6° C. Reduction of the temperature of the cubicle to around 22° C. led to a fall in the temperatures of the toes to 23° C. Thus, the toes were sensitive indicators of the environmental temperature and needed some degree of insulation to maintain the changes upwards. Such insulation could raise the temperature markedly and with two extra blankets at the lower environmental temperature the temperatures of the toes were only some 2° C. less than those induced by a cubicle temperature of 30·5° C.

The skin temperatures over the thighs and biceps were relatively uninfluenced by different environmental temperatures, but the temperatures of the thumbs were much more sensitive to changes and for their maintenance the patient required at least one sheet over the basic half-sheet.

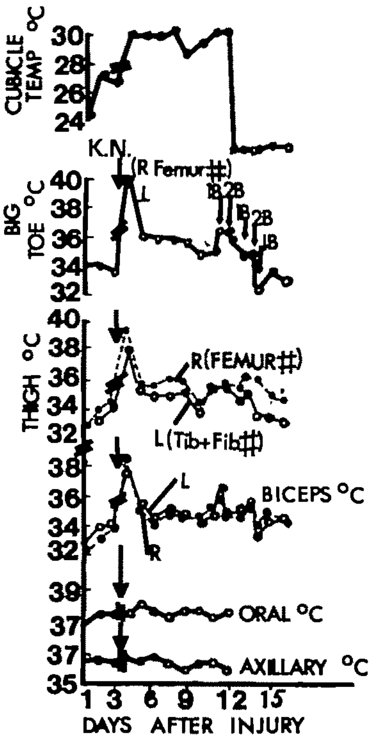

FIG. 3.—*Case* 3. The cubicle temperature was gradually raised to 30° C. On the day of his accident a Steinmann pin was inserted to fix the malleolar displacement and 4 days later a Kuntschner nail (K N) was inserted into the femur. On the twelfth day the temperature of the cubicle was reduced to 23° C. From this point onwards the patient was covered by one or two blankets.

Case 2.—J. S., a male aged 54 years, had a fracture of the right femur, compound fractures of the tibia and fibula of the left side, and lacerations of his right forearm with severance of vessels, nerves, and tendons. A Steinmann pin was inserted in the tibia for traction. The patient was studied for 17 days at 20–20° C. and then for 7 days at 30–32° C. with a drop to 21° C. on the twenty-third day (*Fig.* 2). On the thirteenth day exploration of the right wrist and resuturing were carried out. The temperatures of both big toes reflected the changes in the ambient temperature in a parallel fashion. Even the skin over the upper portion of the thighs showed comparable changes. The effects of the traumatic fever associated with injury were superimposed on the changes due to the ambient temperature, the degree of fever being reflected by the changes in the axillary and oral temperatures only. The oral temperature was about 0·5° C. higher than the axillary temperature.

The effect of increasing the ambient temperature to 30–32° C. on the seventeenth day after injury was to cause a rapid rise in the skin temperature of the big toe from 22–23° C. to 34–35° C. These temperatures were little affected by an additional blanket or sheets.

It is obvious from *Fig.* 2 that the big toe is a particularly sensitive index of both the ambient temperature change and the febrile response to injury.

Case 3.—A. J., a male aged 17 years, had sustained a fracture of the middle of the right femur, fractures of the left tibia and fibula, and a left bimalleolar fracture with diastasis in a road-traffic accident (*Fig.* 3).

The temperature of the ward cubicle was gradually raised to 30° C. by the fourth day after admission. A Steinmann pin was inserted to fix the malleolar displacement on the day of the accident and 4 days later a Küntschner nail was inserted into the femur.

It was found that the skin over different parts of the body surface responded vigorously not only to the changes in the ambient temperature but also to the effects of accidental or surgical trauma, whereas the oral and axillary temperatures were relatively little affected. This type of reaction was characteristic of patients with a rapid compensating vascular shunting and conduction.

The addition of one blanket to the one already being used at the high ambient temperature appeared to have no effect on the skin temperatures, and it was uncertain whether the use of one blanket as well as the routine half-sheet covering to the waist had any real effect at the lower ward temperature.

Case 4.—E. F., a male aged 50 years, had compound fractures of the tibia and fibula as well as fractures of the medial and lateral malleoli of the left leg. He was nursed at 28–29° C. with two extra sheets bed cover from the first day after injury.

The oral temperature remained very constant and the big toes showed first a small drop of 1·5–2° C. followed by a rise to the original levels by the fifth day. After the first day the injured side showed a rather higher temperature than the opposite side. All his other measurements remained very constant.

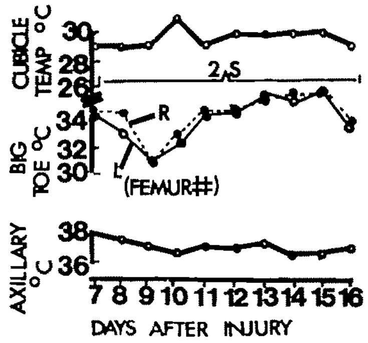

FIG 4.—*Case* 5. This patient was nursed at 29–30° C from the seventh day after injury and was covered by two extra sheets throughout.

Case 5.—R. K., a male aged 65 years, had a fracture of the left femur following a fall. He was nursed at 29–30° C. with two extra sheets bed cover (*Fig.* 4).

The patient's big toes showed the same temperature changes as *Case* 4, with first a fall in temperature of about 4° C., followed by a return to the earlier level, and subsequently a rise of 1° C. There was no sign of traumatic fever.

Case 6.—A. D., a male aged 14 years, had a fractured pelvis, right clavicle, and right tibia and fibula as the result of a road-traffic accident. He was put in a warm cubicle but on the third day after injury he complained of the heat and this was then reduced to normal levels. He was covered throughout with a half-sheet to the waist (*Fig.* 5).

There appeared to be no thermal response to the trauma and the changes in the ambient temperature resulted in corresponding fluctuations in the peripheral skin temperatures (nail beds of big toes and thumbs). The oral temperature fell slightly throughout the first 5 days and thereafter was steady. The injured side possibly showed a greater response to changes in the ambient temperature.

Case 7.—H. A., a male aged 34 years, had fractures of the right clavicle, humerus, ulna, tibia, and fibula as the result of a road-traffic accident. The patient was placed in a warm cubicle at 29° C. for the first 3 days after his accident, and then the cubicle temperature was lowered to 20–23° C.

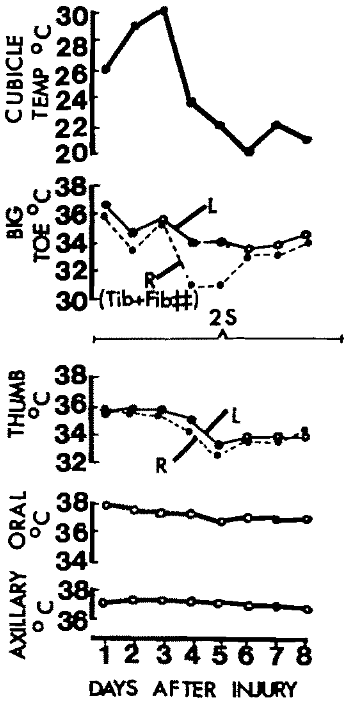

FIG. 5.—*Case* 6. This patient was nursed at high and then low cubicle temperatures He had two extra sheets throughout.

The oral and axillary temperatures and those of the skin over the forehead and mastoid processes showed parallel responses with an early small rise of 1–1·5° C. However, the temperature of the small toes seemed to be mainly influenced by the changes in the ambient temperature and the fall which appeared to follow the drop in the environmental temperature from 29 to 20–22° C. could not be arrested by the addition of two extra blankets.

Case 8.—R. S., a male aged 39 years, had fractures of the tibia and fibula. He was nursed at a temperature of 30° C. but each night the heat was switched off for 8 hours. The temperature never fell below about 25° C. The patient's oral temperature remained fairly constant throughout and the temperature of the big toes was relatively steady at 33·5–35° C.; the patient had only one extra sheet but this did not cover his big toe. He was studied from the first day after injury.

Case 9.—P. N., a male aged 59 years, had multiple fractures involving the left femur, right acetabular ring with displacement, left clavicle, first left rib, several left metacarpals, and a right Smith's fracture. He was studied without any attempt to raise the environmental temperature but the temperature of his cubicle varied between 21 and 25° C.

The temperature of the big toe of the uninjured right leg was always higher (1·5—3° C.) than that of the left leg for the first week after injury and then the difference disappeared. The same temperature trend was shown for the skin of the thighs and for a few days over the biceps also. When one blanket was applied this raised the temperature of both toes from 31·5 to 34·2° C. Two blankets did not increase the temperature of the toes further but had a slight effect on the temperature of the thighs. One blanket raised the temperature over the biceps and the abdomen slightly but a second blanket again had no additional effect. As might be expected, extra blankets did not affect the skin temperatures over the mastoid and frontal areas. The axillary temperature was about 0·6° C. below that of the mouth. There was no obvious effect of one or two blankets on these zones.

This patient felt that even an environment of 25° C. was warmer than he liked but it had not been intended to place him in the higher temperature.

It appeared that so far as the lower extremities were concerned two blankets at an environmental temperature of 25° C. and with the use of orthopaedic appliances had no greater effect than one blanket, but that in the case of the thighs two blankets raised the skin temperature slightly more than one.

Case 10.—J. F., a male aged 32 years, had a fracture of the medial and lateral malleoli with dislocation of the ankle of the left leg (*Fig.* 6). The patient was nursed at 19–20° C., but exhibited very constant oral and big-toe temperatures, the toe being maintained at 34–35° C. and the oral temperature at 36·5–37° C. He needed only one extra bed sheet to maintain these temperatures.

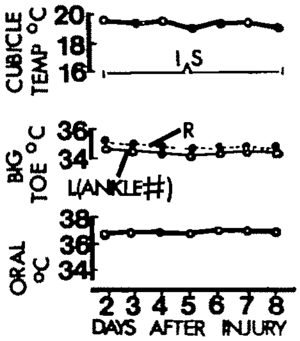

FIG. 6—*Case* 10. This patient was nursed at 20° C throughout with one extra sheet covering.

This patient can be compared with *Case* 8, who also exhibited great constancy but had a lower skin temperature under warmer conditions.

Case 11.—C. McI., a male aged 57 years, had compound fractures of the left tibia and humerus. He was kept at a normal temperature (20–23·5° C.) with two sheets. There was very little fluctuation in any of the skin temperatures or in the oral and axillary temperatures, the latter being about 0–1·0° C. lower than the oral temperature. The temperature of the big toes oscillated around 32·5° C.

Case 12.—V. N., a male aged 27 years, had a fracture of the mid-shaft of the right femur as the result of a road-traffic accident. Detailed temperature observations were made some 20 days after the accident and were concerned mainly with the effect of extra blankets when the cubicle had a temperature ranging from 23° C. up to 28° C. with a relative humidity of 60–70 per cent.

At 23–24° C. the effect of one extra blanket was to raise the temperature of the toes and thighs by about 2° C.; two blankets produced a further rise of about 1° C. in these areas. At 28° C. and without a blanket the temperature of the toes was only a little higher than that with two blankets at the lower temperature, while the temperature of the thighs was unchanged. One extra blanket plus heat produced no further change in the temperature of the toes, but two blankets produced an increase of about 2° C. and four blankets a further rise of about 2° C., i.e., the final temperature of the toes was about 9° C. higher than that with no extra blankets at 23° C. The temperature of the thighs rose only about 2·5° C. after applying four blankets. The oral temperatures were unaffected by the number of blankets.

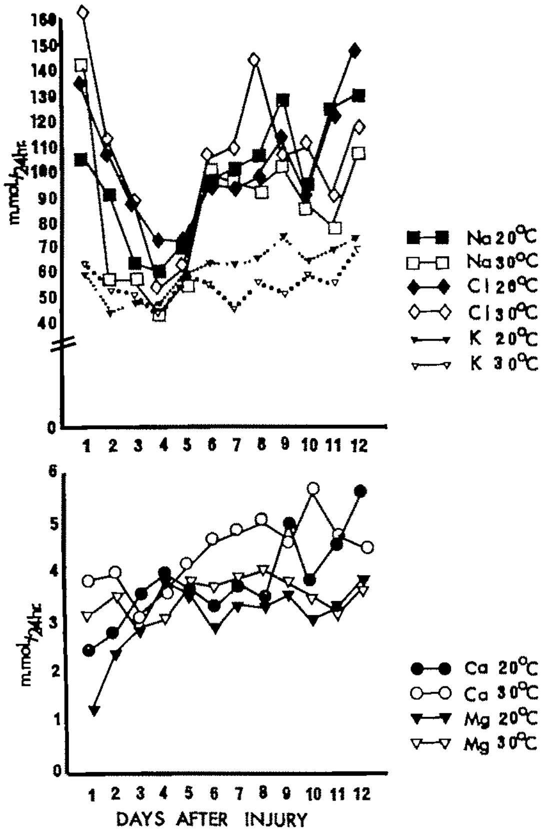

FIG. 7.—Mean daily excretion of urinary electrolytes of patients with major long bone injuries nursed at 20 or 30° C.

Whereas the oral and axillary temperatures which appeared to differ by 0·5–0·8° C., the former being higher, were apparently influenced mainly by the degree of traumatic fever, the extremities—the toes in particular—varied with the temperature of the environment and to a variable degree as the result of extra bed coverings. The fingers sometimes also showed similar rapid vasomotor responses. The other areas of the body surface do not have this capacity to shunt blood so effectively.

It was noted with interest that the temperature of the forehead and over the mastoid processes in the present cases exhibited changes similar to those in the mouth.

On occasions, despite the high ambient temperature the temperature of the toes could not be sustained without some extra bed covering. In one case it was found that when the extra sheet was taken away the temperature of the big toe dropped by 8° C. The reverse of such a change was noted in another case where a 10° C. rise in the toe temperature resulted from a 10° C. rise in the cubicle temperature, and a fall of 11° C. in the toe temperature resulted from a fall of 8° C. in the cubicle temperature. The dramatic changes in the big toe temperatures were accompanied by smaller changes in the temperatures of the skin of the thighs and biceps and even smaller ones over the abdomen. The thumbs reacted in a similar way to the toes.

In some instances relatively high distal temperatures could be achieved by the use of additional bed coverings, but such insulation obviously related to the area covered and not to the whole body.

2. Comparative Series.—The effects of the two ambient temperatures when continuously applied were also studied on the 3rd, 6th, 9th, and 12th days after injury. The influence of the high cubicle temperature (30° C.) on the skin temperature (mainly of the big toes) and the axilla temperatures was also investigated. There were 9 comparable patients at each temperature level.

Although the mean temperature of the big toes was slightly higher in the 30° C. group than in the 20° C. group on days 3, 6, and 12 of observation the differences were not statistically significantly different. On the ninth day, however, the differences reached significance. There was no significant difference in the axillary temperatures between the two groups.

The application of one blanket as an extra bed covering normally raised the skin temperature of the big toes by 3–5° C. in patients who were at the normal ambient temperature. The addition of a second blanket had a slight extra effect.

Urinary Electrolytes (*Fig.* 7).—

Sodium and chloride: As was to be expected there was a very close parallelism between the urinary excretions of sodium and chloride at the two temperatures. There was first a progressive fall lasting approximately 4 days or more, indicating the normal retention effect which has been described by Wilkinson, Billing, Nagy, and Stewart (1949) and Moore and Ball (1952). This was followed by a rise to earlier values. There was no sign of a reduced urinary excretion of chloride at the higher temperature but there was some evidence of a lower excretion of sodium at 30° C. but this was not significant ($P > 0{\cdot}05$).

Potassium: There was a tendency for this ion to fall very slightly over the first few days but this was then followed by a slight rise to a level above that found earlier and this was most marked during the second period of 6 days. The behaviour was according to the pattern described by Wilkinson and others (1950) and Moore and Ball (1952). Although when viewed in terms of 3-day groups there was no significant difference in excretion at the two temperatures, nevertheless calculations based on the total data revealed a significant overall difference ($0{\cdot}05 > P > 0{\cdot}02$). This was a more definite reduction at the higher temperature than that reported in the previous paper (Cuthbertson and others, 1972).

Calcium and magnesium: The courses of excretion of calcium and magnesium moved in parallel at the two temperatures but with slow small rises—more obvious at 20° C.—which did not decline during the period of observation, presumably arising from disruption of muscle and bone and from atrophy. Walker, Fleming, and Stewart (1968) have drawn attention to the rise in magnesium following soft-tissue surgery. The excretions were not statistically significantly different at the two ambient temperatures ($P > 0{\cdot}05$ for each element). The excretions of calcium and magnesium at 30° C. and also at 20° C. were more nearly in parallel as expressed in mmol per 24 hours than were the excretions of these two ions when considered individually at the two temperatures; more particularly at 20° C. (*Fig.* 7).

Osmolality: There was high urine osmolality in the first few days following injury and this was associated with oliguria. A few cases subsequently showed polyuria.

Glycosuria and ketonuria: Glycosuria occurred in some cases and was an early manifestation. One case continued to show these two associated metabolic disturbances in traces for 6 days after injury.

Table I.—SERUM ELECTROLYTES (mmol per litre)

SERUM ELECTROLYTE	DAY AFTER INJURY					
	3		5		10	
	20° C.	30° C.	20° C.	30° C.	20° C.	30° C
Na	137	138	137	138	139	139
Cl	99	100	101	100	99	102
K	4·4	4·2	5·4	4·8	4·2	4·4
Ca	2·4	2·5	2·4	2·4	2·5	2·5
Mg	1·2	1·3	1·2	1·2	1·2	1·3
Osmolality (mosmol per kg)	284	288	286	290	286	289

Serum Electrolytes (*Table I*).—Blood samples were collected on days 3, 5, and 10 after injury and analysed for electrolytes and osmolality. There were no changes from normality with time after injury or with ambient temperature except in the case of potassium, where the values at 30° C. were slightly less than those at 20° C. especially at the time of maximum metabolic response, i.e., around the fifth day after injury, and this was to a significant degree.

Urinary Amino-acids.—In a small series of 4 patients (2 at each of the two ambient temperatures) who were examined in respect of the excretion of α-amino-acids in the urine there appeared to be no group difference in respect of both non-essential and essential amino-acids, although there were differences within each group in respect of the excretion of histidine and lysine in particular. Such differences were not referable to the transfusions administered to 1 patient in each group. The injuries were severe to moderate in each group, the patients with severe injuries receiving multiple transfusions.

The essential amino-acids, threonine, valine, leucine, isoleucine, and methionine, which are not normally detected in the urine, were found and this confirmed Nardi's (1954) observations made, however, in cases with burns.

DISCUSSION

In a previous paper the effect of a dryish and warm (29–30° C.) environment in reducing the catabolic response to moderate to severe injury, mainly of the lower limbs, has been described together with the reduction in the loss of nitrogen, potassium, creatine, and zinc in the urine (Cuthbertson and others, 1972). So far as albumin is concerned the fall which occurs at the higher temperature seems to be due to reduced synthesis in the liver rather than to increased catabolism (Tilstone, Ballantyne, Kahn, and Fleck, 1972). Since 'acute phase reactants' such as C-reactive protein and fibrinogen are almost certainly synthesized at an increased rate after injury it is clear that the metabolic response to trauma, producing increased urinary nitrogen, is not due to an increase in catabolism of all proteins or to a decrease in the synthesis of all proteins. Thus the view that there is increased breakdown of muscle protein is still further emphasized (Tilstone and others, 1972).

In the patients whom we have studied the situation is made complex since coinciding with the greater exposure of the limbs because of the remedial means employed there is also variable degree of cover by plaster, bandages, etc. Furthermore, the normal behavioural responses to facilitate core-temperature maintenance are restricted by the patient's position in bed and the maintenance of muscle tone itself may be painful.

Owing to the greater exposure of an injured lower limb to the prevailing ward temperatures (20–22° C.) there is frequently a degree of cold exposure which will result in an increased firing rate of the peripheral cold receptors, and the changes in temperature gradient induced between the core and the surface will result in increased heat conduction and, if continued, might result in a fall in the core temperature or a contraction in the core of higher temperature. There is also compensating contraction of the peripheral vascular system by shunting. A diminished rate of warm-receptor firing and reduction of the anterior warm inhibition of the posterior hypothalamic centre presumably follow, leaving the posterior centre to mediate heat production (Benzinger, 1969).

Cold-receptor firing is apparently considerable at 20° C. but there is no increase in oxygen consumption if the core temperature remains at 37° C., i.e., the warm inhibition of chemical thermoregulation is still in force (Benzinger, 1969). It has been established that if the core temperature falls by 0·5° C. by core-to-surface conduction losses, then a brisk metabolic response occurs. It is now well established that following injuries of the type that we have studied there is an increase in oxygen consumption and heat production (Cuthbertson, 1932; Cairnie, Campbell, Cuthbertson, and Pullar, 1957) and this constitutes the flow phase with an accompanying increase in protein catabolism, and that at an ambient temperature of 30° C. this increment in heat production is largely if not entirely abolished (Caldwell, 1962; Campbell and Cuthbertson, 1966, 1967) in experimental animals, and diminished in man (Barr, Birke, Liljedahl, and Plantin, 1968). In experimental animals healing of superficial wounds is accelerated (Erici, 1954; Cuthbertson and Tilstone, 1967).

The advantage of a higher ambient temperature in conserving heat compared with the effect of one or two extra sheets or blankets is that while the latter undoubtedly act in respect of their insulating capacity and in reducing the rate of heat flow to the environment the provision of an ambient temperature within the zone of thermoneutrality tends to reduce the resting metabolic rate to basal level as the surface area as a whole is affected. Even a slight increase in surface temperature at the edge of a wound accelerates skin healing in experimental animals (Cuthbertson and Tilstone, 1967). Erici (1954) and Caldwell (1962) have also noted the beneficial effects of a higher ambient temperature on wound healing in rats and rabbits.

Although common experience demonstrates the rapidity and extent of the vascular shunting mechanisms involved in heat conservation we were somewhat surprised on the extent of this lability of skin temperature, particularly in the nail bed of the big toes, though the observations of Gibbon and Landis (1932) and the vascular surgeons who have used the reflex vasodilatation test for testing circulation in the limb should have warned us to expect such findings. It is of interest that the former found no appreciable increase in toe temperatures following the use of blankets at normal ward temperatures in the 2 subjects whom they studied under such conditions.

The temperature of the warm water used by Gibbon and Landis (1932), namely 43–45° C., was based on the temperature of the hot chamber which Lewis and Pickering (1931) had used earlier which was 46° C. It is interesting that we obtained similar increments in toe temperature at the higher environmental temperature as we did at the lower temperature. Reid (1973) found little effect of the higher temperature on thigh temperature. He has also noted that the degree of response of the toes of his patients to warming the hands and forearms is dependent on the ambient temperature, a few degrees making a considerable difference, except where there is vascular occlusion of the lower limb.

Apart from a reduction in the rise in serum potassium to a significant degree around the fifth day after injury and in the increased urinary excretion of potassium already described (Cuthbertson and others, 1972) there were no significant changes in the concentrations of the other serum electrolytes studied as a result of the higher temperature imposed (*Table I*), nor were the characteristic patterns of urinary excretion altered by changes in the ambient temperature except that potassium excretion was significantly less at 30° C. The excretions of calcium and magnesium showed slow small rises at 20° C. There were also no obvious distinctive differences in the pattern of urinary amino-acids at the two cubicle temperatures in the small group investigated.

Acknowledgements.—The senior author (D. P. C.) wishes to express his sincere thanks to the Medical Research Council for a grant for this research. The junior author (A. G. R.) is greatly indebted to the World Health Organization for a travel grant. The authors are grateful for the facilities provided in the Department of Pathological Biochemistry, Glasgow Royal Infirmary, by Professor H. G. Morgan, and the Board of Management of the hospital. They also wish to acknowledge their indebtedness to Professor W. A. Mackey and his nursing staff and also to Mr. John White, Chairman of the Department of Orthopaedic Surgery and Accident Unit, and his surgical colleagues and University staff for their great co-operation, and for making available space for the erection of the special air-conditioned cubicles. Skilled technical assistance has been provided by Miss Christine Hall.

THE SURGICAL MANAGEMENT OF ACUTE RENAL PAPILLARY NECROSIS

BY R. M. JAMESON AND M. R. HEAL

REGIONAL UROLOGICAL CENTRE, SEFTON GENERAL HOSPITAL, LIVERPOOL

SUMMARY

Analgesic nephropathy can present as an obstructive uropathy by ureteric impaction of a sloughed renal papilla. Five out of 12 patients admitted with analgesic nephropathy presented with obstructive renal failure. Endoscopic surgery to deal with the obstruction was successful in every case. Removal of the necrotic renal papilla with a Dormia ureteric stone basket was performed six times whilst ureteric catheterization was sufficient to restore urine flow on two occasions. Two of the 5 patients had had a previous nephrectomy for obstructive pyelonephritis. These results suggest that endoscopic surgery is safe and effective in the treatment of acute obstructive renal papillary necrosis.

THE association of analgesic abuse and chronic renal disease is well known. A leading article in the *British Medical Journal* (1970) noted that patients presented with various symptoms and that occasionally separated renal papillae may produce acute renal failure by ureteric obstruction. The prognosis in acute renal papillary necrosis is poor, it being a major cause of death in Edmondson, Reynolds, and Jacobson's (1966) series; 20 out of 105 alcoholics with pyelonephritis had papillary necrosis in their post-mortem study. As healed lesions at autopsy were rare Edmondson and others believed that most patients died in the acute phase. Immediate nephrectomy has been recommended (Harrow, 1967) but most of these cases are in poor condition and may have a solitary kidney. A more conservative approach is advocated here and an account is given of experience with endoscopic methods to relieve obstruction.

PATIENTS AND METHODS

In the past 2 years 12 patients were admitted to the Liverpool Regional Urological Centre with renal papillary necrosis. Approximately double this number are seen annually in out-patients' clinics. Five of the 12 patients presented with acute obstruction; their history and management are summarized in *Table I*. *Case* 2 is of particular interest and is described fully.

A detailed history was taken from each patient to determine the cause of the renal condition. Urine culture and microscopy, measurement of the haemoglobin, blood-urea and electrolytes, and serum creatinine, and infusion pyelography were done routinely. A urethral antiseptic was introduced before any catheterization or instrumentation and most of the endoscopic procedures were done with the aid of the image intensifier. The papilla was demonstrated as a filling defect by passing a Dormia basket alongside the ureteric catheter and injecting contrast medium. The Dormia stone basket was passed no higher than the pelvic ureter, although in every case the necrotic renal papilla was never more than 10 cm. from the ureteric orifice. The tissue that was retrieved was sent for histological examination and proved in every case to be a renal papilla. The ureteric catheter was maintained in position by strapping it to a Foley balloon catheter which drains the bladder. Each catheter was connected to a closed drainage system. As the urine is frequently infected antibiotics were given and continued in reduced dosage for a long period.

Once the patient had recovered from the acute obstruction as shown by absence of fever, loin tenderness, and an improvement in renal function the draining catheters were removed. Prevention of further episodes was attempted by stopping analgesics, insisting upon a high fluid intake, and giving long-term antibiotic therapy—a régime similar to that used in the treatment of chronic pyelonephritis. Subsequently 2 men required resection of the prostate gland.

CASE REPORT

Case 2.—A woman aged 43 years had had a right nephrectomy for pyonephrosis in 1959. She had remained well until 2 weeks before her present admission when she had had left ureteric colic. A pyelogram demonstrated a dilated

Table I.—SUMMARY OF 5 CASES WITH ACUTE RENAL PAPILLARY NECROSIS WHO PRESENTED WITH ACUTE OBSTRUCTION

CASE No.	AGE AND SEX		PREDISPOSING CONDITION	DURATION OF ANALGESIC INGESTION (yr)	BLOOD-UREA AT ADMISSION (mg. per cent)	OPERATION	CLINICAL COURSE
1	68	M	Osteoarthritis	5	280	Dormia extractions (2 operations)	Improved
2	43	F.	Addiction	6	103	Dormia extractions (3 operations)	Defaulted
3	48	M.	Rheumatoid arthritis	16	160	Retrograde ureteric catheter	Improved
4	55	M.	Addiction	20	200	Retrograde ureteric catheter; transurethral resection 1 year later	Improved
5	60	M.	Addiction	7	140	Dormia extraction; transurethral resection 1 year 4 months later	Improved

left kidney and ureter down to the level of the intramural ureter. She was tender over the solitary kidney and became anuric. She was immediately transferred from the local hospital to the Regional Urological Centre, Liverpool.

On admission her blood-urea was 103 mg. per cent and serum potassium 5·3 mEq. She did not respond to diuretics, and cystoscopy was performed within 24 hours of admission. The bladder was normal apart from a bulge over the left intramural ureter and some blood-clot protruded from the left ureteric orifice. A No. 5 catheter was passed easily to the renal pelvis. A Dormia stone basket was manipulated alongside the catheter and a 2-cm. piece of tissue was removed from the intramural ureter. This was later proved to be a renal papilla. The ureteric catheter was left in situ and strapped to a urethral Foley catheter to hold it in position. Both catheters were connected to sterile closed-drainage systems. During the next 24 hours the patient passed 8 litres of urine and her temperature which had previously been 38° C. fell to normal. As her general condition improved with a fall in the blood-urea to normal the catheters were removed on the second postoperative day. That evening she wished to be discharged but was persuaded to stay in hospital. Thirty hours later she became anuric, had left loin pain, and a fever (39° C.). A blood culture grew *Bacillus proteus*. She was treated with intramuscular gentamicin and frusemide. The blood-urea rose and she did not respond to the diuretic. At cystoscopy a No. 5 ureteric catheter was passed to the renal pelvis, a slight obstruction being noted 6 cm. from the left ureteric orifice. There was an immediate copious flow of urine. Two passages of the Dormia stone basket in the lower ureter failed to produce tissue. A urethral catheter was passed as before and the urinary tract was drained. Four days later the patient was afebrile with a normal blood-urea and the catheters were removed. Five days after the second cystoscopy she became anuric for the third time and again at cystoscopy Dormia extraction of a sloughed renal papilla was performed. At operation retrograde pyelography using an image intensifier showed no further upper urinary-tract obstruction. A week later the catheters were removed. The patient repeatedly wished to be discharged and she finally signed herself out the day that the catheters were removed. Her demeanour was odd even allowing for the original toxicity and she denied habitual self-medication with analgesics. Long-term antibiotics with a high fluid intake were recommended but the patient has persistently defaulted from review.

RESULTS

Every endoscopic operation for acute obstructive renal papillary necrosis was rewarded by an immediate and profuse diuresis. Simple retrograde ureteric catheterization was sufficient on two occasions. A whistle-tip catheter is preferred. Manipulation of a Dormia ureteric stone basket was used to retrieve an impacted renal papilla six times. If a ureteric renal papilla was shown radiologically it could always be removed as it impacted in the lower ureter. Large papillae offer little resistance to the passage of a Dormia ureteric catheter compared with ureteric calculi of a similar size, and their size should not discourage attempted extraction.

We stress that combined medical and surgical management is essential. The obstruction having been relieved and the fluid and electrolyte disturbances corrected, the patient must stop all analgesics and maintain a high urinary output, and long-term antibiotics must be given to prevent urinary infection. Because outflow obstruction hinders renal recovery this must be dealt with, as illustrated by *Cases* 4 and 5. Both cases had proved analgesic nephropathy, one having passed a necrotic renal papilla 2 years previously. Having stopped analgesics the renal function of these patients slowly improved. Subsequent pyelography showed residual urine in the bladder after micturition with some thickening of the bladder wall. The urine was found to contain white cells on microscopy and repeated culture failed to reveal a significant bacteriuria. Each of these patients had minimal prostatic symptoms, but the serum creatinine which was raised above 3 mg. per cent only fell to normal after resection of the small obstructing prostate glands.

Although 1 patient has persistently defaulted from review (*Case* 2) all the other cases have improved as shown by an absence of symptoms, freedom from pyuria and infection, and a fall in the serum-creatinine levels to normal. The period of review has been for a minimum of 6 months.

DISCUSSION

Analgesic damage to the kidney results from papillary necrosis following interruption of the blood-supply in the vasa recta (Kincaid-Smith, 1968). Some patients take analgesics for the relief of chronic pain (e.g., in arthritis as *Cases* 1 and 3), but the majority take them for ill-defined reasons such as general fatigue or chronic headache (Prescott, 1966). In one series an addiction to phenacetin was noted and two-thirds of the patients had psychiatric abnormalities (Dawborn, Fairley, Kincaid-Smith, and Kings, 1966). In the present series the majority of the patients are 'odd' and habitually take analgesics. Retrospective study of the records in all our cases confirms the finding of a sterile pyuria antedating the acute symptoms by many years. Direct questioning about analgesic intake is helpful as a screening test. Where the patient denies self-medication with analgesics the relatives may confirm that tablets have been regularly taken for years (*Case* 2). Whilst few of our patients were as advanced as those in the series of Bell, Kerr, Swinney, and Yeates (1969), in which 3 out of 14 patients died of acute pyelonephritis, there was improvement after the withdrawal of analgesics. The combination of obstruction with infection can be lethal and major surgery carries some risk. Emergency nephrectomy has been recommended for acute papillary necrosis (Harrow, 1967) and this had been performed in 3 cases subsequently referred to the Regional Centre. One of the patients needed nephrectomy for pyonephrosis with suspected carcinoma of the renal pelvis, which may occur in conjunction with analgesic nephropathy. Another patient had carcinoma of the lower ureter. Patients with analgesic nephropathy do not withstand surgery well (Koutsaimanis and de Wardener, 1970) and endoscopic surgery is safer. Retrograde ureteric catheterization has been used to by-pass the obstruction (Rutner and Smith, 1961; Bonnin, 1964; Hellebusch, 1969), and recently this has been used with the addition of proteolytic enzyme instillation into the ureter (Jones and Morrow, 1971). We have found the renal papillae impact in the lower ureter and removal using the Dormia stone basket is safe and successful. If subsequent improvement is slow and residual urine is present, endoscopic treatment of the bladder-neck obstruction will produce a further improvement. Sloughing of a renal papilla may still occur after analgesics have been discontinued for many months.

Prompt endoscopic surgery in patients with acute papillary necrosis is recommended. This conservative approach removes the obstructing tissue and ensures prompt drainage of the affected kidney. Unlike immediate nephrectomy it can be applied in patients with a solitary kidney. Retrieval of the tissue with the Dormia stone basket enables histological confirmation and preserves renal tissue in a potentially bilateral disease.

Acknowledgements.—We thank our colleagues in the Liverpool region who have promptly referred the cases, and Mr. N. O. K. Gibbon, Dr. Goldsmith, and Dr. Finn for permitting us to include some of their cases from the Regional Urological Centre in this series.

DIAPHRAGMATIC RUPTURE DUE TO BLUNT TRAUMA

BY HUSSEIN BIN MOHAMED SALLEH

GENERAL HOSPITAL, KUALA LUMPUR, MALAYSIA

SUMMARY

With the increasing number of abdominal, pelvic, and thoracic injuries due to trauma as a result of road-traffic accidents rupture of the diaphragm is becoming more frequent. Two personal cases are presented and the literature as regards symptomatology, mechanism of rupture, site of rupture, and treatment is reviewed. Early operative treatment is recommended.

RUPTURE of the diaphragm is a serious condition because although the lesion itself may not threaten life the function of the heart and lungs may be seriously impaired owing to herniation of intraperitoneal viscera into the chest. Furthermore, it may cause gastro-intestinal symptoms and signs unless treated. Indeed, the herniated viscera may strangulate and produce an emergency situation.

This paper reports 2 cases which were personally seen and treated by the author and reviews the literature on the various aspects of the subject.

CASE REPORTS

Case 1.—A 22-year-old man was admitted to the General Hospital, Johore Bahru, Malaysia, in August, 1967, having been knocked down by a motor-car. On examination the patient was in a state of shock but was conscious. There was a haematoma on the left and right subcostal margins in the midaxillary line. The abdomen was tender and rigid in the left upper quadrant. Radiological investigation revealed no abnormality in the chest. A diagnosis of rupture of the spleen was made and he was immediately subjected to laparotomy. The spleen and other intraperitoneal organs were found to be normal. There was no blood in the peritoneal cavity.

On the second postoperative day the patient began to develop dyspnoea. Radiological examination of the chest showed the presence of air in the lower part of the left hemithorax. A diagnosis of pneumothorax was made. The chest was drained by needle suction and this produced 50 ml. of brownish fluid. However, the dyspnoea became worse and further radiological examination of the chest 4 days later showed that the amount of air had greatly

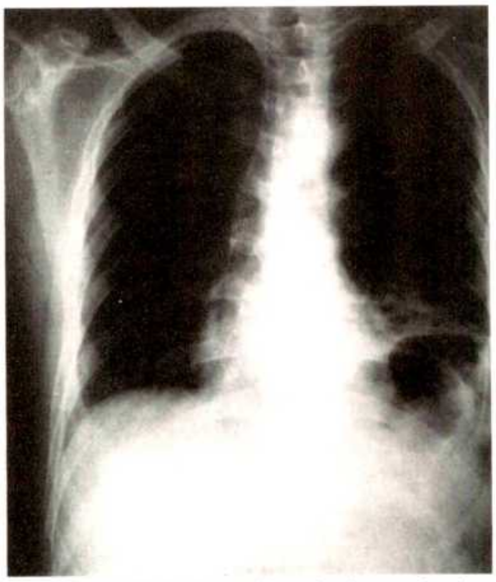

FIG. 1.—*Case* 2. Plain chest radiograph taken on the day of admission. Gas is present in the lower part of left hemithorax.

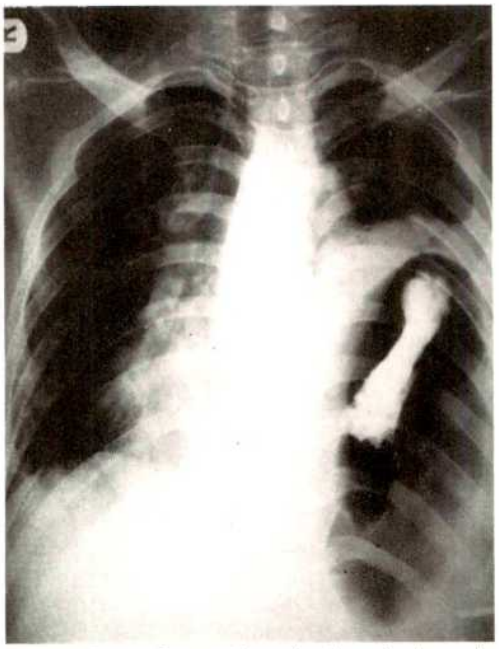

FIG. 3.—*Case* 2. Gastrografin-meal radiograph taken 3 days after admission, showing the presence of dye in an intrathoracic stomach.

increased. At this stage diaphragmatic rupture with herniation of the stomach was suspected. A Gastrografin-meal radiological examination on the same day confirmed this finding. The patient was immediately subjected to an operation. A thoracotomy incision was made through the left ninth intercostal space. The upper half of the stomach was found to have herniated through a 5-cm. anteroposterior tear in the dome of the left hemidiaphragm. The fundus of the stomach was gangrenous. This portion was excised and the defect in the stomach was repaired in two

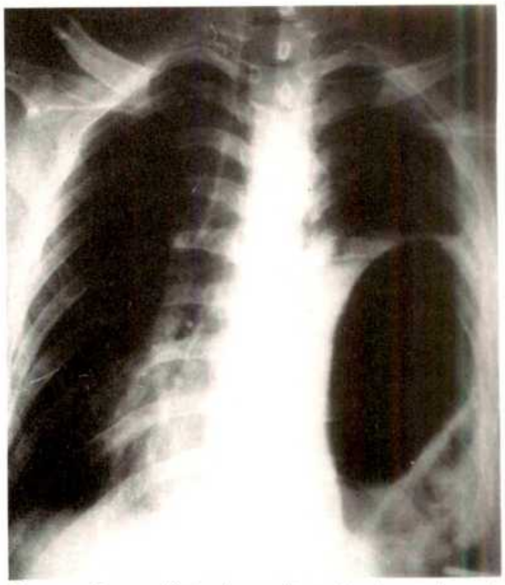

FIG. 2.—*Case* 2. Plain chest radiograph taken 3 days after admission. The amount of gas in the left hemithorax is much increased and is obviously in the stomach.

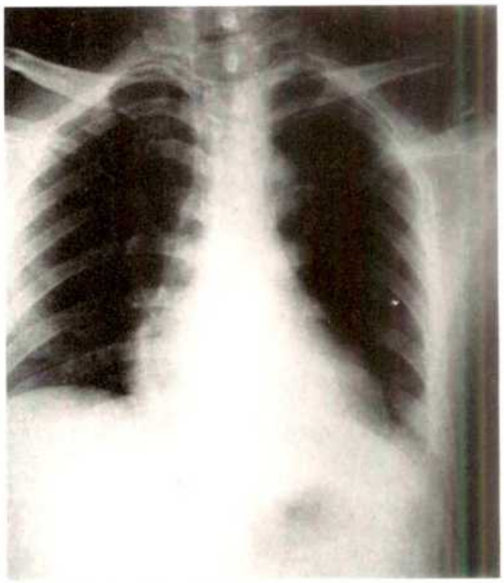

FIG. 4.—*Case* 2. Plain chest radiograph the day after operation, showing a return to normal.

layers using catgut. The stomach was reduced into the peritoneal cavity and the tear in the diaphragm was repaired in two layers with interrupted silk and continuous catgut. An underwater-seal drain was inserted into the left chest. The patient subsequently made an uneventful recovery.

Case 2.—A 27-year-old man was admitted to the General Hospital, Kuala Lumpur, Malaysia, in March, 1972, after a road-traffic accident. On examination his condition was good. He was not in shock and the abdomen was soft. He had multiple abrasions all over the body including one over the left subcostal margin anteriorly. Radiological examination of the chest revealed the presence of air in the lower zone of the left chest (*Fig.* 1) and drainage of this yielded some blood-stained fluid. Two days later his respiration became laboured and this was made worse by lying down. A diagnosis of a ruptured left diaphragm with herniation of the intraperitoneal contents was made. This was confirmed by a further radiological examination of the chest and a Gastrografin-meal radiograph (*Figs.* 2, 3). A laparotomy through a left upper paramedian incision was performed on the same day. There was a 7·5-cm. tear running anteroposteriorly in the dome of the left hemidiaphragm and through this the upper half of the stomach and the spleen had herniated. These organs were brought down into the peritoneal cavity. The splenic hilum was found to be slightly lacerated and there was some oozing of blood. Splenectomy was carried out. The tear in the diaphragm was repaired in two layers using interrupted silk and continuous catgut. An underwater-seal drain was inserted into the left chest cavity. A repeat radiological examination of the chest on the following day showed a normal picture (*Fig.* 4). The patient subsequently made a good postoperative recovery.

DISCUSSION

Bowditch (1853) reviewed 68 cases of diaphragmatic hernia which had all been diagnosed at autopsy. He recognized the following signs:—

1. Absence of respiratory sounds in the affected hemithorax.
2. A change in the position of the heart, with its displacement to the right or left of the midline depending on whether the rupture is in the left or right hemidiaphragm respectively.
3. Abnormal gurgling sounds in the affected hemithorax.
4. A tympanitic note on percussion of the lower part of the affected hemithorax.
5. Prominence and reduced movement of the affected hemithorax.

In 1886 Riolfi (quoted by Hedblom, 1925) successfully operated on a diaphragmatic stab wound. Walker in 1899 successfully repaired a torn left diaphragm caused by a tree falling on a patient (Walker, 1900).

The diagnosis of diaphragmatic rupture may be made fairly easily soon after the injury from the history, examination, and usual radiological investigations of the chest. This is shown in *Case* 2, where the diagnosis was made within 72 hours of the injury. The Gastrografin-meal radiograph was used merely to confirm a confident diagnosis. Contrast radiological studies are needed in difficult cases, such as the present *Case* 1, where there is a long delay in diagnosis. In right hemidiaphragmatic rupture diagnosis is often difficult as the herniated liver may easily be mistaken for an elevated intact right hemidiaphragm. Air may be introduced into the peritoneal cavity and if this leads to a right pneumothorax, then the right hemidiaphragm is ruptured (Lavender and Potts, 1959; Noon, Beall, and DeBakey, 1966).

The mechanism of disruption of the diaphragm due to blunt trauma is unknown. Magee (1935) postulated that the diaphragm was a membrane stretched tightly over a hoop. If the hoop is distorted by pressure, the membrane tears. Desforges, Strieder, Lynch, and Madoff (1957) thought that the diaphragm ruptured as a result of the force transmitted to it through the abdominal viscera. Probert and Havard (1961) considered that diaphragmatic rupture was due to respiratory effort acting on a diaphragm fixed by a crushing force. Ebert, Gaertner, and Zuidema (1967) suggested that diaphragmatic rupture occurred after thoracic rather than after abdominal trauma. In fact, when the chest has suffered severe blunt trauma there may be associated diaphragmatic rupture (Bassett, Gibson, and Wilson, 1968). In any patient with an abdominal or pelvic injury it should be considered that the diaphragm may rupture (Evans and Simpson, 1950; Levine and Crampton, 1963; Peltier, 1965). This is illustrated in *Case* 1 where no attempt was made at the original operation to inspect the diaphragm.

Herniation of the peritoneal contents into the chest does not always occur when the diaphragm is ruptured (Wren, Texada, and Krementz, 1962). This is shown in *Case* 1 where a diaphragmatic rupture was not diagnosed at the first operation although it was present at the time. Abdominal viscera tend to herniate into the thorax through a rupture in the diaphragm as there is normally a pressure differential between the peritoneal and thoracic cavities, the abdominal pressure being higher. There is disagreement about the level of intra-abdominal pressure (Keddie and Neill, 1967). Marchand (1957) stated that the difference in pressures ranged from 7 to 20 cm. of water during quiet respiration. This may increase to 100 cm. of water with deep breathing. Any increase of intra-abdominal pressure, such as in ileus, vomiting, or pregnancy, causes herniation when the diaphragm is ruptured. Bernhardt and Lawton (1966) reported delayed herniation associated with increased intra-abdominal pressure in pregnancy. Herniation may occur while the patient is straining under anaesthesia (Hamdi and Sturdy, 1955).

The common sites of rupture in the left hemidiaphragm are the dome and posterior half of the left leaf (Harrington, 1950), the posterocentral part extending towards the pericardial attachment (Ebert and others, 1967), and the anterolateral or pericardial part (Sutton, Carlisle, and Stephenson, 1967; Pomerantz, Rodgers, and Sabiston, 1968). Childress and Grimes (1961) believed that there was no particular site of localization. The pericardium protects the diaphragm immediately beneath it. Rupture of the diaphragm in this area is rare and may result in cardiac compression due to herniation of intraperitoneal viscera into the pericardial space (Moore, 1959). Owing to the protective effect of the liver, rupture of the right hemidiaphragm is rare compared with the left side. Hughes, Kay, Meade, Hudson, and Johnson (1948) recorded 5 ruptures on the right side and 23 on the left. Hedblom (1925) stated that 95 per cent of diaphragmatic ruptures were left-sided. Diagnosis of a right hemidiaphragmatic tear is usually made late (Epstein and Lempke, 1968).

TREATMENT

The tear in the diaphragm should be repaired as soon as possible, the ideal time being when the diaphragm is found to be ruptured at laparotomy for a suspected intraperitoneal injury. For a diaphragmatic tear which is diagnosed preoperatively the urgency of the operation is dictated by the general condition of the patient. In the presence of cardiorespiratory embarrassment with such effects as cyanosis, respiratory distress, and shock the enlarging hernia should immediately be repaired. Another reason why early surgery is advisable is the ever present possibility of early strangulation of the herniated peritoneal contents, as occurred in *Case* 1. Grage, Maclean, and Campbell (1959) recorded the death of a patient within 3 days of injury as a result of gangrene of a stomach strangulated by a traumatic diaphragmatic hernia. Hedblom (1925) described 126 patients with diaphragmatic hernia and reported that the death-rate doubled after the patient developed intestinal obstruction due to the hernia. D'Arcy Sutherland (1958), in describing 10 cases of ruptured diaphragm, reported 3 deaths which were all due to delay in diagnosis or failing to undertake immediate surgical treatment. It can thus be seen that it is better to repair the hernia as soon as possible after the injury.

An operative approach through an abdominal incision is the most suitable as it is possible to inspect the intraperitoneal organs at the same time. However, the thoracic approach is better for rupture of the right hemidiaphragm as access to the right hemidiaphragm would be hindered by the liver if the abdominal approach were used. In a long-standing chronic traumatic diaphragmatic hernia a thoracic approach would also be better as it is then easier to free the dense intrathoracic adhesions which are present and reduce the hernia into the peritoneal cavity. Either incision may be extended for increased exposure so that an abdominal incision becomes abdominothoracic and a thoracic incision becomes thoraco-abdominal.

The actual tear in the diaphragm is best repaired in two layers, using interrupted silk reinforced by continuous catgut. Each silk suture should pass through the pleura, diaphragm, and peritoneum bounding the tear in the diaphragm (Allison, 1962). To repair a very large tear or an old-standing tear it may be necessary to use a supporting piece of pericardium or synthetic material (Waldhausen, Kilman, Helman, and Battersby, 1966). At the end of the operation the pleural cavity on the affected side should be drained and the drain connected to an underwater seal.

Acknowledgements.—My thanks are due to the Director-General, Ministry of Health, Malaysia, Dato (Dr.) Abdul Majid Ismail, for permission to publish this article, and to Dato (Dr.) Omar Din, Senior Consultant Radiologist, General Hospital, Kuala Lumpur, for the radiological reports in *Case* 2. I am indebted to Professor M. Balasegaram, Senior Consultant Surgeon, General Hospital, Kuala Lumpur, for advice in preparing this paper. The help of the medical officers, house doctors, and nursing staff in managing the 2 cases is gratefully acknowledged.

THE REDUCTION OF SURGICAL WOUND INFECTIONS BY PROPHYLACTIC PARENTERAL CEPHALORIDINE

A CONTROLLED CLINICAL TRIAL

By CHRISTINE EVANS AND A. V. POLLOCK
SCARBOROUGH HOSPITAL, YORKSHIRE

SUMMARY

In a series of 762 general surgical wounds 376 were selected at random to receive three parenteral doses of cephaloridine and 386 remained as untreated controls. In all types of operation, with the exception of wounds in the lower extremities associated with arterial surgery, the rate of wound infection was lowered by the prophylactic use of cephaloridine. The results were statistically significant for total wounds, clean wounds, total contaminated wounds, and contaminated wounds other than in colorectal surgery. We therefore recommend the routine use of three doses of cephaloridine.

DESPITE the high standard of sterility of surgical instruments, dressings, and ligatures, improved operating-theatre design, and strict aseptic technique, many patients whose wounds are expected to heal by first intention suffer the discomfort, inconvenience, and, sometimes, actual danger of a wound infection.

The incidence of wound infection in the Scarborough Hospital (Jackson, Pollock, and Tindal, 1971a, b; Pollock and Tindal, 1972) is comparable with that in most other hospitals. In the three trials reported the infection rates were 12·7, 12·7, and 13·5 per cent, whereas the Public Health Laboratory Service (1960) reported an incidence of clinical infection in 14 per cent of 2746 wounds in 21 hospitals. In these trials three different methods were tested to try to reduce the wound-infection rate. They were the use of a plastic adhesive drape, a prophylactic antibiotic spray, and a prophylactic, single, parenteral dose of ampicillin preoperatively. None of these was effective.

Davidson, Clark, and Smith (1971) have produced a valuable computer analysis of some of the factors responsible for wound infections in 1000 operations and found only 5 out of 14 which strongly influenced the infection rate. These were a potentially dirty operation, the presence of bacteria in the wound at the end of the operation, old age, a long operation, and the nursing of patients in large, multi-bed, open wards as opposed to wards consisting of single beds and small groups. The factors which were of less significance were glove punctures, the presence of *Staphylococcus pyogenes* in patients' noses, emergency operations, skin towelling, and differences in technique. They found no significance in wound drainage, the presence of pathogens on the patients' skin, or different methods of, or even poor, skin disinfection. Perhaps the most important factors are endogenous contamination of wounds (Altemeier, Culbertson, and Hummell, 1968) and large, open wards.

Davidson and others (1971) did not analyse certain other predisposing causes of wound infection including obesity (Welch, 1891), a long preoperative stay in hospital (Todd, 1968), and the site of operation. Clean operations on the head and neck, for instance, rarely become infected.

Unfortunately the principal causes of wound infection cannot, as yet, be controlled and we have therefore turned our attention to the prophylactic role of another antibiotic, cephaloridine. Various authors have reported conflicting results with prophylactic antibiotics. Fekety, Chiff, Sabiston, Seidl, Smith, and Thorburn (1969) reported a trial of penicillin and methicillin against controls in 213 cases of cardiac surgery, and found no reduction in the wound-infection rate with either antibiotic. Altemeier and others (1968) came to the conclusion that 'the incidence of wound infection following the use of preoperative or prophylactic antibiotics was greater than the infection rate of wounds in patients not treated with them'.

There has been one favourable, adequately controlled, prospective study of a prophylactic parenteral antibiotic. This was by Polk and Lopez-Mayor (1969), who studied 172 gastroduodenal and colorectal operations and found a spectacular reduction in the wound-infection rate with the intramuscular use of three 1-g. doses of cephaloridine, the first given immediately preoperatively and the second 5 hours and the third 12 hours later.

METHODS

In the present trial cephaloridine has been used in the same dosage as given by Polk and Lopez-Mayor (1969) in randomly selected cases, the remainder of the cases being given no antibiotic. The preoperative dose was, however, administered intravenously during induction of anaesthesia, the other two doses being given intramuscularly. The method of random selection has been, as before, by the toss of a coin, and the definition of a wound infection has remained the standard one adopted in previous surveys from this hospital, namely the presence of pus which either discharged or needed to be released from the wound (*see also* Ljungqvist, 1964; Stoker and Ellis, 1972). If the operation entailed two incisions these wounds were counted separately. The results refer to the number of wounds, which is greater than the number of patients.

The wounds have been divided into 'clean' and 'contaminated'. The degree of contamination is likely to be much less in a cholecystectomy, for example, than in a large-bowel operation. The contaminated operations, therefore, have been subdivided into those with a low expectation of infection (gastro-duodenal, intestinal, biliary, urological, and appendicectomy apart from perforated appendices) and those with a high expectation of infection (perforated appendices and colorectal surgery). We previously named these groups 'potentially contaminated' and 'contaminated' (Jackson and others, 1971a, b; Pollock and Tindal, 1972).

Table I.—WOUND-INFECTION RATE WITH AND WITHOUT CEPHALORIDINE

TYPE OF WOUND	CEPHALORIDINE			NO CEPHALORIDINE			χ^2	*P*
	No. of Wounds	No Infected	Per cent	No. of Wounds	No Infected	Per cent		
Clean

Varicose veins	20	0	25	1
Other groin incisions	14	0	12	4
Amputations	9	0	8	1
Total	164	3	171	11

Patients under the age of 16 years were excluded because we do not favour injections in children if they can be avoided. Thirty-two patients who died within 2 weeks of operation in whom the presence or absence of infection was uncertain have been excluded from the study, leaving 762 wounds for analysis out of a total of 794. All patients were seen by one of us for at least 4 weeks. When the infection developed in hospital the pus was cultured and the sensitivity to cephaloridine tested by the Multidisc method. Five late wound infections escaped bacteriological study and 7 pus swabs were sterile. No restriction was placed on the use of therapeutic antibiotics, but no other prophylactic antibiotic was allowed except for the usual oral preparations for colonic surgery.

To avoid bias the details were entered not in the patients' case notes but on punch cards which were kept separately and analysed manually.

RESULTS

Seven hundred and sixty-two wounds were studied, 91 of which became infected (11·9 per cent). There were 376 wounds in patients who were given cephaloridine and 386 in patients who were not. Thirty-four wounds in the former group became infected (9·1 per cent) and 57 in the latter (14·7 per cent). The difference is statistically significant ($\chi^2 = 5{\cdot}25$, $P < 0{\cdot}05$) (*Table I*).

Table III.—CONTAMINATED WOUNDS: TYPES OF OPERATION

TYPE OF OPERATION	CEPHALORIDINE		NO CEPHALORIDINE	
	No. of Wounds	No. Infected	No. of Wounds	No. Infected
Perforated appendices	7	4	11	5
Colorectal	34	10	35	15

Hysterectomy	1	0	3	0
Excision of infected lesions	7	2	7	3
Total	144	11	123	19

Clean Wounds.—Clean wounds are not uniform in their infection rate. There were no infections after head and neck surgery, and only one in any wound above the abdomen (*Table II*). On the other hand, incisions for arterial reconstruction in the lower limbs were much more likely to become infected. Most of these infections were probably acquired in the ward postoperatively on the basis of discharging haematomas. Long operating times and the presence of drains in these wounds may also have contributed.

There were 73 clean wounds for arterial disease of the lower extremities; 27 in patients given cephaloridine and 46 in patients who were not. There were 6 infections in the first group (22·2 per cent) and 7 in the second (15·2 per cent). This was the only area in the entire series which showed poorer results using prophylactic cephaloridine and the difference is not significant.

There were 335 clean wounds apart from those for arterial disease in the lower limbs, with 14 infections (4·2 per cent); 164 in patients given cephaloridine and 171 in patients who were not. In the former there were 3 infections (1·8 per cent) and in the latter 11 infections (6·4 per cent). The difference is significant ($\chi^2 = 4{\cdot}43$, $P < 0{\cdot}05$).

Table IV.—THE INCIDENCE OF WOUND INFECTIONS IN OBESE AND NON-OBESE PATIENTS: CONTAMINATED OPERATIONS

	NO OF WOUNDS	NO OF INFECTIONS	PER CENT	χ^2	P
Obese	77	20	26·0	4·14	<0·05
Non-obese	277	44	15·8		

Contaminated Wounds.—There were 354 contaminated wounds with 64 infections (18·0 per cent) (*Tables I* and *III*). Of 185 wounds in patients protected by cephaloridine, there were 25 infections (13·5 per cent), whereas in 169 wounds not so protected there were 39 infections (23·1 per cent). The difference is significant ($\chi^2 = 5{\cdot}45$, $P < 0{\cdot}02$).

In the contaminated group with a low expectation of infection (30 infections in 267 wounds, 11·2 per cent) there were 144 wounds in patients given prophylactic cephaloridine and 123 in patients who were not. Of the former, 11 wounds became infected (7·6 per cent) and of the latter, 19 (15·4 per cent). The difference is significant ($\chi^2 = 4{\cdot}05$, $P < 0{\cdot}05$).

In the smaller group of colorectal surgery and perforated appendices (87 wounds with 34 infections, 39·1 per cent) 14 out of 41 wounds became infected in patients protected by cephaloridine (34·1 per cent) and 20 out of 46 wounds in patients not so protected (43·5 per cent). These figures are not significant ($\chi^2 = 0{\cdot}79$).

As in previous surveys, we have found that obese patients are more liable to wound infections than non-obese ones. This is shown in the contaminated group, in which 20 out of 77 wounds in obese patients became infected (26·0 per cent) compared with 44 out of 277 wounds in non-obese patients (15·8 per cent) ($\chi^2 = 4{\cdot}14$, $P < 0{\cdot}05$) (*Table IV*). Clean wounds have not been tabulated for obesity because the numbers were small.

As in other series (Davidson and others, 1971) we found that on the whole older patients were more liable to wound infections than younger ones, and this difference was statistically significant for all wounds except in the arterial group and for contaminated wounds other than those for colorectal operations. Nine contaminated wounds out of 145 (6·2 per cent) became infected in the under-60 age-group, compared with 21 wounds out of 122 (17·4 per cent) in patients over 60 ($\chi^2 = 8{\cdot}05$, $P < 0{\cdot}01$). The difference between the infection rate in young and old patients is not significant in clean wounds or in wounds associated with colorectal surgery (*Table V*).

Table V.—THE INCIDENCE OF WOUND INFECTIONS IN PATIENTS UNDER 60 YEARS ('YOUNG') AND OVER 60 YEARS ('OLD')

TYPE OF WOUND	TREATMENT	YOUNG			OLD			χ^2	P
		No. of Wounds	No. Infected	Per cent	No. of Wounds	No. Infected	Per cent		
Clean (non-arterial)	Cephaloridine	83	1	1·2	81	2	2·5	0·36	N.S.

	No cephaloridine	10	5	50·0	36	15	41·7	0·22	N.S.
	Total	18	10	55·5	69	24	34·8	2·58	N.S.
Contaminated (other)	Cephaloridine	79	2	2·5	65	9	13·8	6·46	<0·02
	No cephaloridine	66	7	10·6	57	12	21·1	2·55	N.S.
	Total	145	9	6·2	122	21	17·4	8·04	<0·01
All wounds (except arterial)	Cephaloridine	170	8	4·7	179	20	11·2	4·94	<0·05
	No cephaloridine	168	16	9·5	172	34	19·7	7·10	<0·01
	Total	338	24	7·1	351	54	15·4	11·77	<0·01

N.S. = not significant.

Table VI lists the organisms cultured from infected wounds. Five infected wounds were not submitted to bacteriological examination, pus swabs were sterile in 7 cases, and organisms were frequently multiple. The figures, therefore, do not tally with the number of infected wounds. The majority of the infections were due to staphylococci in clean wounds and to intestinal organisms in the contaminated group. Most of the organisms were sensitive to cephaloridine whether or not the patient had received it prophylactically.

DISCUSSION

Cephaloridine has been shown to exert a significantly favourable influence on the wound-infection rate. In total wounds, in clean wounds other than those for arterial diseases of the lower extremities, in total contaminated wounds, and in contaminated wounds other than those for colorectal surgery, the improvement with cephaloridine was statistically significant.

The results of the present trial are not as startling as those of Polk and Lopez-Mayor (1969), who studied both wound and intra-abdominal infections. In 32 patients with gastroduodenal operations given cephaloridine prophylactically they found no infections, whereas in 36 patients given a placebo 11 infections occurred. In 54 colorectal operations protected by cephaloridine there were 4 infections and in 50 without cephaloridine there were 15 infections.

Cephaloridine is a bactericidal antibiotic active against *Staphylococcus pyogenes* and other Gram-positive cocci (but only some strains of *Streptococcus faecalis*). The Gram-negative organisms which are sensitive to cephaloridine include *Proteus mirabilis* (but not other species of *Proteus*), *Escherichia coli*, and most strains of *Klebsiella pneumoniae*. It has no activity against *Pseudomonas aeruginosa*. In the present series wound infections were mainly due to staphylococci and intestinal organisms. The administration of cephaloridine did not result in any change in the type of organism or, curiously enough, in the emergence of cephaloridine-resistant organisms.

Table VI.—ORGANISMS ISOLATED FROM INFECTED WOUNDS

ORGANISMS	CEPHALORIDINE				NO CEPHALORIDINE			
	Clean Wounds		Contaminated Wounds		Clean Wounds		Contaminated Wounds	
	+	−	+	−	+	−	+	−

+, Organism sensitive to cephaloridine. −, Organism not sensitive to cephaloridine.

Against the achievement of this drug must be set the inconvenience to the patient of intramuscular injections in the immediate postoperative period, the slight increase in nurses' work, and the cost of the drug. However, assuming a daily cost for in-patient treatment in a non-teaching hospital of approximately £10 per day and keeping in mind the discomfort of any wound infection, the saving due to the use of cephaloridine more than outweighs these disadvantages.

There have been several favourable reports on the topical use of antibiotics in the prevention of wound infection. Local ampicillin reduced the wound-infection rate after grid-iron appendicectomy (Mountain and Seal, 1970) and after biliary and gastro-intestinal surgery (Stoker and Ellis, 1972). Longland, Gray, Lees, and Garrett (1971) reported benefit from the application of a solution of tetracycline to appendicectomy wounds, while Moylan and Brockenbrough (1968) reported improvement with 1 per cent kanamycin irrigation. On the other hand, Jackson and others (1971b) failed to show a significant reduction in the wound-infection rate by the use of a bacitracin–polymixin–neomycin spray.

We think it may be more acceptable to staff and patients to instil cephaloridine into the wound before closure rather than to use it parenterally. If its topical use can be shown to have equally satisfactory results we will be prepared to change to this method. This is at present under investigation.

Acknowledgements.—We gratefully acknowledge the assistance of Dr. R. D. Foord of Glaxo Laboratories Ltd., who also supplied the cephaloridine (Ceporin).

THE EFFECT OF INSULIN HYPOGLYCAEMIA ON SERUM GASTRIN AND GASTRIC ACID IN NORMAL SUBJECTS AND PATIENTS WITH DUODENAL ULCER

By D. J. COWLEY,* J. H. BARON,
DEPARTMENT OF SURGERY, ROYAL POSTGRADUATE MEDICAL SCHOOL, LONDON

J. HANSKY, AND M. G. KORMAN
MONASH UNIVERSITY, DEPARTMENT OF MEDICINE, PRINCE HENRY'S HOSPITAL, MELBOURNE, AUSTRALIA

SUMMARY

Serum gastrin was measured by radio-immunoassay in normal subjects and in patients with duodenal ulcer during insulin hypoglycaemia with and without concomitant aspiration of gastric acid. Insulin hypoglycaemia alone caused a rise in serum gastrin from 8·0 to 45·0 pg. per ml. in patients with duodenal ulcer, which was significantly greater than the rise from 13·0 to 29·0 pg. per ml. in normal subjects. During gastric aspiration serum-gastrin levels remained elevated for longer periods. The maximum increase of serum gastrin after insulin during gastric aspiration provided an almost complete discrimination between patients with duodenal ulcer and normal subjects. This discrimination between the groups was complete when serum gastrin was measured during insulin hypoglycaemia combined with intragastric neutralization of acid. The timing of the peak serum gastrin and the lowest blood-glucose coincided, but the peak acid output occurred 15–30 minutes later. Serum gastrin was inversely correlated with blood-glucose. Blood-glucose decreased to significantly lower levels in unaspirated than in aspirated subjects.

These studies suggest that patients with duodenal ulcer produce more gastrin than normal subjects in response to insulin hypoglycaemia (and, by inference, to vagal stimulation). The results support the concept of an increased functional G-cell mass in duodenal ulcer patients, and indicate the physiological roles of vagally released gastrin and of the acid inhibitory mechanism. Discriminant functions observed in the study could form the basis of tests for the presence of the duodenal ulcer diathesis.

GASTRIN release in response to both food stimulation and insulin hypoglycaemia has been extensively studied in normal subjects (Korman, Soveny, and Hansky, 1971a, b) and in patients with duodenal ulcer (Hansky, Korman, Cowley, and Baron, 1971; Korman, Soveny, and Hansky, 1971c). It has been shown that concomitant acid secretion modifies the gastrin response to insulin hypoglycaemia (Hansky and others, 1971). However, the relationship between the stimulatory effects on acid secretion of direct vagal impulses, on the one hand, and of gastrin, on the other, is unknown.

In an attempt to resolve this question and to study further the effect of acid inhibition on gastrin release, the serum-gastrin response to insulin hypoglycaemia has been investigated, with and without simultaneous aspiration of gastric juice, both in normal subjects and in patients with duodenal ulcer.

MATERIALS AND METHODS

Seventeen patients, comprising 15 men and 2 women of mean age 39 years, with radiologically proven duodenal ulcer were studied. These were compared with 11 normal subjects: 10 men and 1 woman of mean age 34 years. All the investigations were performed after an overnight fast. Venous blood was collected for gastrin and glucose estimation 30 minutes before and at 15-minute intervals for 2 hours after the rapid intravenous injection of soluble insulin (Insulin B.P., Boots), 0·2 U. per kg. body-weight.

1. Insulin Hypoglycaemia with No Gastric Aspiration.—Eight patients with duodenal ulcer and 8 normal subjects were studied.

2. Insulin Hypoglycaemia with Gastric Aspiration.—Thirteen patients with duodenal ulcer and 7 normal subjects were investigated. Two of the patients with duodenal ulcer and 4 normal subjects had previously been studied without gastric aspiration.

Gastric juice was aspirated continuously via a nasogastric tube which had been positioned fluoroscopically so that the tip lay in the gastric antrum. Collections were made in 15-minute fractions for 1 hour in the basal state and for 2 hours after insulin. An intramuscular injection of pentagastrin, 6 μg. per kg., was then given and four further 15-minute collections of gastric juice were obtained. The volume of gastric aspirate was measured and the acidity determined by electrometric titration with 0·1 *N* sodium hydroxide to *p*H 7·0. Acid output (mEq. per 15 minutes) was obtained by the product of volume and acidity.

Blood-glucose was estimated using a glucose oxidase AutoAnalyzer method (Wincey and Marks, 1961). The serum was separated by centrifugation and the gastrin was estimated in duplicate by radioimmunoassay (Hansky and Cain, 1969; Hansky and others, 1971). The sensitivity of this assay is 5 pg. per ml. and it should be noted that the levels obtained in our laboratory are lower than in previous reported studies.

Conventional statistical methods were employed. The significance of the difference of means and of mean differences was calculated from unpaired and paired *t* tests. Linear regression lines were calculated from the correlation coefficient, *r*. The significances of differences between regression lines were derived from the standard deviations of the slopes (difference of slopes) and the standard deviations of the intercepts (separation of slopes).

RESULTS

Gastrin Response to Insulin Hypoglycaemia with No Gastric Aspiration.—*Fig.* 1 shows the serum-gastrin response to insulin in 8 patients with duodenal ulcer and in 8 normal subjects. The mean basal gastrin level was insignificantly lower in the patients with duodenal ulcer ($P = 0{\cdot}2$). After insulin the serum-gastrin level of the patients with duodenal ulcer increased significantly, from a mean basal level of 8·5 pg. per ml. to a peak of 45·1 pg. per ml. 45 minutes after the injection ($P = 0{\cdot}00006$). In normal subjects there was a smaller, significant increase in serum gastrin from 13·4 to 29·2 pg. per ml. 45 minutes after the injection of insulin ($P = 0{\cdot}00003$). The mean increase of serum gastrin was significantly greater in patients with duodenal ulcer than in normal subjects ($P = 0{\cdot}003$).

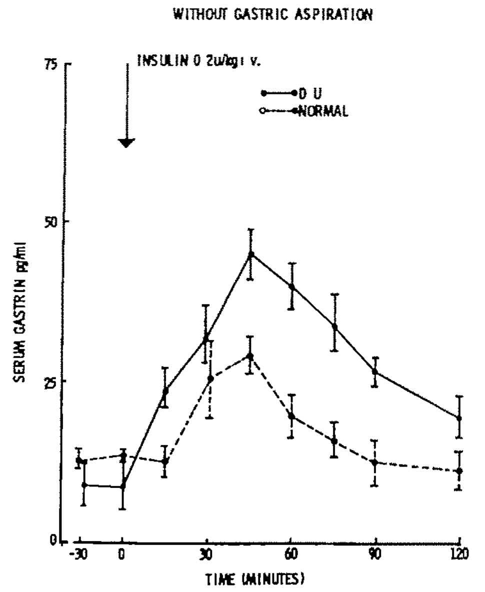

FIG. 1.—Serum-gastrin responses to intravenous insulin, 0·2 U. per kg., in 8 patients with duodenal ulcer and in 8 normal subjects studied without gastric aspiration.

As the peak rise in gastrin level occurred at varying times after the injection of insulin in each subject the peak gastrin level has been compared with the corresponding basal gastrin for each individual (*Fig.* 2). Although the mean peak gastrin level after insulin was still significantly higher in patients with duodenal ulcer than in normal subjects ($P = 0{\cdot}03$), there was no discrimination between the two groups, as every value of the ulcer group falls within the range found in the normal subjects. A clearer separation of the two groups can be obtained by plotting the absolute rise in serum gastrin of individual subjects (*Fig.* 3), and when treated in this way the values in the majority of patients with duodenal ulcer are above those in the normal group.

Gastrin Response to Insulin Hypoglycaemia with Concomitant Gastric Aspiration.—*Fig.* 4 shows the mean serum-gastrin response to insulin with concomitant gastric aspiration in 13 patients with duodenal ulcer and in 7 normal subjects. The mean basal gastrin levels were almost identical in the two groups ($P = 0{\cdot}8$). The mean basal gastrin level in duodenal ulcer patients was lower with gastric

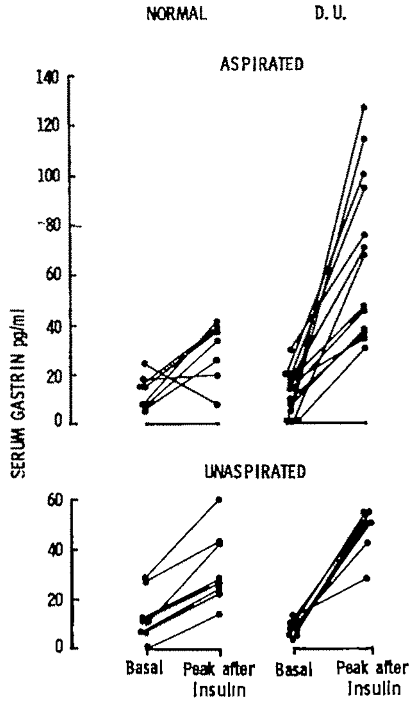

FIG. 2.—Basal serum-gastrin and peak serum-gastrin levels after intravenous insulin, 0·2 U. per kg., in patients with duodenal ulcer and in normal subjects, with and without gastric aspiration.

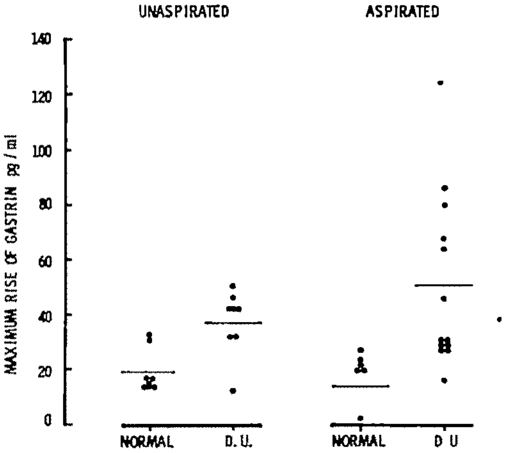

FIG. 3.—Maximum rise in the serum-gastrin level after intravenous insulin, 0·2 U. per kg., in patients with duodenal ulcer and in normal subjects, with and without gastric aspiration.

aspiration than without but the difference was not significant (*Fig.* 1). After insulin the serum-gastrin level of the patients with duodenal ulcer increased significantly from a basal level of 12·5 pg. per ml. to a peak of 51·4 pg. per ml. 75 minutes after the injection ($P = 0·003$). In normal subjects there was a smaller increase in the mean serum gastrin from 13·7 to 24·4 pg. per ml. 60 minutes after the injection of insulin but this increase was not significant ($P = 0·16$). The failure to elicit a significant rise in the normal group is due to the variation in the timing of the peak gastrin level between individuals.

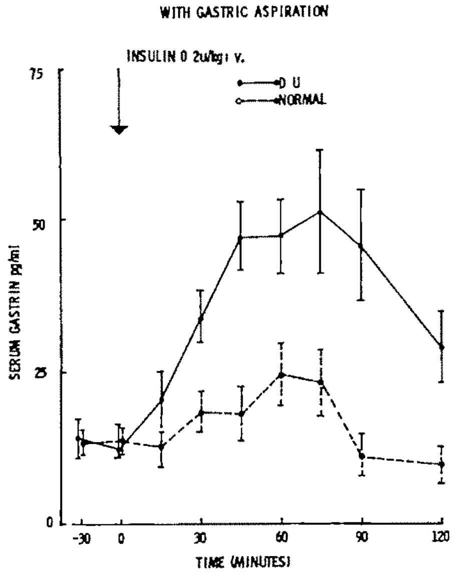

FIG. 4.—Serum-gastrin responses to intravenous insulin, 0·2 U per kg., in 13 patients with duodenal ulcer and in 7 normal subjects studied with concomitant gastric aspiration.

Table I.—COMPARISON OF BASAL SERUM-GASTRIN LEVELS OF PATIENTS WITH DUODENAL ULCER AND NORMAL SUBJECTS, SHOWING THE EFFECT OF CONCOMITANT GASTRIC ASPIRATION

GROUP	BASAL SERUM GASTRIN (pg per ml)		*P*
	Duodenal Ulcer Patients	Normal Subjects	
Aspirated	12·5±2·60	13·7±2·48	0·76
Not aspirated	8·5±0·82	13·4±3·56	0·20
P	0·26	0·89	

Fig. 2 shows the basal and peak gastrin levels of the individual subjects, and the mean peak gastrin level is significantly higher than the basal level in the normal subjects ($P = 0·045$). It can also be seen that the majority of the ulcer patients had peak levels above the range found in the normal group.

Comparing the aspirated and unaspirated series (*Fig.* 2), there was no significant difference between the mean peak levels of the normal subjects with aspiration and those with no aspiration ($P = 0·1$). However, half the patients with duodenal ulcer in the aspirated group attained serum-gastrin levels which were considerably higher than the highest level in the unaspirated group.

Fig. 3 shows that the mean absolute rise in serum gastrin was significantly greater in the patients with duodenal ulcer than in the normal subjects ($P = 0·01$) and 12 of the 13 ulcer patients had values above those achieved in the normal group.

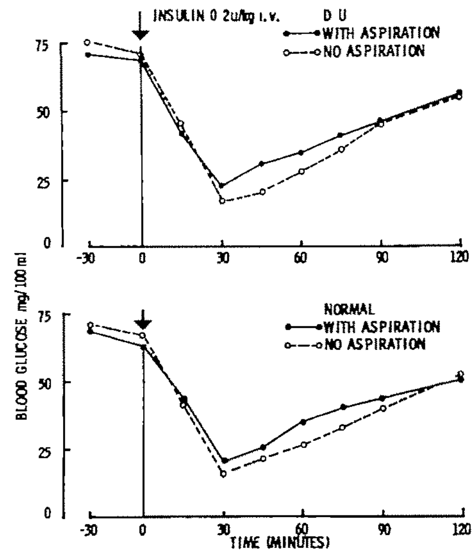

FIG. 5.—Mean changes in the blood-glucose after intravenous insulin, 0·2 U. per kg, in patients with duodenal ulcer and in normal subjects, with and without gastric aspiration.

Table II.—COMPARISON OF ACID OUTPUTS OF PATIENTS WITH DUODENAL ULCER AND NORMAL SUBJECTS

ACID OUTPUT	HCl (mEq. per hr.)		*P*
	Duodenal Ulcer Patients	Normal Subjects	
Basal acid output	4·06±0·76	1·62±0·33	0·037
Peak acid output to insulin	27·68±3·50	20·43±4·36	0·22
Peak acid output to pentagastrin	36·30±3·15	33·70±6·37	0·68

Comparing *Figs.* 1 and 4, it can be seen that the serum-gastrin response in the duodenal ulcer patients persisted for a longer time in the aspirated group than in the unaspirated group and 2 hours after the injection of insulin it remained significantly higher than basal levels ($P = 0·01$).

Blood-glucose Response to Insulin Hypoglycaemia.—*Fig.* 5 shows the mean blood-glucose levels after the injection of insulin in normal subjects and in patients with duodenal ulcer, both with and without concomitant gastric aspiration. The blood-glucose decreased to a nadir 30 minutes after the injection and then recovered progressively towards basal levels. Gastric aspiration appeared to influence the degree of hypoglycaemia after insulin. Thirty and 45 minutes after intravenous insulin the blood-glucose decreased to lower levels in subjects who had no gastric aspiration than in those with aspiration. These differences were significant in patients with duodenal ulcer ($P = 0{\cdot}01$) but not in normal subjects ($P = 0{\cdot}1$). However, when both these groups were combined the differences at 30 and 45 minutes were highly significant ($P = 0{\cdot}003$).

Gastric Acid Secretion by the Two Groups.—In *Table II* the gastric acid secretion of the patients with duodenal ulcer has been compared with that of normal subjects. The mean basal acid output of the patients with duodenal ulcer was significantly greater than that of the normal subjects. On the other hand, in this small series there was no significant difference between the mean peak acid outputs (in response to insulin or to pentagastrin) of the two groups.

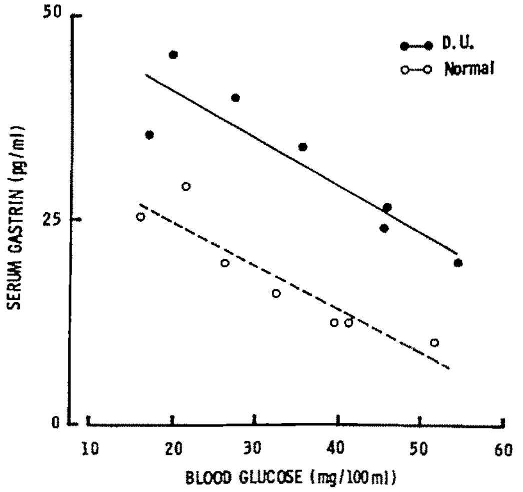

FIG. 6.—Relationship between blood-glucose and serum-gastrin levels at the end of each 15-minute period after intravenous insulin. Mean values of 8 patients with duodenal ulcer and of 8 normal subjects without gastric aspiration. For duodenal ulcer patients $y = -0{\cdot}568x + 52{\cdot}1$; $r = -0{\cdot}90$, $P = 0{\cdot}003$. For normal subjects $y = -0{\cdot}526x + 35{\cdot}1$; $r = -0{\cdot}92$; $P = 0{\cdot}001$. Difference between the slopes, $P = 0{\cdot}2$; separation of the slopes, $P = 0{\cdot}001$.

Temporal Relationships of the Changes in Blood-glucose, Serum Gastrin, and Gastric Acid Secretion.—After insulin the blood-glucose level falls while serum-gastrin and gastric acid output increase. Each measured function is changing rapidly, reflecting a highly unsteady state; their interrelationships have been studied by finding meaningful significant correlations between the separate measurements.

a. Blood-glucose and Serum Gastrin.—Changes in the serum gastrin paralleled changes in the blood-glucose. *Fig.* 6 shows that in subjects who did not have gastric aspiration there was a highly significant inverse correlation between the blood-glucose level at the end of each 15-minute period and the corresponding serum-gastrin level. It can be seen further from this graph that there was a clear, significant separation of the two groups ($P < 0{\cdot}05$) and that at any level of blood-glucose after insulin, gastrin levels were approximately 50 per cent greater in the patients with duodenal ulcer than in the normal subjects. This temporal relationship was not found in subjects who had concomitant gastric aspiration; aspiration appeared to prolong the serum-gastrin response but it did not prolong the blood-glucose response to insulin.

b. Blood-glucose and Gastric Acid Secretion.—Changes in the gastric acid secretion lagged approximately 30 minutes behind changes in the blood-glucose. This can be seen from *Fig.* 7, in which the mean blood-glucose level at the end of each 15-minute period has been plotted against the mean gastric acid output 15–30 minutes later. A highly significant inverse correlation between these two groups of values was found both in patients with duodenal ulcer and in normal subjects, with significant separation of the two regression lines ($P < 0{\cdot}05$). This correlation was not found if the blood-glucose level at the end of each 15-minute period was plotted against the acid output for the same 15-minute period or for that 0–15 minutes later.

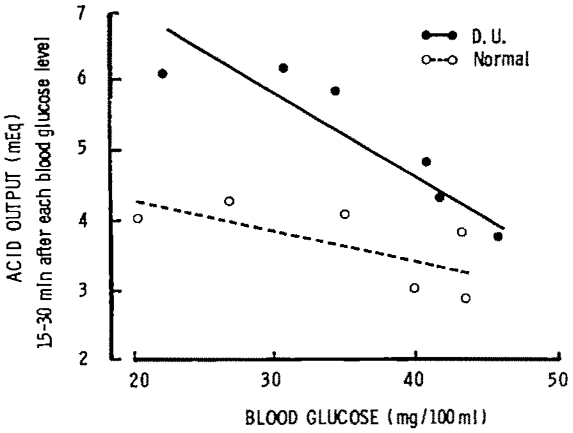

FIG. 7.—Temporal relationship between blood-glucose in each 15-minute period after intravenous insulin and gastric acid output 30 minutes later. Mean values of 13 patients with duodenal ulcer and of 7 normal subjects. For duodenal ulcer patients $y = -0{\cdot}121x + 9{\cdot}45$, $r = -0{\cdot}89$; $P = 0{\cdot}009$. For normal subjects $y = -0{\cdot}045x + 5{\cdot}20$; $r = -0{\cdot}69$; $P = 0{\cdot}06$. Difference between the slopes, $0{\cdot}05 < P < 0{\cdot}1$, separation of the slopes, $P < 0{\cdot}001$.

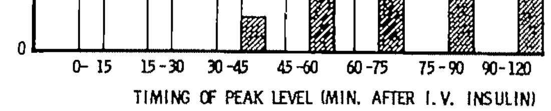

FIG 8.—Time intervals during which the peak gastrin levels and peak acid outputs occurred after insulin in 20 individuals (13 patients with duodenal ulcer and 7 normal subjects). Serum gastrin was measured at the end of each 15-minute period, whereas gastric juice was collected continuously during each 15-minute period.

c. Serum Gastrin and Gastric Acid Secretion.—*Fig.* 8 shows the timing of the peak gastrin level and of the peak acid output in 20 individual subjects (including all the ulcer patients and normal subjects). Serum gastrin was measured at 15-minute intervals at a precise instant in time. Gastric juice was collected over a period of 15 minutes and measurements of gastric acid are therefore not timed so precisely. However, it is clear that changes in the serum gastrin preceded changes in gastric acid secretion; peak gastrin levels occurred at any time from 0 to 75 minutes, whilst the peak acid output lagged 15–30 minutes behind, over the range of 30–120 minutes. The individual relationships which are not shown in the figure were as follows: in 15 subjects the peak gastrin level occurred 15–30 minutes before the peak acid output, in 4 subjects the peaks coincided, and in 1 subject the peak gastrin level followed the peak acid output by 15 minutes.

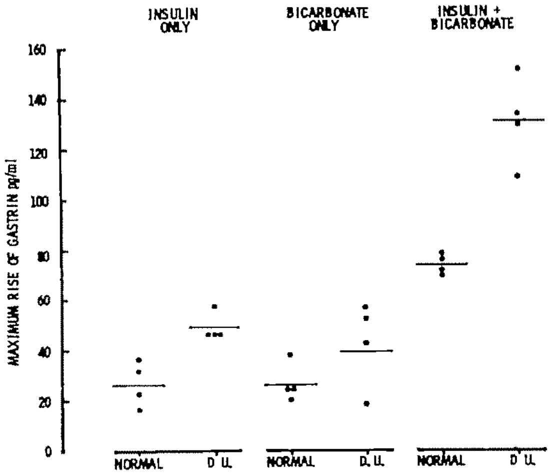

FIG. 9.—Maximum rise in serum-gastrin level in 4 normal subjects and 4 patients with duodenal ulcer after insulin, 0·2 U. per kg, during intragastric $NaHCO_3$ instillation, and in response to intravenous insulin and intragastric $NaHCO_3$ given simultaneously.

Relationships between Blood-glucose, Serum Gastrin, and Gastric Acid Output.—

a. Basal Levels.—Fasting blood-glucose was not related to basal gastrin or to the basal gastric acid output in either patients with duodenal ulcer or in normal subjects. No relationship was found between basal gastrin levels and the basal acid output in patients with duodenal ulcer ($r = -0·04$, $P = 0·45$), but there was a significant correlation between them in normal subjects ($r = 0·73$, $P = 0·03$).

b. Peak Serum-gastrin and Peak Acid Output.—Peak serum-gastrin and peak acid output after insulin were not related in patients with duodenal ulcer ($r = 0·01$, $P = 0·5$) but in normal subjects there was a relationship of doubtful significance ($r = 0·6$, $P = 0·08$).

DISCUSSION

Insulin hypoglycaemia consistently produced a greater increase in serum gastrin in patients with duodenal ulcer than in normal subjects. In the present study not only was the mean rise in serum gastrin significantly higher in patients with duodenal ulcer, but the absolute peak serum-gastrin levels were also significantly higher. This difference had not been found in our previous study of a smaller group of subjects (Korman and others, 1971b). In another study (Hansky and others, 1971) we suggested that patients with duodenal ulcer have an increased G-cell mass as well as an increased parietal-cell mass. In the present study, in which a group of patients with duodenal ulcer had insignificantly higher peak acid outputs than normal, the peak serum gastrin in the patients with duodenal ulcer was about 50 per cent greater than normal. This increased functional G-cell mass could be due either to an increased number of G cells (hyperplasia) or to a higher than normal rate of release of gastrin from each G cell in response to cholinergic stimuli. This point cannot be resolved until the number of G cells in the stomachs of patients with duodenal ulcer and of normal control subjects has been compared. However, the fact that the two regression lines in *Fig.* 6 are parallel but separate is compatible with the hypothesis that patients with duodenal ulcer do have increased numbers of G cells, and that for any degree of vagal stimulation produced by hypoglycaemia the rate of release of gastrin per G cell is the same as normal. Extrapolation of the lines of *Fig.* 6 might suggest that patients with duodenal ulcer should have higher serum-gastrin levels at normal fasting glucose levels, whereas the opposite is the case (Hansky and others, 1971). However, the data used in *Fig.* 6 are confined to measurements after insulin, so that such extrapolation is not appropriate. If measurements in the fasting state are included, then the lines do converge towards normal levels of blood-glucose.

In a previous study (Hansky and others, 1971) attempts were made to counteract the mechanism of acid inhibition of the release of antral gastrin by neutralizing gastric acid *in vivo* with sodium bicarbonate, and in the present study by aspirating gastric juice as it was secreted. With gastric aspiration the effect of insulin hypoglycaemia in increasing serum-gastrin levels was prolonged but the peak level attained was not significantly different from that of the unaspirated groups. The results of intragastric neutralization from our previous study are summarized in *Fig.* 9. Intragastric neutralization greatly increased the serum-gastrin response to insulin hypoglycaemia and in this small group there was complete discrimination between the serum-gastrin responses of normal subjects and of patients with duodenal ulcer. Presumably the neutralization of gastric acid raised the *p*H of the gastric contents and suppressed the mechanism for inhibition of the release of antral gastrin from the G cells. Gastric aspiration, while removing most of the acid as it was secreted, still allowed some juice of a low *p*H to remain in contact with the G cells. These results support the suggestion made by Woodward, Lyon, Landor, and Dragstedt (1954) that an increasing hydrogen-ion concentration in the pyloric antrum inhibits the release of gastrin. Measurement of the serum gastrin after insulin hypoglycaemia and intragastric neutralization in the non-intubated subject is a relatively simple procedure. If the excellent discrimination between patients with duodenal ulcer and normal subjects is confirmed when larger numbers are tested, this procedure might form the basis of a simple test for the duodenal ulcer diathesis.

The role of the vagus nerves in stimulating acid secretion by the stomach is complex. Vagal stimulation can cause the parietal cells to release acid even if all the antral gastrin-producing tissue has been extirpated (Pevsner and Grossman, 1955). However, in this animal study it was impossible to be certain that all the non-antral G cells had been removed. Antral gastrin is released by stimulation of the vagi electrically (Fyro, 1967) or by insulin hypoglycaemia (Korman and others, 1971b). The relationships between this gastrin release and the acid secretion during vagal stimulation by insulin hypoglycaemia have been examined in the present study. After the injection of insulin serum-gastrin levels increased as blood-glucose levels decreased and there was a highly significant inverse correlation between these two concentrations. On the other hand, the peak serum-gastrin level was attained about 15–30 minutes before the peak acid output, suggesting that the vagally released gastrin could play some part in stimulating acid secretion. The size of this contribution is uncertain. We found no correlation between the peak serum-gastrin level and the peak acid output. Furthermore, in some normal subjects, relatively low peak gastrin levels were associated with peak acid outputs which lay in the upper half of the range in duodenal ulcer patients. Thus, gastrin released by vagal stimulation may indirectly (by a chemical stimulus) 'prime' the parietal cells to respond to direct cholinergic vagal stimulation.

In this study gastric aspiration appeared to influence the degree of hypoglycaemia achieved after insulin injection. The mean blood-glucose levels at 30 and 45 minutes after the injection of insulin were significantly lower in the unaspirated group in spite of having fallen from a slightly higher basal level than in the aspirated group. The finding may well be due to chance, but it is interesting to speculate that acid passing into the duodenum initiated the release of a hormone which increased the hypoglycaemia by release of endogenous insulin.

THE SIGNIFICANCE OF HUMORAL ANTIBODIES IN THE LOCALIZATION OF HUMAN MALIGNANT MELANOMA

By MARTIN G. LEWIS,

FACULTY OF MEDICINE, MEMORIAL UNIVERSITY OF NEWFOUNDLAND, ST. JOHN'S, NEWFOUNDLAND, CANADA

E. McCLOY, AND J. BLAKE

WESTMINSTER HOSPITAL AND MEDICAL SCHOOL, LONDON

SUMMARY

A study of patients with malignant melanoma, in various stages of the disease, by means of regular repeated examination of sera for the presence of tumour antibodies is presented.

These antibodies were mostly seen in patients with early or localized tumours and were not related to the total mass or volume of the tumour present. Sequential testing in individual patients showed not only the disappearance of antibodies as the disease progressed from localized to disseminated, but also that the disappearance preceded the appearance of disseminated tumour by several months. It is, therefore, suggested that circulating tumour antibodies are important in preventing or delaying blood-borne metastases.

THE existence of some form of host immune response to human malignant melanoma is now beyond reasonable doubt and has been established by means of several types of investigation, indicating the presence of both humoral antibodies and cellular immunity (Lewis, 1967; Morton, Malmgren, Homes, and Ketcham, 1968; Lewis, Ikonopisov, Nairn, Phillips, Hamilton-Fairley, Bodenham, and Alexander, 1969; Muna, Marcus, and Smart, 1969; Zeigler, Lewis, Luyombya, and Kiryabwire, 1969; Fass, Herberman, Zeigler, and Kiryabwire, 1970; Currie, Lejeune, and Hamilton-Fairley, 1971; Hellstrom, Hellstrom, Sjogren, and Warner, 1971; Nagel, Piessens, Stilmant, and Lejeune, 1971). These investigations were originally stimulated by clinical observations on the natural history of malignant melanoma, exemplified by such phenomena as the variable natural history (Bodenham, 1968; Lewis and Kiryabwire, 1968), spontaneous regression (Smithers, 1964; Everson and Cole, 1966), the apparent presentation of tumours in regional lymph-nodes (Das Gupta, Bowden, and Berg, 1963), and the appearance of metastases many years after removal of the primary tumour (Eve, 1903; Allen and Spitz, 1953; Pack and Miller, 1961). The more sophisticated methods of detecting immune responses in patients with variable types of tumour have now made it possible for more detailed examination of the original clinical factors which first stimulated these studies. It is the purpose of this paper to present data illustrating relationships between circulating humoral antibodies and particular aspects of the natural history of malignant melanoma, namely, the length of time of the phase of localization and the possible influence on dissemination.

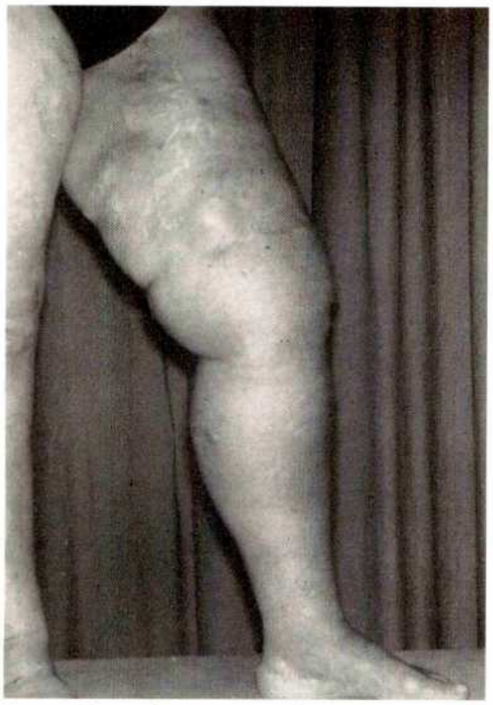

FIG. 1.—*Case* 1. Large amounts of subcutaneous melanoma deposits confined to one leg with no extension beyond the groin. (Antibody studies were positive at this time.)

MATERIALS AND METHODS

All the patients with malignant melanoma attending the Westminster Hospital are examined regularly at the follow-up clinic, where 10 ml. of venous blood are taken. The serum is then coded and stored in vapour-phase liquid nitrogen. Tumours removed by operation from any of these patients are prepared in cell suspension by a method which has previously been described (Pulvertaft, 1965; Lewis, 1967) and stored with dimethyl sulphoxide (DMSO) in liquid nitrogen. In addition, cytological smears are made from the tumour cells on glass slides and snap-frozen in liquid nitrogen and isopentane (Nairn, 1969; Phillips and Lewis, 1970). These are stored in plastic bags in the vapour phase of liquid nitrogen (− 136° C.).

This study so far comprises over 70 patients who have been subjected to regular follow-up, and their blood samples have been tested on each visit by means of immunofluorescence (Lewis and others, 1969; Phillips and Lewis, 1970) against their own stored tumour cells, fresh tumour cells or smears, and on some occasions by means of complement-dependent cytotoxicity (Lewis, 1967; Lewis and others, 1969).

RESULTS

The investigations carried out have continued to support previous work in this area indicating that in the majority of cases the early or localized melanomas have positive antibodies in their sera but that the disseminated cases showed no antibodies detectable by any of the test systems used (Lewis and others, 1969). It has now been possible by means of these sequential testings to show in individual patients the progression from localized to disseminating disease accompanied by the loss of antibodies. Of particular note during this study were several examples showing a clear relationship between the degree of localization of the tumour and the presence of antibodies, independent of the mass of tumour, with the drop in the antibody titre preceding the appearance of more disseminated tumour sometimes by several months. Some typical cases are presented to illustrate the phenomena.

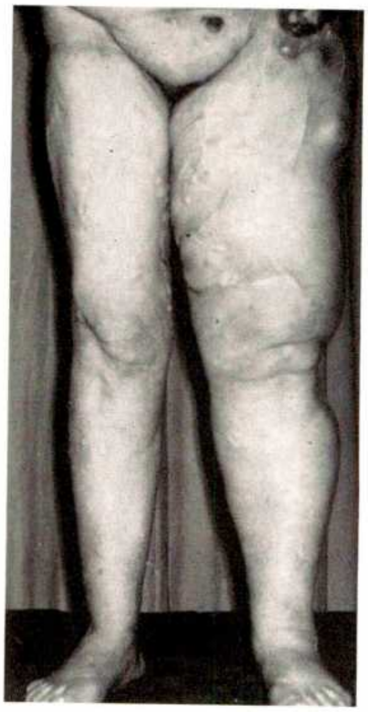

FIG. 2.—*Case* 1. Extension of the tumour, beyond the groin, including early deposits on the anterior abdominal wall. (Antibody studies were negative at this time.)

CASE REPORTS

Case 1.—A 51-year-old woman presented with a primary malignant melanoma of the thigh in 1963, and following excision she remained free of the disease until 1968. She then developed multiple subcutaneous deposits, including deposits in the regional groin lymph-nodes. Numerous attempts at local excision resulted in a gradually increasing mass of tumour, largely replacing most of her leg (*Fig.* 1). The first antibody studies carried out on this patient were in 1969 and showed a positive serum against her own melanoma cells and against fixed melanoma cells of other patients in high titres. Between 1969 and May, 1971, repeated serum samples showed a persistence in the positivity of her serum and there was still no sign of the tumour spreading beyond the groin. Extensive clinical examination revealed no sign of metastases elsewhere. In May, 1971, her serum was shown to be completely negative against autologous and homologous melanoma cells for the first time. In June, 1971, the first evidence of spread beyond the groin, namely to the anterior abdominal wall, was demonstrated (*Fig.* 2). Following this, over a period of 3 months, further metastases appeared at various sites. Throughout this time she remained completely antibody-negative. These results are summarized in *Fig.* 3.

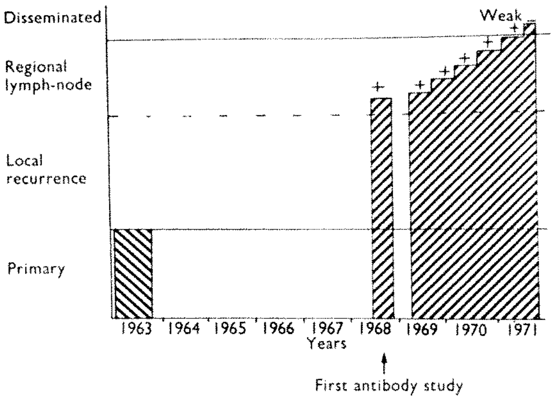

FIG. 3.—*Case* 1. Schematic representation on the slow progression of the natural history of malignant melanoma with a positive (+) antibody titre obtained on several occasions when the tumour remained localized.

Case 2.—A 37-year-old woman presented with a primary malignant melanoma of the left buttock in February, 1967. This was excised, and in July, 1969, further excision of a lump in the left groin was shown to be a lymph-node metastasis. She remained well with no further signs of recurrence of the tumour until December, 1970, when a new lump appeared in the left groin. Serum antibodies were shown to be strongly positive to malignant melanoma cells at this time. The groin nodule was excised in January, 1971, and on routine follow-up 1 month later her serum-antibody levels were found to be unrecordable. Three months following this she developed hepatomegaly and a mass in the right iliac fossa, and pulmonary metastases were seen on a radiograph. The course of the disease is summarized in *Fig.* 4.

Case 3.—A 36-year-old female was first diagnosed as having primary malignant melanoma of the left thigh in 1966. Several local recurrences were treated by excision until January, 1971, when a removal of regional groin lymph-nodes revealed metastatic tumour. At this time serum-antibody studies gave positive results Three months later a routine check of the serum showed no detectable antibodies, and within 3 months dissemination of tumour beyond the limb was noticed, when again no antibodies were detected in the serum (*Fig.* 5).

Case 4.—A 27-year-old male had a small primary malignant melanoma on the left calf. This was excised and was shown histologically to be an invasive malignant melanoma but serum antibodies were persistently negative. On very careful investigation no clinical metastases could be found but examination of the sternal bone-marrow revealed pigmented malignant melanoma cells.

Case 5.—A 20-year-old female presented with a primary malignant melanoma on the back, followed 6 months later by an isolated lymph-node containing tumour cells in the right axilla. This was excised and 3 months later a solitary nodule removed from the breast also revealed metastatic malignant melanoma. Very careful clinical examination revealed no further metastatic disease. This has been reconfirmed 7 months later. During this time serum samples showed no antibody activity.

DISCUSSION

The main findings in this study are that the presence of circulating humoral antibodies is not related to the volume or mass of tumour present, since several cases with massive amounts of tumour localized within the area of the draining lymph-nodes showed persistently positive antibodies, whereas patients with dissemination beyond the regional draining lymph-nodes, however small the deposits were, showed a loss of antibody detection. The next important feature is the apparent drop in antibody detection preceding metastatic disease in several cases. In view of the considerable amount of work reported in the recent literature on the importance of cellular immunity in malignant disease and particularly the impression gained that antibodies appear to be of no value but rather may even be a disadvantage to the patient, it seemed necessary to present the results of this study. It would appear from this investigation and from previously reported results in malignant melanoma from Africa (Lewis and Kiryabwire, 1968; Zeigler and others, 1969), Europe (Nagel and others, 1971), and America (Jehn, Nathanson, Schwartz, and Skinner, 1970; Morton, Eilber, Malmgren, and Wood, 1970) that the presence of

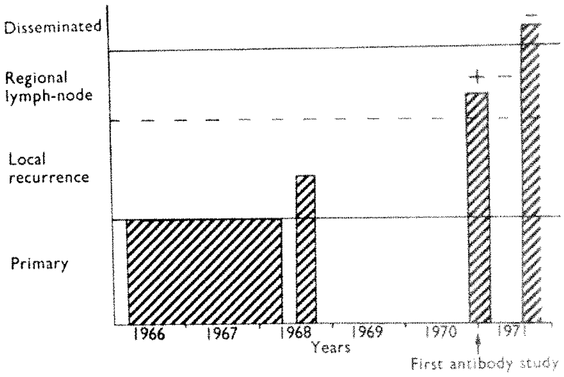

FIG. 4.—*Case* 2. Schematic representation, showing a positive (+) antibody titre changing to a negative (—) one prior to dissemination of the tumour.

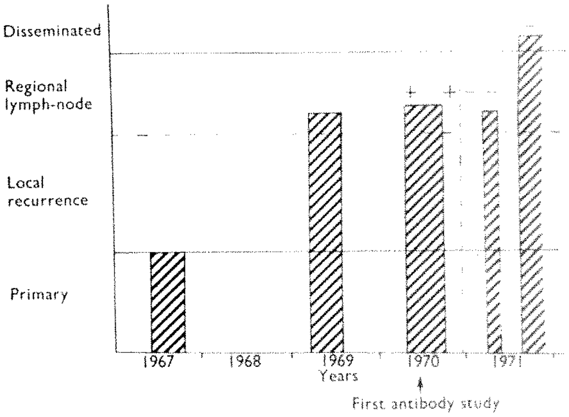

FIG. 5.—*Case* 3. Schematic representation, showing progression of the tumour over a period of years with a long phase of localization and a positive (+) antibody titre, followed by a negative (—) antibody titre and subsequent rapid dissemination of the disease.

humoral circulating antibodies in the course of the natural history of this disease is of considerable significance and has a direct relationship with the process of dissemination. We would like to suggest, on the basis of these results, that the role of circulating humoral antibodies in this disease is important in protecting the blood-stream from blood-borne metastatic tumour. The demonstration of the cytotoxic action of such antibodies (Lewis, 1967) and the close correlation between cytotoxicity and immunofluorescence in previous investigations of the tumour support this theory (Lewis and others, 1969; Ikonopisov, Lewis, Hunter-Craig, Bodenham, Phillips, Cooling, Proctor, Hamilton-Fairley, and Alexander, 1970). The importance of cellular immunity in the early phase of this tumour and its involvement in solid tumour deposits are beyond any reasonable doubt, though in most cases of established cancer the mechanism appears to have failed, but surely the most critical stage in the natural history of this disease, as in all forms of malignancy, is the change from localized to disseminated. It is, after all, the metastasis that is the important process in malignant disease. We would like to emphasize, therefore, the importance of continuing with such studies, particularly the sequential testing of patients' immunity, both humoral and cellular, during and related to the natural history of the disease. Since it was the natural history and the clinical manifestations of this particular tumour which first led to immunological studies it does seem very appropriate at this time that we should return time and time again to such observations and relate our laboratory data to them if we are to understand further the complexities involved in this relationship.

The immediate questions raised, of course, are: if the circulating antibodies are so important in preventing dissemination, why, in certain individuals, do these disappear early in the course of the disease and why, even in patients with long histories of localization, does the mechanism eventually become ineffective?

The suggestion that the antibody levels falling are merely a reflection of the mass in disseminated tumour is to some extent challenged by these results, and in other studies we have indicated the presence of what appears to be a blocking substance in the antibody-negative serum directed against the antibody positive in the same patient (Lewis, Phillips, Cook, and Blake, 1971). The nature of the blocking substance, which appears to be acting at a different site from that described by others in preventing cellular immunity from being effective, is at present under investigation (Hellstrom and Hellstrom, 1970; Bansal and Sjogren, 1971).

DEEP-VEIN THROMBOSIS IN PATIENTS WITH FRACTURE OF THE UPPER PART OF THE FEMUR

A PHLEBOGRAPHIC STUDY

By S. A. SMYRNIS, A. S. KOLIOS, and J. K. AGNANTIS

THIRD SURGICAL UNIT, EVANGELISMOS HOSPITAL, ATHENS

SUMMARY

Deep-vein thrombosis was found by phlebography in 60·3 per cent of 58 patients with fracture of the upper end of the femur. The incidence was higher on the left side. Thrombus was detected in the uninjured leg in many cases, and therefore the need for bilateral investigation is emphasized.

The convenience of the radioactive fibrinogen test and ultrasound technique for detecting thrombosis in patients has been widely accepted, but we also consider that phlebography, using a portable radiograph machine, is a valuable and easy method for the detection of deep-vein thrombosis in seriously ill patients.

THE most common cause of death in patients with a fractured femur is pulmonary embolism (Sevitt and Gallagher, 1959). A large number of these patients develop thrombosis in the deep veins of the leg (Hamilton, Crawford, Gardiner, and Wiley, 1970; Field, Nicolaides, Kakkar, and Crellin, 1972) which is inadequately diagnosed by clinical methods (McLachlin and Paterson, 1951; Coon and Coller, 1959). Many patients show no signs of thrombosis and yet die from a fatal embolus (Sevitt, 1962).

It is well known that the early treatment of thrombosis gives the best immediate results and helps to prevent permanent damage to the valves and the post-thrombotic syndrome (Kakkar, 1969). It is therefore obvious that there is a need for methods other than clinical to be used in the detection of this condition.

Recent studies have clearly demonstrated that it is possible to detect thrombi using radioactive-labelled fibrinogen (Hobbs and Davies, 1960; Atkins and Hawkins, 1965, 1968; Flanc, Kakkar, and Clarke, 1968; Negus, Pinto, LeQuesne, Brown, and Chapman, 1968). The ultrasound technique is another new diagnostic method for venous thrombosis (Evans, 1971; McIlroy, 1972), but phlebography has undoubtedly been established because of its high degree of accuracy in detecting the presence and extension of a thrombotic lesion (Kakkar and Flanc, 1968; Negus and others, 1968).

The initial clinical impression was that the incidence of thrombo-embolic episodes in patients with a fracture of the femur admitted to the Third Surgical Unit of the Evangelismos Hospital, Athens, was small. However, many of these injured patients developed the late sequelae of deep-vein thrombosis: swelling and pain of the leg, varicose veins, and other changes. Because these findings indicated inadequate diagnosis and treatment of thrombosis at the time of the fracture we considered that it would be interesting to investigate this subject using phlebography.

MATERIAL AND METHODS

The patients studied were admitted to the hospital between September, 1970, and September, 1971, with a fracture of the upper part of the femur. All had been fully ambulant before the injury and were operated on within 6 days of admission. Fifty-eight patients were included in this investigation. Patients with other serious injuries or neoplastic disease, as well as those with clinical evidence of a previous thrombosis, were excluded from the study.

There were 25 males and 33 females. The mean age of the males was 58 years and for the females 69·5 years (youngest 19, oldest 91).

Thirty-six patients had a fracture on the right side and the remaining 32 on the left side. In 24 cases the fracture was subcapital and in 34 pertrochanteric.

All except 3 patients were managed surgically. Two of the fractures which were treated conservatively were in patients who were admitted to hospital 3 weeks after injury, and 1 patient was not operated on because of severe cardiopulmonary failure.

The phlebographic study was carried out within 10 days of admission but never more than 6 days after the operation. Although no special criterion was used to determine the timing of this radiography, in the event of a venous thrombosis being suspected clinically or signs of pulmonary embolism being present a phlebogram was done. It must be noted that the patients were examined only during regular ward rounds, unless some urgent complaint arose. Otherwise no clinical examination was done for the detection of a possible thrombosis in the legs.

Phlebography.—During the present investigation phlebography was done using a portable radiograph machine with the patient staying in his bed. The patient was placed in the supine position and the head of the bed was elevated 20 cm. so that the patient's legs were placed in a position which permitted a better mixing of the contrast medium with his blood.

A needle was inserted into a vein in the dorsum of each foot. Sometimes percutaneous puncture was difficult, but a cut-down was only necessary in 6 cases. A single tourniquet was placed just above each ankle to exclude the superficial blood-flow. The needle was connected to a set of rubber tubing and a syringe containing 50 ml. of 60 per cent Urografin. Then 20 ml. of the contrast medium were slowly injected simultaneously bilaterally, at the completion of which the first radiograph was taken on a 30 × 40-cm. film placed behind the lower part of the limbs.

Following this, a radiograph cassette was placed behind the thigh and lower pelvic regions. The bed was lowered to the horizontal position and the tourniquet was removed from the ankle and placed just below the knee. Immediately after the injection of about 30 ml. of contrast medium the second exposure was taken, resulting in visualization of the popliteal and femoral veins. This technique frequently filled the iliac veins but the demonstration was not always of diagnostic value.

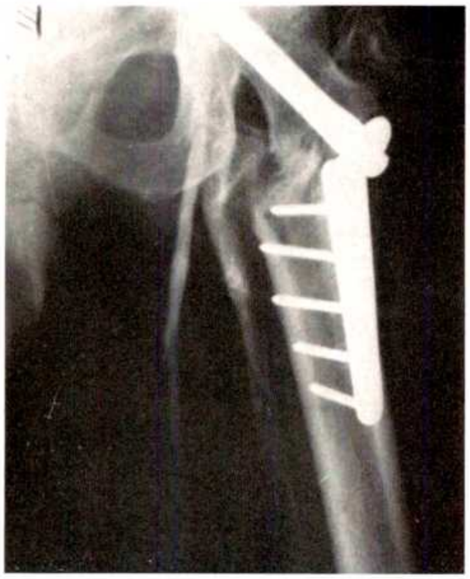

FIG. 1.—Phlebogram showing thrombosis in the veins of the fractured limb.

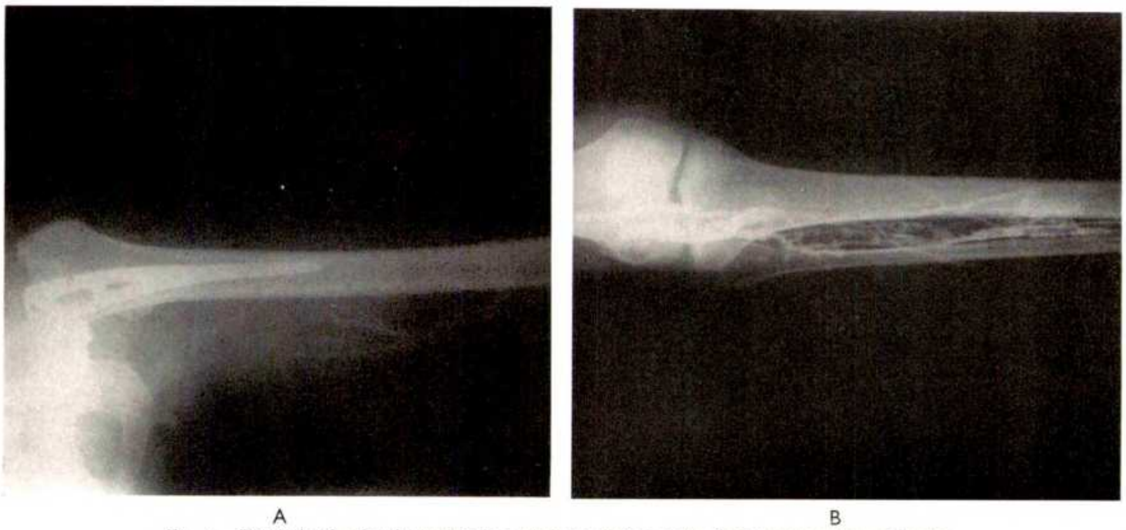

A B

FIG. 2.—The lesion is often located in more than one region of the deep venous system of the leg.

This was the standard method used, but in some cases the contrast medium was injected, when it was possible, into a vein just below the knee for better visualization of the femoral and iliac veins. In 12 patients the new technique described by Nicolaides, Kakkar, and Renney (1970) was used for detecting thrombus in the soleal sinuses. Cotton and Clark (1965) have shown that the vast network of these sites is quite impossible to fill completely by the common phlebographic methods.

The amount of contrast medium usually required was 50 ml. for each side, but more was used if repeated injections were given when necessary for re-examining doubtful areas in the films. No complications have been experienced using this technique of phlebography.

RESULTS

Table I shows that deep-vein thrombosis was detected phlebographically in 35 (60·3 per cent) of the 58 patients studied. In 20 patients thrombosis was found in the veins of the fractured limb (*Fig.* 1), in 9 cases on the opposite side, and in 6 patients the thrombotic process was detected bilaterally.

The sites of the thrombi are shown in *Table II*. It is clear that in almost half of the cases the lesion was located in more than one region of the deep venous system of the leg (*Fig.* 2). In 3 out of the 10 patients in whom we used the method described by Nicolaides and others (1970) a defect was outlined within the soleal sinuses, but in all 10 there was additional thrombosis elsewhere.

Table III shows the higher incidence of thrombus found on the left side, although the overall number of patients with a fracture of the left side was lower than those with a right-sided injury. Thirty-six patients had a fracture of the right femur and of these, 7 developed thrombosis in the unfractured left limb (*Fig.* 3). Only 2 out of the 22 patients with a fracture of the left side had thrombosis in the veins of the opposite limb. One of the 3 patients who did not have an operation developed femoral thrombosis. The phlebogram (*Fig.* 4) of this patient shows numerous collateral veins, indicating that the thrombotic process had existed for some weeks.

Pulmonary embolism was confirmed by a radiograph of the chest in 6 patients. Two of these presented with symptoms suggesting this condition before deep-vein thrombosis was diagnosed. Furthermore, phlebography was done in 4 other patients because of clinical signs of thrombosis, but in 1 of these cases no thrombus was found.

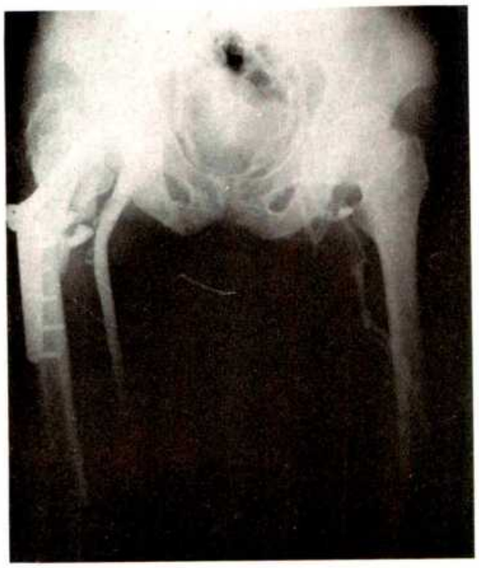

FIG. 3.—A patient who had a fracture of the right femur and developed thrombosis in the unfractured left limb.

Table I.—INCIDENCE OF DEEP-VEIN THROMBOSIS COMPARED WITH AGE IN 58 PATIENTS

AGE-GROUP	NO. OF PATIENTS	INCIDENCE OF THROMBOSIS (60·3 per cent)			
		Fractured Leg	Un-fractured Leg	Both Legs	Total No. of Cases
10–19	4	—	—	—	—
20–29	2	1	—	—	1
30–39	4	2	1	—	3
40–49	1	—	1	—	1
50–59	7	1	2	1	4

70–79	16	7	1	3	11
80–89	11	4	—	2	6
90 +	1	—	—	—	—
Total	58	20	9	6	35

Two patients died in this series. One of these died from a massive haematemesis and the other, who had a multiple thrombosis, from renal failure. In both cases no post-mortem examination was done.

DISCUSSION

On the basis of clinical criteria deep-vein thrombosis seemed to be rare in patients with a fractured femur. However, using phlebography a positive diagnosis of thrombosis was made in 35 (60·3 per cent) of the 58 patients investigated. These results, together with those of Hamilton and others (1970) and Field and others (1972), clearly show the high incidence of this condition in such cases.

In the series of Hamilton and others (1970) in which thrombosis was detected phlebographically in 75 per cent of patients with fractured limbs, 26 per cent of the thromboses were in the uninjured limb. Field and others (1972), using a radioactive fibrinogen technique, found an incidence of thrombosis of 54 per cent in the fractured limb and of 34 per cent in the opposite side. These findings show that the presence of thrombi in the veins of the uninjured leg must never be overlooked and indicate the importance of bilateral investigation. The present study confirms this. In 20 of our cases the thrombosis was located in the injured leg and in 9 cases the thrombosis was found in the uninjured leg.

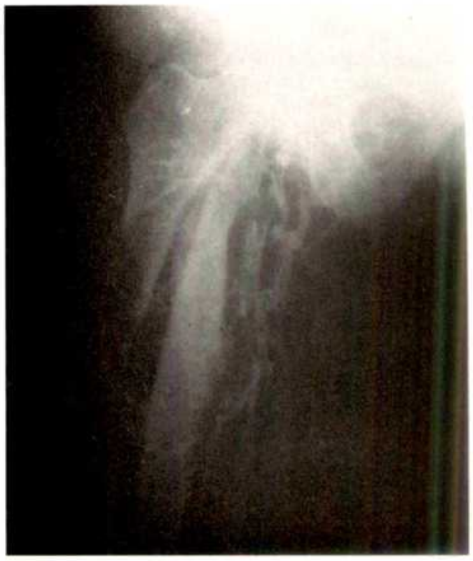

FIG. 4.—Phlebogram showing numerous collateral veins which indicate that the thrombotic process had existed for some weeks.

Total	41

Table III.—SIDE OF DEEP-VEIN THROMBOSIS COMPARED WITH SIDE OF FRACTURE

SIDE OF FRACTURE	NO. OF PATIENTS	SIDE OF THROMBOSIS		
		Right	Left	Both Legs
Right	36	11	7	4
Left	22	2	9	2
Total	58	13	16	6

Analysis of our data showed that thrombosis developed at a particularly high rate in the left leg. More than half of the 35 patients with thrombosis had the lesion in the left side, though only 37 per cent of these had a fracture of this side. Probably the higher incidence of thrombosis in the left leg is due to the left common iliac vein being compressed at a point where it is crossed by the right common iliac artery (Cockett, 1967).

Although over half of the cases of deep-vein thrombosis could be accurately diagnosed by taking a combination of two or more of the clinical signs—pain, tenderness, and oedema (Hall and Clark, 1971)—many are overlooked in routine practice so that treatment is often late or not given at all. Kakkar (1969) emphasized the fact that early detection of venous thrombosis of the leg is of the utmost importance if the treatment of this condition is to be improved.

Using the radioactive fibrinogen technique it is possible to detect thrombi early and with greater certainty than by the clinical method alone (Atkins and Hawkins, 1965, 1968; Flanc and others, 1968; Negus and others, 1968; Field and others, 1972). The ultrasound technique is also a promising diagnostic method and there are no contra-indications even in seriously ill patients with venous thrombosis (Evans, 1971; McIlroy, 1972). However, the value of phlebography is without doubt. This method is used to correlate the accuracy of ultrasonic findings and to check all the positive results obtained with the radio-isotope technique.

Many phlebographic methods have been described. We have tried to make the procedure as simple as possible for the convenience of patients with fractures. We feel that phlebograms taken with a portable radiograph machine give sufficient information to make an accurate diagnosis of deep-vein thrombosis.

Acknowledgements.—We wish to thank the Director of the Radiology Department, Associate Professor L. Stergiou, and also Dr. G. Vrachlio and the technicians of this department for the invaluable help in this investigation.

AN OPERATION FOR LARGE SCROTAL HYDROCELE

BY J. L. WILKINSON*
DEPARTMENT OF SURGERY, MANCHESTER ROYAL INFIRMARY

SUMMARY

A relatively minor operation of partial eversion in which some residual sac is left in situ has been performed in over 500 cases of large tropical hydrocele. The method is applicable to smaller hydroceles, and also provides a method of treating recurrent testicular torsion.

THE desirability of relatively bloodless surgery in the radical cure of hydrocele was recognized in the operations described by Andrews (1907), Solomon (1955), Özdilek (1957), and Lord (1964), and the method of the last author has been widely accepted with excellent results, as reported by Efron and Sharkey (1967) and Doyle and Rush (1968).

In many tropical countries scrotal hydrocele is of more frequent occurrence than in temperate climates. Such hydroceles are often very large, sometimes bilaterally so, as noted by Burkitt (1951), Burkitt and Williams (1964), and Davey (1968).

A reappraisal of surgical technique for large scrotal hydrocele was carried out, and later a historical review of the principles involved. During the yea 1955 to 1971, 889 scrotal hydroceles were operat on at the Nixon Memorial Hospital, Sierra Leon West Africa, mostly by the author. Inherent con plications in many patients included gonococc epididymo-orchitis, filarial lymphangitis, schist somal funiculitis, or previous unskilled tappin Occasionally there were gross abnormalities such filarial elephantiasis, greatly thickened and ev calcified tunica vaginalis, or a sac filled with sem solid debris associated with testicular degeneratio The majority of hydroceles were similar to tho seen in Europe, though larger, and for these t following operation was designed.

OPERATIVE TECHNIQUE

In a large hydrocele the testicle is situated on t upper part of the posteromedial aspect of the sa The operation consists of preparing a pouch betwe the parietal layer of the tunica vaginalis and t internal spermatic fascia, into which the testis implanted. In a big hydrocele much of the origin sac which is emptied is left in situ.

Following induction of anaesthesia, the skin havi been cleansed with chlorhexidine, the scrotum is he so that the skin is tense. For a unilateral hydroce a 3–4-cm. oblique anterolateral incision is made in the line of and between the skin vessels of the upper scrotum (*Fig.* 1). For a bilateral case a single transverse incision is placed at right angles to the median skin raphe, about 4 cm. below the penoscrotal junction. A low-power cutting diathermy with a fine needle, preferably angled, is used to divide the dartos and the layer made up of external spermatic fascia, cremasteric fascia, and internal spermatic fascia. Any tiny bleeding points are sealed off. When the tunica vaginalis is exposed it is separated digitally from the internal spermatic fascia to form a pouch below the incision large enough to accommodate the testis (*Fig.* 2). This is a natural plane of cleavage and there should be no bleeding at all. The two layers of the tunica, though individually distinguishable, are closely adherent to one another and are picked up together. Through a small incision the contained fluid is aspirated, or a trocar and cannula may be used. In a small hydrocele the testis may then be extruded through the incision, but in a large sac Babcock's forceps are used to deliver it to the surface. When the testicle is drawn outwards through the skin the naturally mobile tunica becomes everted until the edges of the sac incision come to lie alongside the spermatic cord. (With a small hydrocele the effect is to turn the sac inside out almost entirely, ensheathing the cord.) The cut edges of the sac opening are then sutured together on the upper aspect of the cord, catching in the coverings of the cord (*Fig.* 3). This has the dual effect of narrowing the sac incision sufficiently to prevent prolapse of the testis into the original sac, yet by leaving the latter in continuity with the extruded serosal tunica a natural conduit is established.

---

* Present address: Department of Surgery, University Hospital of Wales, Cardiff CF4 4XN.

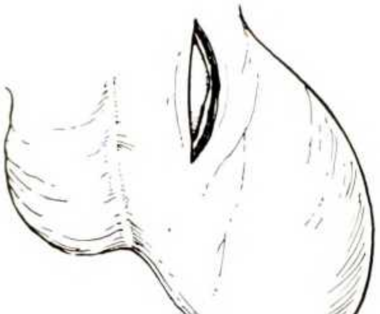

FIG. 1.—The skin incision in the upper scrotum.

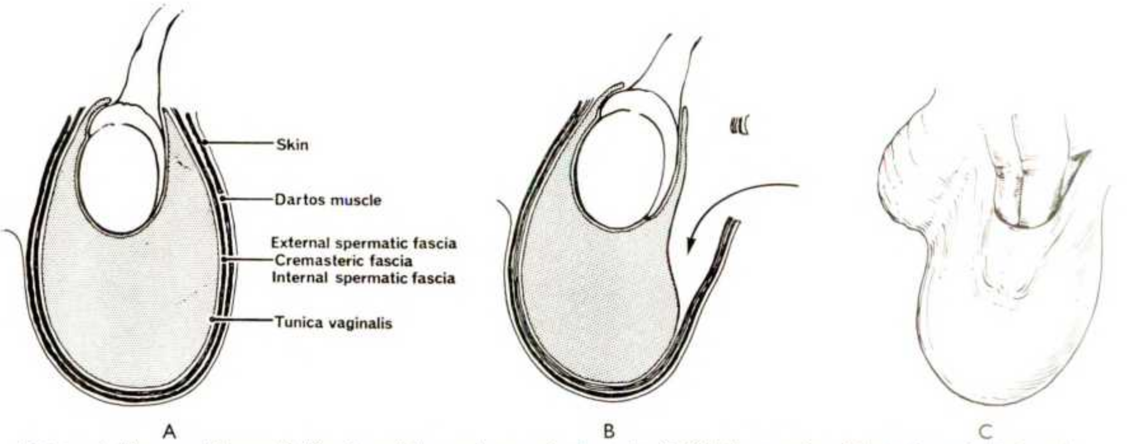

FIG. 2.—A, The normal layers. B, The plane of the pouch to receive the testis. C, Digital separation of the tunica vaginalis from the internal spermatic fasia, developing a pouch into which the testis may be transferred.

Lane's forceps are used to hold up the skin, dartos, and fasciae as the testicle is tucked into the prepared pouch. The fasciae and dartos are approximated with interrupted 00 chromic catgut. Initially 16 mm. Michel skin-clips were used for closure, but recently a continuous intradermal 00 Dexon suture has been found more satisfactory in terms of comfort, healing, and postoperative care. The scrotum is gently compressed to expel any air or fluid, the skin is wiped with ether, and nobecutane spray is applied to the wound and ribbon gauze applied. With large hydroceles a scrotal compression bandage is used, but in Europe an appropriate scrotal support over gamgee is all that is required, the patient being discharged from hospital on the following day.

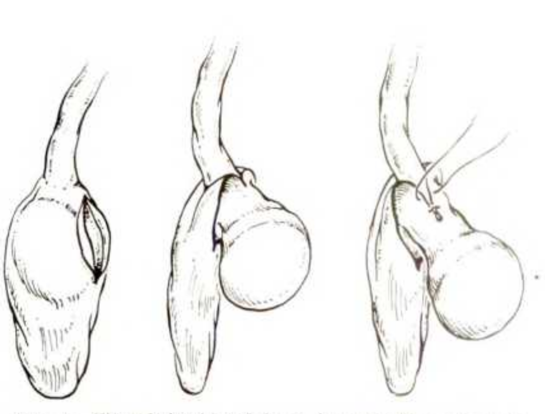

FIG. 3.—The relationship of the tunica vaginalis to the testis and spermatic cord as the latter are withdrawn through an incision in the sac.

RESULTS

The operation described here has been carried out in over 500 cases since 1959, and no redevelopment of a hydrocele has been reported. Complete routine follow-up is not feasible where patients often travel over 100 miles to a surgical centre, as in many tropical areas.

The everted epithelium of the tunica vaginalis quickly loses its secretory nature, and becomes, together with the testis, adherent to the internal spermatic fascia. In large hydroceles the fluid which for a time continues to be formed in the residual sac passes alongside the ensheathed cord to be absorbed by lymphatics. When the sac walls are no longer separated by fluid, adherence and atrophy take place. Subsequent to operation on truly massive hydroceles there may be some transient oedema of the lax scrotal tissues. If there is redundant scrotal skin it is best left for 3 months, by which time some contraction has taken place and it is rarely necessary to remove it.

DISCUSSION

Operative procedures for hydrocele have been a source of debate for hundreds of years. Recently an extrusion operation without sac excision or plication was described by Solomon (1955) and McGowan and Howley (1969), suturing the sac edge to the epididymis, with satisfactory results, and Andrews's (1907) 'bottle operation' has been well tried since the first decade of this century. Jaboulay's eversion operation is frequently referred to in standard texts, but the source of the original account was surprisingly difficult to ascertain (Bèrard, 1895; Jaboulay, 1902). The technique was also recorded by Vautrin (1893, 1913) and Barral (1896). Doyen (1895) performed an eversion operation through a 2·5-cm. incision which in some respects is comparable to that described here. The basic concept of these operations that sac eversion *per se* by exposing the secretory layer of the tunica to the parietes inhibits fluid formation has withstood the test of over 80 years of surgical practice. The operation described here indicates that even in large hydroceles a form of partial eversion is an adequate and effective procedure.

This method of eversion has been used by the author as a simple means of fixing the congenitally mobile testis in which the tunica commonly sheathes the cord to some extent and the gubernaculum may be absent. Displaced operatively into a pouch under the spermatic fascia, the testicle quickly becomes adherent and unable to rotate. Symptoms such as deep iliac fossa discomfort which may have been present for months rapidly subside after operation.

Dexamethasone sodium phosphate/MSD

20 mg/ml (new strength)

In severe shock, treatment with Injection 'Decadron' Shock-Pak is an adjunct to, and not a substitute for, specific or supportive measures that the patient may require, e.g. restoration of circulating blood volume, correction of fluid and electrolyte balance, oxygen, surgical measures, and antibiotics.

Supplied in 5 ml ampoules containing per ml, dexamethasone sodium phosphate equivalent to 20 mg dexamethasone. Detailed information is available to physicians on request. ® denotes registered trademark.

COMPARISON OF SINGLE-LAYER INVERTING, TWO-LAYER INVERTING, AND EVERTING ANASTOMOSES IN THE RABBIT COLON

By T. T. IRVIN and J. P. EDWARDS

UNIVERSITY DEPARTMENT OF SURGERY, LEEDS GENERAL INFIRMARY

SUMMARY

Inverting methods of suture should be used in colonic anastomosis. A two-layer inverting anastomosis is usually recommended but it has been suggested that a single-layer technique is preferable and safer.

Single-layer inverting, two-layer inverting, and everting anastomoses were compared in the unprepared rabbit colon. Everting anastomoses gave inferior results by comparison with both inverting methods with respect to tensile strength, anastomotic leakage, and histological evidence of healing, but no difference was found between the single-layer and two-layer methods using these criteria and measurement of colonic collagen.

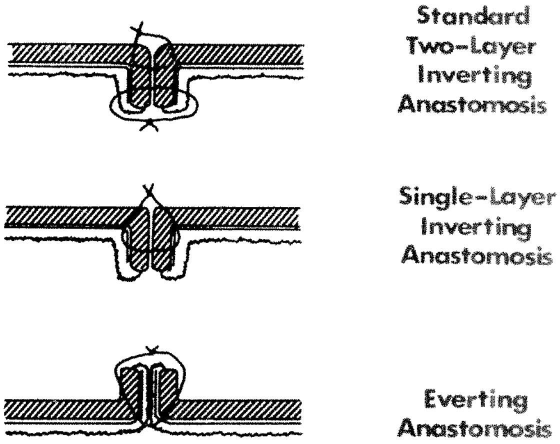
It was concluded that single-layer inverting methods of anastomosis had no particular advantages over the standard two-layer inverting method.

THERE can be little doubt that inverting methods of suture should be used in anastomosis of the colon (Goligher, Morris, McAdam, de Dombal, and Johnston, 1970) and the method of suture usually recommended is the two-layer inverting technique (Goligher, 1967; Muir, 1969; Turnbull and Kyle, 1969). Single-layer inverting techniques have been used less frequently in the colon, although Halsted (1887) suggested that this was the method of choice, and Gambee, Garnjobst, and Hardwick (1956) were favourably impressed with this method in clinical practice. Experimental evidence implies that the single-layer method is safer than the two-layer method in small-bowel anastomosis (Letwin and Williams, 1967), but there is little objective information regarding the relative merits of the two methods in anastomosis of the colon.

In the present study single-layer inverting, standard two-layer inverting, and everting anastomoses have been compared in the rabbit colon.

MATERIALS AND METHODS

Ninety-three male and female rabbits were anaesthetized with Nembutal by intravenous injection in a dose of 30 mg. per kg. of body-weight. Intestinal preparation was not used except for restriction of the diet to liquids only for 48 hours prior to surgery. The abdomen was opened through a midline incision and a 2-cm. segment of the right colon was resected. The resected specimen was retained for estimation of collagen content and the method of anastomosis—single-layer inverting, two-layer inverting, or everting—was allocated randomly in each case. The techniques used for the different types of anastomosis are shown in *Fig.* 1. The standard two-layer anastomosis comprised a continuous 0000 polyglycolic acid suture (Davis & Geck) incorporating all the coats of the bowel wall for the inner layer and an outer layer of interrupted 0000 silk Lembert sutures. The single-layer inverting anastomosis was made with interrupted 0000 silk vertical sutures through all the layers except the mucosa and the same suture was used through all the coats of the bowel wall for the single-layer everting anastomosis. Diet was restricted to fluids only for 72 hours after surgery and the animals were sacrificed in a random fashion at 0, 7, 14, 21, and 28 days after operation.



Standard Two-Layer Inverting Anastomosis
Single-Layer Inverting Anastomosis
Everting Anastomosis

FIG. 1.—Single-layer inverting, two-layer inverting, and everting methods of anastomosis.

At autopsy the presence of obstruction, peri-anastomotic sepsis, and anastomotic leakage was noted and a 12-cm. length of intestine including the anastomosis was resected. A barium-enema study was performed on most of the specimens and the degree of anastomotic stenosis was assessed on radiological examination by the method of McAdams, Meikle, and Taylor (1970). This method of assessment is shown in *Fig.* 2. The diameters of the anastomosis (a) and the bowel at two points 2 cm. proximal and distal to the anastomosis (b and c) were measured and the percentage reduction in the lumen or 'index of stenosis' was obtained from the calculation $100[1 - \{2a/(b + c)\}]$. The bursting pressure of each specimen was measured on a mercury manometer after distension of the specimen with air at a constant rate. Paraffin sections of the anastomosis were stained with haematoxylin and eosin and van Geison's stain for histological examination.

Half of each anastomosis was dried to constant weight using acetone and desiccation and the dried tissue was hydrolysed in a hot-air oven at 120° C. for 16 hours with 6 *N* hydrochloric acid. Collagen was estimated by a modification of the method of Neuman and Logan (1950) after neutralization of the hydrolysate with 6 *N* sodium hydroxide. Prior separation of hydroxyproline from the tissue hydrolysate was unnecessary since preliminary studies based on spectral characteristics of the chromogen obtained using the modified method revealed that the hydrolysate did not contain significant quantities of interfering substances. These observations are in accordance with previously published recommendations (LeRoy, 1967).

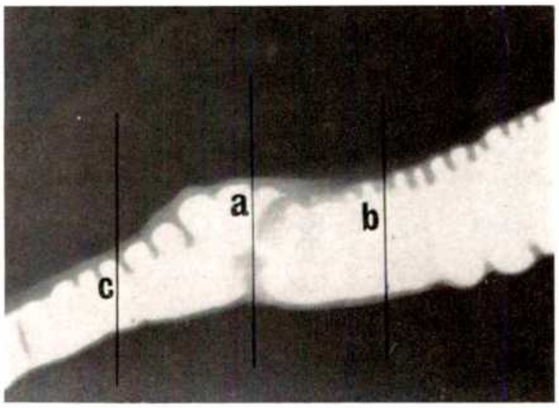


FIG. 2.—Barium-enema study of a colonic anastomosis in the rabbit. The percentage reduction in the lumen or the 'index of stenosis' is derived from the diameters of the anastomosis (a) and the bowel at two points 2 cm. proximal and distal to the anastomosis (b and c), using the calculation 100[1 – {2a/(b + c)}].

Table I.—THE INCIDENCE OF COMPLICATIONS ASSOCIATED WITH THE THREE METHODS OF ANASTOMOSIS

COMPLICATION	SINGLE-LAYER INVERTING ANASTOMOSIS		TWO-LAYER INVERTING ANASTOMOSIS		EVERTING ANASTOMOSIS	
	No.	Per cent	No.	Per cent	No.	Per cent
Intestinal obstruction	3	12	7	27	0	0
Leaking anastomosis	1	4	1	4	14	54
Intraperitoneal abscess	1	4	1	4	4	15

RESULTS

Mortality and Incidence of Anastomotic Complications.—Each method of anastomosis was tested in 31 animals, but 5 animals in each group were sacrificed immediately and anastomotic healing was studied in the remaining 26 rabbits in each group. Three deaths in the single-layer inverting group and 7 deaths in the two-layer inverting group resulted from intestinal obstruction and 2 deaths occurred in the everting group as a result of anastomotic dehiscence. Because of these deaths the numbers of animals available for sacrifice on the seventh, fourteenth, twenty-first, and twenty-eighth postoperative days differed slightly in the three groups. Thus, in the single-layer inverting group, 11 animals were sacrificed on the seventh day, 7 on the fourteenth day, 3 on the twenty-first day, and 2 on the twenty-eighth day. The corresponding numbers for the two-layer inverting group on these days were 11, 6, 2, and 0, and for the everting group, 10, 9, 3, and 2.

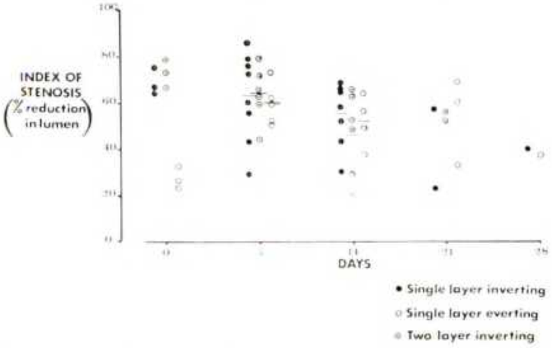

FIG. 3.—The 'index of stenosis' or percentage reduction in the bowel lumen measured in 21 single-layer inverting, 17 two-layer inverting, and 16 everting anastomoses.

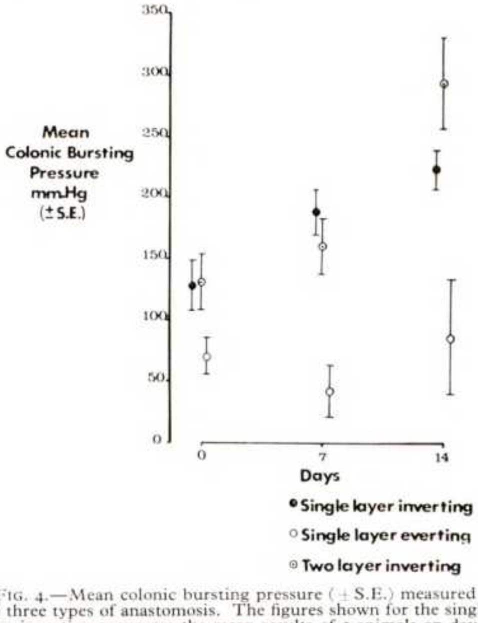

FIG. 4.—Mean colonic bursting pressure (± S.E.) measured in the three types of anastomosis. The figures shown for the single-layer inverting group are the mean results of 5 animals on day 0, 11 animals on day 7, and 7 animals on day 14, and the corresponding numbers of animals in the two-layer inverting group on these days are 5, 11, and 6, and for the everting group, 5, 10, and 9.

The incidence of complications associated with the three methods of anastomosis is shown in *Table I*. The complications comprised obstruction resulting in the death of the animal, anastomotic dehiscence, and perianastomotic abscesses unassociated with anastomotic leakage at the time of autopsy. The total incidence of complications associated with single-layer inverting, two-layer inverting, and everting anastomoses was 15, 35, and 69 per cent respectively. The complication rate in single-layer and two-layer inverting anastomoses was not significantly different but there was a significant difference between single-layer inverting and everting anastomoses ($\chi^2 = 7{\cdot}348$,

$P < 0\cdot01$). The difference between two-layer inverting and everting anastomoses was not quite statistically significant, but intestinal obstruction accounted for most of the complications arising with the two-layer method and it is doubtful if any significance should be attached to this complication since inverting anastomoses in the rabbit undoubtedly produce a degree of narrowing of the bowel lumen which has little resemblance to the situation in the human colon. There is no doubt, however, that the incidence of anastomotic dehiscence and intraperitoneal abscess was significantly higher after everting suture compared with either of the two methods of inverting suture ($\chi^2 = 12\cdot800$, $P < 0\cdot001$).

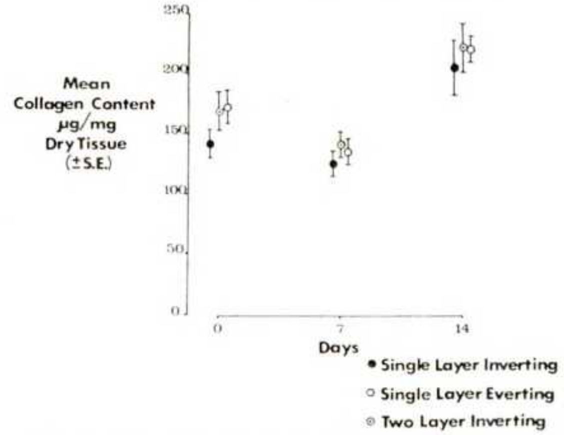

FIG. 5.—Mean collagen content (± S.E.) of the three types of anastomosis. The figures for the single-layer inverting group are the mean results of 10 animals on day 7 and 7 animals on day 14 and the corresponding numbers of animals in the two-layer group on these days are 11 and 6, and in the everting group, 10 and 9. The results in each group obtained on day 0 are measurements of normal colon resected at operation in the animals which were sacrificed subsequently on the seventh day.

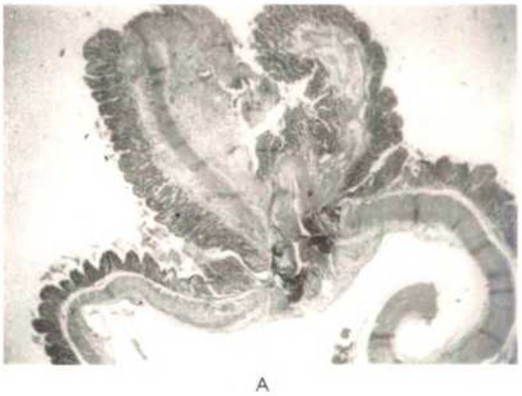
Anastomotic Stenosis.—*Fig.* 3 shows the degree of stenosis found on radiological assessment of 21 single-layer inverting anastomoses, 17 two-layer inverting anastomoses, and 16 everting anastomoses. Measurements made on completion of the anastomosis showed that the everting suture produced less narrowing of the bowel than the two methods of inversion but, surprisingly, this difference was not apparent on subsequent assessment and the results at 7, 14, 21, and 28 days showed no difference between the three types of anastomosis.

Bursting Pressure.—*Fig.* 4 shows the mean colonic bursting pressure for the animals in the three groups sacrificed at 0, 7, and 14 days. The everting anastomosis was significantly weaker than both types of inverting anastomosis on the day of surgery ($P < 0\cdot05$) and the tensile strength of the everting anastomosis had actually diminished by 7 days after operation, whereas the bursting pressure had increased by this time in both types of inverting anastomosis and the latter were significantly stronger than everting anastomoses at 7 days ($P < 0\cdot001$) and 14 days ($P < 0\cdot01$). Rupture of the intestine on testing occurred invariably through normal bowel adjacent to the anastomosis at 14 days after both types of inverting suture, but there was no difference between single-layer and two-layer inverting anastomoses with respect to tensile strength.



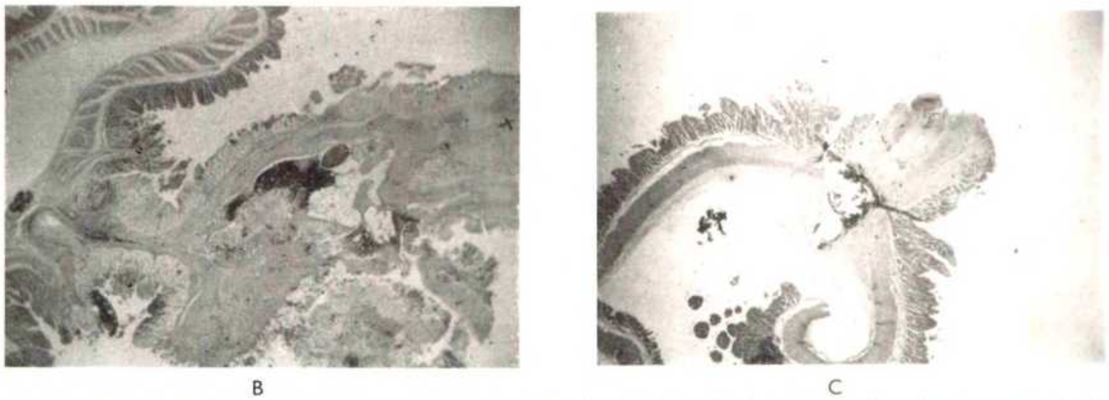


FIG. 6.—The variable degree of necrosis observed in the inverted cuff of tissue at 7 days after the two types of inverting anastomosis. In (A) most of the inturned tissue has survived in a single-layer inverting anastomosis but significant necrosis is shown in the single-layer anastomosis in (B), and (C) shows a two-layer anastomosis in which most of the tissue has sloughed. H. and E. (× 2·7.)

Collagen.—*Fig.* 5 shows the collagen content of the anastomoses in the three groups of animals sacrificed at 7 and 14 days after operation and the results are compared with the collagen content of the normal colon obtained at operation in the animals which were killed subsequently at 7 days. The mean collagen content of the three types of anastomosis at

7 days after operation was slightly lower than the control value in normal colon, but by 14 days the collagen content had increased beyond the values obtained in normal colon. However, there was no difference between the three types of anastomosis with respect to collagen content at 7 or 14 days.

Table II.—HISTOLOGICAL FEATURES OF THE THREE TYPES OF ANASTOMOSIS ASSESSED AT 7, 14, 21, AND 28 DAYS AFTER OPERATION WITH RESPECT TO COLLAGEN AND MUCOSAL UNION AND, IN THE CASE OF THE INVERTING ANASTOMOSES, THE PRESENCE OR ABSENCE OF SIGNIFICANT NECROSIS IN THE INVERTED CUFF OF TISSUE

HISTOLOGICAL FEATURE	DAY OF SACRIFICE AND TYPE OF ANASTOMOSIS											
	7 Days			*14 Days*			*21 Days*			*28 Days*		
	1	2	EV	1	2	EV	1	2	EV	1	2	EV
Necrosis of more than 50 per cent of inturned cuff of tissue	7	8	—	4	4	—	2	2	—	1	—	—
Collagen union present	9	8	4	7	6	7	3	2	3	2	—	2
Mucosal union present	0	0	0	2	2	0	1	1	0	2	—	2
Number of animals	11	11	10	7	6	9	3	2	3	2	0	2

1, Single-layer inverting anastomosis. 2, Two-layer inverting anastomosis. EV, Everting anastomosis.

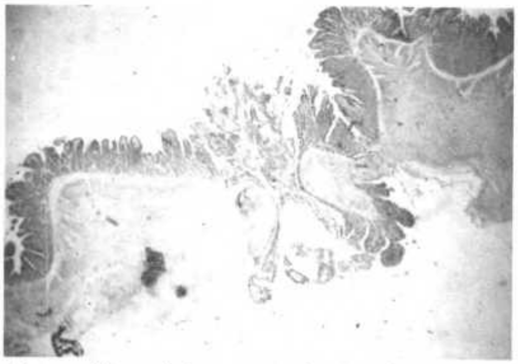

FIG. 7.—The typical appearance of an everting anastomosis at 7 days showing non-union of mucosa and connective tissue. H. and E. (× 2·7.)

Histological Features.—*Table II* shows the histological features of the three types of anastomosis assessed at 7, 14, 21, and 28 days after operation with respect to connective-tissue and mucosal union and, in the case of the inverting anastomoses, the presence or absence of significant necrosis in the inverted cuff of tissue. Some evidence of collagen union across the anastomosis was observed in the majority of single-layer and two-layer inverting anastomoses at 7 days and collagen union was present in all the inverting anastomoses by 14 days after operation. However, mucosal union in inverting anastomoses was less rapid and was not invariably present at 21 days after surgery. Examination of the inturned cuff of tissue in inverting anastomoses showed no difference between the single-layer and two-layer methods and *Fig.* 6 shows that a variable amount of tissue necrosis occurred with both methods of suture.

Connective-tissue and mucosal union in everting anastomoses was much delayed by comparison with the inverting methods of suture. *Fig.* 7 shows the typical appearance of an everting anastomosis at 7 days and there is no definite evidence of connective-tissue or mucosal union.

DISCUSSION

A controlled clinical trial comparing everting and inverting methods of suture in the colon (Goligher and others, 1970) demonstrated that everting anastomoses are prone to disruption and this has been amply confirmed in the present study. The tensile strength and healing of everting anastomoses in the rabbit colon were distinctly inferior to those found in inverting anastomoses and similar observations have been reported in previous experimental studies (Loeb, 1967; Hargreaves and Keddie, 1968; Mellish, Ty, and Keller, 1968; Gill, Fraser, Carter, and Hill, 1969; Trueblood, Nelson, Kohatsu, and Oberhelman, 1969; Abramowitz and Butcher, 1971). It is surprising, perhaps, that the collagen content of everting anastomoses, many of which were leaking or in close proximity to peritoneal sepsis, was no different from that found in inverting anastomoses, but Hawley (1972) found that the total collagen or hydroxyproline content of an anastomosis was not significantly altered in the presence of anastomotic dehiscence since increased lysis of mature collagen was matched by an increased rate of collagen synthesis in such cases.

An inverting method using two layers of sutures is usually recommended for intestinal anastomosis (Goligher, 1967; Muir, 1969; Turnbull and Kyle, 1969), but there is no clinical evidence which would indicate that this technique is any better than an inverting method using one layer of sutures. Indeed, Halsted (1887) suggested that a single layer of inverting sutures was the most acceptable method of intestinal anastomosis, and Gambee and others (1956) advocated this method, based on their clinical experience of 153 single-layer anastomoses. Moreover, Letwin and Williams (1967) showed that the single-layer inverting method gave better results than the two-layer method in the small bowel of the dog and they claimed that the amount of vascular damage and tissue necrosis was less in single-layer anastomoses. Similarly, the studies of Hamilton (1967), Gill and others (1969), and Orr (1969) moved these authors to recommend the single-layer inverting anastomosis as the safest method and the one least likely to interfere with the vascularity of the suture line. However, there have been few studies of single-layer and two-layer inverting anastomoses in the colon of experimental animals and it is significant, perhaps, that

McAdams and others (1970) found no difference between these methods in the dog colon.

In the present study of the rabbit colon we have found no difference between the two types of inverting anastomosis with respect to their tensile strength, collagen content, and the incidence of tissue necrosis and anastomotic complications. However, it would be wrong to dismiss the single-layer method on the basis of these results since there are important differences between man and the experimental animal with regard to intestinal anastomosis. Thus, the size of the suture material used in the experimental anastomosis is relatively greater than that which obtains in man, and the degree of luminal obstruction produced by inversion in the intestine of animals is similarly greater than that which is apparent in the human colon. Accordingly, the final decision regarding the merits of the single-layer inverting anastomosis must await the results of properly controlled clinical trials.

The results of a randomized, prospective, clinical trial comparing single-layer and two-layer inverting anastomoses are described on p. 457 of this JOURNAL.

A RANDOMIZED PROSPECTIVE CLINICAL TRIAL OF SINGLE-LAYER AND TWO-LAYER INVERTING INTESTINAL ANASTOMOSES

By T. T. IRVIN, J. C. GOLIGHER, and D. JOHNSTON

UNIVERSITY DEPARTMENT OF SURGERY, LEEDS GENERAL INFIRMARY

SUMMARY

Most surgeons recommend an inverting technique for anastomosis of the intestine using two layers of sutures, but it has been suggested that greater safety would be achieved by using an inverting method which involves only a single layer of sutures.

Single-layer inverting and standard two-layer inverting intestinal anastomoses were compared in a randomized prospective clinical study of 60 patients. A similar incidence of anastomotic dehiscence and obstructive complications occurred after both types of anastomosis and it was concluded that single-layer methods of anastomosis do not possess qualities which surpass the standard two-layer method.

MOST surgeons recommend that end-to-end anastomosis of the intestine should be accomplished by inversion of the cut edges of the bowel using two layers of sutures (Grey Turner, 1955; Dunphy and Pikula, 1959; Goligher, 1967; Muir, 1969; Turnbull and Kyle, 1969). There can be little doubt that inversion is necessary in intestinal anastomosis (Goligher, Morris, McAdam, de Dombal, and Johnston, 1970), but Halsted (1887) suggested that this can be achieved with the greatest safety by using a technique which involves only a single layer of sutures and some surgeons have been favourably impressed by the results of single-layer methods of anastomosis (Gambee, Garnjobst, and Hardwick, 1956). However, experimental studies of single-layer and two-layer inverting anastomoses have produced conflicting results and there have been no randomized clinical trials comparing these two methods.

Anastomotic dehiscence and serious, sometimes fatal, septic complications associated with the standard two-layer method of anastomosis remain a source of concern and it seemed logical to assess the merits of single-layer inverting anastomoses in a randomized prospective clinical trial, comparing this method with the standard two-layer method.

METHODS

Sixty patients undergoing resection with end-to-end anastomosis of the small or large intestine during the course of emergency or elective operations were studied and the method of anastomosis used in each case was allocated randomly. Thirty-one patients (17 males and 14 females) had a two-layer anastomosis and 29 patients (12 males and 17 females) were given a single-layer anastomosis. The average ages of the patients in the two-layer and single-layer groups were 57 years (S.D. ± 19) and 64 years (S.D. ± 13) respectively.

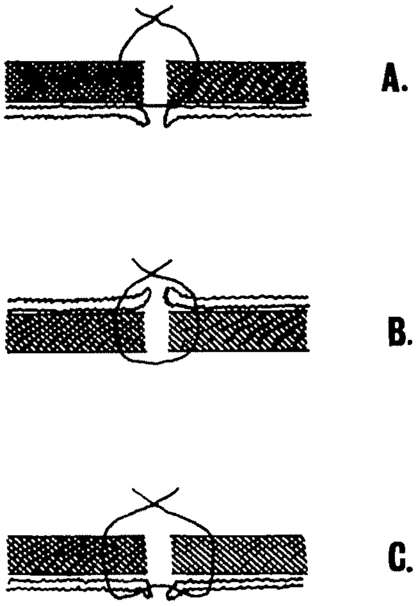

FIG. 1.—The methods used in single-layer inverting intestinal anastomoses. A, Submucosal suture. B, Suture inserted from the mucosal aspect through all the coats of the bowel. C, Gambee suture.

All the patients underwent intestinal preparation for 5 days prior to elective surgery. Mechanical preparation consisted of the daily administration of enemata and magnesium sulphate, and a single dose of castor oil was given on the day preceding operation. Diet was restricted to liquids only for 24 hours prior to surgery and intestinal antiseptics were used routinely in conjunction with mechanical bowel preparation. Phthalylsulphathiazole was administered daily for 5 days and kanamycin was given during the 48 hours prior to surgery.

The standard two-layer inverting anastomosis needs little description and, in our hands, consisted of an inner layer of continuous chromic catgut, including all coats of the bowel wall, and an outer layer of interrupted Lembert sutures, using silk as the suture material. The techniques used for single-layer inverting anastomoses are depicted in *Fig.* 1. Vertical, interrupted, atraumatic silk sutures were used in all cases. In 12 cases a submucosal suture (A) was used throughout. In 6 cases the posterior aspect of the anastomosis was made with sutures inserted from the mucosal aspect of the bowel through all the coats and knotted on the mucosa (B), and a submucosal suture (A) was used for the anterior aspect of the anastomosis. In the remaining 11 cases method B was used for the posterior layer but a Gambee suture (Gambee and others, 1956) was used for the anterior aspect of the anastomosis (C). The technique used in each case was left to the discretion of the surgeon.

The radiological appearance of the anastomosis was assessed by a barium-enema examination on the fourteenth postoperative day in all the surviving patients, with the exception of 1 patient who had undergone small-bowel resection, and anastomoses involving the rectum were also examined by sigmoidoscopy on the tenth postoperative day.

RESULTS

Similarity of the Groups.—The nature of the pathology, types of operation, and various other clinical features which may be of relevance to the success or failure of anastomotic healing were assessed in patients treated by single-layer anastomosis and in those given a standard two-layer anastomosis to determine whether or not these two groups of patients could be regarded as well matched.

Table I.—PATHOLOGY IN THE TWO GROUPS OF PATIENTS UNDER STUDY

PATHOLOGY	SINGLE-LAYER INVERTING ANASTOMOSIS		TWO-LAYER INVERTING ANASTOMOSIS	
	No.	Per cent	No.	Per cent
Carcinoma	17	59	13	43
Crohn's disease	5	18	6	20
Benign tumour	0	0	2	6
Diverticular disease	2	7	2	6
Loop colostomy	2	7	5	16
Mechanical obstruction	1	3	2	6
Intestinal infarction	1	3	1	3
Tuberculosis	1	3	0	0

Table II.—VARIOUS TYPES OF OPERATION IN THE TWO GROUPS OF PATIENTS UNDER STUDY

OPERATION	SINGLE-LAYER INVERTING ANASTOMOSIS		TWO-LAYER INVERTING ANASTOMOSIS	
	No	Per cent	No.	Per cent
Small-bowel resection	0	0	1	3
Right hemicolectomy	17	59	13	42
Transverse colectomy	0	0	1	3
Left hemicolectomy	2	7	3	10
High anterior resection	7	24	7	23
Subtotal colectomy and ileorectal anastomosis	1	3	1	3
Colostomy closure	2	7	5	16

Table III.—INCIDENCE OF VARIOUS CLINICAL FEATURES WHICH MAY BE OF RELEVANCE IN ANASTOMOTIC HEALING IN THE TWO GROUPS OF PATIENTS UNDER STUDY

CLINICAL FEATURE	SINGLE-LAYER INVERTING ANASTOMOSIS		TWO-LAYER INVERTING ANASTOMOSIS	
	No.	Per cent	No.	Per cent
Obesity	13	45	9	29
Anaemia (haemoglobin <12 g per 100 ml)	5	17	4	13
Steroid therapy	1	3	2	6
Palliative operation for carcinoma	5	17	3	10
Emergency operation	5	17	5	16
Defunctioning colostomy	2	7	2	6
Faecal loading of bowel or intestinal obstruction	12	41	11	35
Faecal soiling at operation	4	14	3	10
Peritoneal sepsis at operation	2	7	4	13
Postoperative antibiotic therapy	9	31	8	26

Table I shows the various types of pathology encountered in the two groups. Carcinoma of the colon and Crohn's disease were the most common indications for surgery and it is apparent that the two groups were similar with regard to pathology.

In *Table II* the incidence of the various types of surgical operation is compared in the two groups. The operation most frequently performed in each group was right hemicolectomy and it can be seen that the two groups were well matched with respect to the various surgical operations although there was a slightly higher incidence of colostomy closures in the group treated by two-layer anastomosis.

Table IV.—MORTALITY AND INCIDENCE OF ANASTOMOTIC DEHISCENCE IN THE TWO GROUPS OF PATIENTS UNDER STUDY

	SINGLE-LAYER INVERTING ANASTOMOSIS		TWO-LAYER INVERTING ANASTOMOSIS	
	No.	Per cent	No	Per cent
No of cases	29	—	31	—
No. of deaths	3	10	3	10
Clinical evidence of anastomotic dehiscence	2*	7	3*	10
Subclinical anastomotic dehiscence	3	10	2	6
Total incidence of anastomotic dehiscence	5	17	5	16

* Died as a result of anastomotic dehiscence.

Table V.—NATURE OF THE PATHOLOGY AND THE TYPES OF OPERATION IN 10 PATIENTS WHO DEVELOPED CLINICAL OR SUBCLINICAL EVIDENCE OF ANASTOMOTIC DEHISCENCE

ANASTOMOSIS	AGE AND SEX		PATHOLOGY	OPERATION	RESULT
Single-layer	64	F	Crohn's disease	Right hemicolectomy	Peritonitis—death
Single-layer	72	F.	Carcinoma	Subtotal colectomy	Peritonitis—death
Single-layer	66	F.	Diverticular disease	Left hemicolectomy	Subclinical dehiscence
Single-layer	54	M.	Carcinoma	Left hemicolectomy	Subclinical dehiscence
Single-layer	71	F.	Carcinoma	High anterior resection	Subclinical dehiscence
Two-layer	75	M.	Carcinoma	Right hemicolectomy	Peritonitis—death
Two-layer	71	M.	Intestinal infarction	Right hemicolectomy	Peritonitis—death
Two-layer	68	F.	Carcinoma	Colostomy closure	Peritonitis—death
Two-layer	67	M.	Carcinoma	High anterior resection	Subclinical dehiscence
Two-layer	69	M.	Carcinoma	High anterior resection	Subclinical dehiscence

In *Table III* the incidence of various clinical features which may be of relevance in anastomotic healing is compared in the two groups. Again, it appears that the groups were well matched. There was little difference between the two groups with regard to the incidence of obesity, anaemia, steroid therapy, palliative and emergency operations, defunctioning colostomy, faecal loading of the bowel and intestinal obstruction, faecal soiling and peritoneal sepsis at operation, and postoperative antibiotic therapy.

Mortality and Incidence of Anastomotic Dehiscence.—*Table IV* shows the mortality and incidence of anastomotic dehiscence in the two groups of patients given a single-layer or standard two-layer anastomosis. The mortality in each group was 10 per cent. One patient in the single-layer group died of respiratory complications on the twelfth postoperative day but there was no clinical evidence of anastomotic dehiscence in this case. Two deaths in the single-layer group and 3 deaths in the two-layer group resulted from anastomotic dehiscence and a further 3 cases in the single-layer group and 2 cases in the two-layer group were shown to have subclinical anastomotic dehiscence on postoperative barium-enema examination. Thus, the total incidence of anastomotic dehiscence was 17 per cent in the single-layer group and 16 per cent in the two-layer group.

Table V shows the nature of the pathology and the types of operation in the 10 patients who developed clinical or subclinical evidence of anastomotic dehiscence. Carcinoma was the pathology involved in 7 of the 10 cases, but anastomotic disruption was not confined to any one particular operation and occurred after anastomosis of the right colon, left colon, and rectum, and in 1 case after colostomy closure.

Postoperative Ileus or Mechanical Obstruction.—Six patients in each group developed ileus or some degree of mechanical intestinal obstruction during the postoperative period. In each group 3 of the patients who developed ileus also had either clinical or subclinical evidence of anastomotic disruption. No patient in either group required a further laparotomy for persisting mechanical obstruction.

DISCUSSION

An inverting technique using two layers of sutures is usually recommended for anastomosis of the intestine (Grey Turner, 1955; Dunphy and Pikula, 1959; Goligher, 1967; Muir, 1969; Turnbull and Kyle, 1969), but Halsted (1887) suggested that an inverting method employing only one layer of sutures provided the greatest margin of safety and some surgeons have been impressed by the results of single-layer inverting anastomoses. Gambee and others (1956) found that anastomotic complications accounted for a mortality of only 3 per cent in a study of 153 single-layer anastomoses, and Beling (1957) observed no complications in his series of 60 cases treated by single-layer anastomosis. Buchin and Van Geertruyden (1960) concluded that the single-layer inverting anastomosis was associated with a lower incidence of anastomotic disruption and postoperative intestinal dysfunction by comparison with the standard two-layer method, on the basis of a retrospective analysis of 437 anastomoses, of which 133 were single-layer anastomoses. However, there has been no comparison of the two methods in controlled clinical trials and rather conflicting results have accrued from experimental studies. Letwin and Williams (1967) showed that single-layer inverting anastomoses in the small bowel of the dog resulted in less tissue destruction and anastomotic disruption by comparison with two-layer anastomoses. Similarly, Orr (1969) compared single-layer and two-layer small-bowel anastomoses in the dog and he observed less tissue destruction and more rapid healing after single-layer anastomosis. On the other hand, McAdams, Meikle, and Taylor (1970) were unable to detect any significant difference between single-layer and two-layer inverting anastomoses in the colon of the dog and the incidence of anastomotic disruption was slightly higher after single-layer anastomoses. Similarly, we have found no difference between single-layer and two-layer inverting anastomoses in the rabbit colon with regard to tensile strength, collagen content, histological features, and the incidence of septic complications (*see* p. 453 of this JOURNAL).

In the present study the incidence of anastomotic complications associated with the single-layer method was not significantly different from that encountered with the standard two-layer method in a controlled clinical trial. Clinical or subclinical evidence of anastomotic dehiscence occurred in 17 per cent of single-layer anastomoses and in 16 per cent of two-layer anastomoses, and similarly there was no difference between the two methods of anastomosis with regard to postoperative obstructive complications. The patients treated by these two methods were well matched with respect to age, pathology, and the types of operation performed, and other clinical features such as peritoneal sepsis, faecal loading of the bowel, and faecal soiling which may be of particular relevance in the breakdown of intestinal anastomoses (Goligher, Graham, and de Dombal, 1970; Hawley, 1970; Dunphy, 1971), were evenly distributed between the two methods. It appears, therefore, that there was no bias which favoured either method of anastomosis.

The results of the present study imply that single-layer inverting methods of anastomosis do not possess qualities which surpass the standard two-layer method and it seems unlikely that the continuing problem of anastomotic disruption would be affected significantly by the more liberal use of the single-layer method in clinical practice.

Acknowledgements.—We are grateful to Miss Jane Horrocks and Mr. F. T. de Dombal for invaluable assistance in the computer-assisted analysis of the results.

AETIOLOGY OF DISRUPTION OF INTESTINAL ANASTOMOSES

By T. T. IRVIN AND J. C. GOLIGHER

UNIVERSITY DEPARTMENT OF SURGERY, LEEDS GENERAL INFIRMARY

SUMMARY

Various factors have been cited in the aetiology of disruption of intestinal anastomoses but their relative clinical importance is uncertain.

A retrospective study was made of 204 patients treated by resection and standard end-to-end anastomosis of the intestine.

Clinical evidence of anastomotic dehiscence occurred in 14 per cent of cases and the incidence of dehiscence was significantly increased in cases where faecal loading of the bowel obtained and after operations involving low anterior resection of the rectum or surgery for fixed tumours. The presence of a defunctioning colostomy did not remove the threat of anastomotic complications. A significant reduction in preoperative plasma proteins was found in patients who developed anastomotic dehiscence and the incidence of disruption was highest in patients over the age of 60 years.

RECENT experimental and clinical studies have suggested that numerous factors may compromise healing of colonic anastomoses. Thus, anastomotic technique, shock, peritoneal sepsis, inadequate bowel preparation, inexpert surgery, the nutritional status of the patient, and the nature of the operation must all be considered (Goligher, Graham, and de Dombal, 1970; Goligher, Morris, McAdam, de Dombal, and Johnston, 1970; Hawley, 1970; Whitaker, Dixon, and Greatorex, 1970; Dunphy, 1971; Daly, Vars, and Dudrick, 1972), but the relative clinical importance of these different aspects is uncertain.

In an attempt to elucidate the factors which may be of most importance in clinical practice to the success or failure of anastomotic healing we have reviewed the case records of patients undergoing intestinal resection with anastomosis in the Professorial Surgical Unit, Leeds General Infirmary, during the period 1968–72.

METHODS

The case records of 204 patients undergoing intestinal resection with anastomosis in the Professorial Surgical Unit at the Leeds General Infirmary during the period 1967–72 were studied. A standard method of end-to-end anastomosis of the intestine was used in all the cases, namely, double-layer inversion using continuous chromic catgut for the inner layer which incorporated all the coats of the bowel wall and interrupted silk for the outer layer of Lembert sutures. A further 62 cases underwent intestinal anastomosis during this period but were not included in the study as everting or single-layer methods of suture were used.

The patients underwent intestinal preparation for 5 days prior to elective surgery. Mechanical bowel preparation consisted of the daily administration of enemata and either magnesium sulphate or liquid paraffin by mouth. Castor oil was administered on the day preceding surgery in most cases and diet was restricted to liquids only for 24–48 hours prior to operation.

Intestinal antiseptics were used routinely in conjunction with mechanical bowel preparation. Phthalylsulphathiazole was administered daily for 5 days prior to surgery and, in most cases, broad-spectrum antibiotics in the form of kanamycin or neomycin were given during the 48 hours preceding operation.

The findings on postoperative barium-enema and sigmoidoscopic examinations in patients who had undergone resections of the left colon or rectum were available only in a proportion of cases and it was clearly impossible to document fully the incidence of subclinical anastomotic breakdown. Accordingly, we have studied only the clinical incidence of anastomotic dehiscence and every case of dehiscence described in the present study had unequivocal evidence of anastomotic breakdown *shown either by a faecal fistula or at further laparotomy for peritonitis.*

RESULTS

Mortality and Anastomotic Dehiscence.—The operative mortality in the 204 cases was 6·5 per cent. There was clinical evidence of anastomotic dehiscence in 28 cases (14 per cent) and this complication accounted for the fatal outcome in 10 of these patients.

Table I.—OPERATIONS PERFORMED IN 203 CASES AND THE RELATED INCIDENCE OF ANASTOMOTIC DEHISCENCE

OPERATION	NO ANASTOMOTIC DEHISCENCE	ANASTOMOTIC DEHISCENCE	PERCENTAGE DEHISCENCE
Small-bowel resection	14	2	13
Right hemicolectomy	52	7	13
Left hemicolectomy	10	0	0
High anterior resection	64	9	12
Low anterior resection	27	9*	25
Subtotal colectomy and ileo-rectal anastomosis	8	1	11

* Significantly higher incidence of dehiscence compared with the cumulative incidence of dehiscence after the other operations ($\chi^2 = 3·985$, $P < 0·05$)

The 204 cases comprised 98 males and 106 females, but the incidence of anastomotic disruption was virtually identical for each sex.

One patient died of a ruptured aortic aneurysm within 72 hours of operation and this case has been excluded from further study.

Type of Operation.—*Table I* shows the operations performed on the 203 cases and the respective incidence of anastomotic dehiscence. The term 'high anterior resection' implies that a colorectal anastomosis was performed above the reflection of the pelvic peritoneum, whereas 'low anterior resection' refers to cases in which the anastomosis was made below the pelvic peritoneum using rectum devoid of a serosal coat. A significantly higher incidence of anastomotic dehiscence was encountered after the latter operation compared with the cumulative incidence of dehiscence after all the other operations ($\chi^2 = 3{\cdot}985$, $P<0{\cdot}05$).

Fourteen per cent of the 203 patients underwent emergency operations involving resection of small bowel or the right colon, but there was no difference between emergency and elective operations with respect to anastomotic dehiscence. Likewise, 34 per cent of the operations were performed by junior staff, usually of senior registrar status, but the incidence of anastomotic dehiscence was not increased in such cases.

Table II.—INDICATIONS FOR SURGERY IN 203 CASES AND THE RELATED INCIDENCE OF ANASTOMOTIC DEHISCENCE

INDICATION FOR SURGERY	NO ANASTOMOTIC DEHISCENCE	ANASTOMOTIC DEHISCENCE
Carcinoma of colon	90	17
Benign tumour	8	0
Polyposis coli	3	0
Diverticular disease	24	5
Crohn's disease	34	3
Intestinal strangulation or infarction	15	2
Ileocaecal tuberculosis	1	1

Table III. RELATIONSHIP BETWEEN AGE AND ANASTOMOTIC DEHISCENCE

AGE (yr)	NO . ANASTOMOTIC DEHISCENCE	ANASTOMOTIC DEHISCENCE	PERCENTAGE DEHISCENCE
<60	91	7	7
>60	84	21*	20

* Significantly higher incidence of dehiscence in patients over the age of 60 ($\chi^2 = 6{\cdot}075$, $P<0{\cdot}02$).

Indications for Operation.—*Table II* compares the indications for surgery in the 203 cases with the respective incidence of anastomotic dehiscence. The most common conditions requiring operation were carcinoma of the colon or rectum, Crohn's disease, and diverticular disease, but there was no significant difference between the different types of pathology with respect to the incidence of anastomotic dehiscence.

Age.—*Table III* shows the relationship between age and anastomotic dehiscence. More than 50 per cent of the patients were over 60 years of age and the incidence of anastomotic breakdown in such cases was significantly higher than that encountered in patients below the age of 60 years ($\chi^2 = 6{\cdot}075$, $P<0{\cdot}02$).

Plasma Proteins.—*Table IV* shows the relationship between preoperative plasma-protein estimations and anastomotic dehiscence. Plasma-protein results were available in 106 cases and 17 of these developed anastomotic disruption. Patients who developed disruption had significantly lower total protein ($t = 2{\cdot}987$, $P<0{\cdot}01$) and plasma-albumin values ($t = 3{\cdot}499$, $P<0{\cdot}001$).

Malignant Disease.—The extent of the disease in 107 cases of carcinoma of the colon or rectum is compared with the incidence of anastomotic dehiscence in *Table V*. In all the cases information was available regarding the presence of metastases at operation, the opinion of the surgeon regarding the radical or palliative nature of the operation, and the extent of spread on pathological examination of the specimen using the criteria of Dukes (1940). Hepatic or peritoneal metastases were present in 24 per cent of cases and the operation was thought to be definitely palliative in 22 per cent of cases. Fifty-seven per cent of cases were classified as Dukes Stage C on pathological examination. It can be seen that the incidence of dehiscence was highest in those patients who had metastases, palliative operations, or Stage C lesions but none of these trends is statistically significant. In 16 cases the surgeon was uncertain regarding the radical nature of the operation because of the local extent of the tumour, and if these dubiously radical or 'uncertain' operations and the definitely palliative excisions are each compared with the radical operations it is apparent that there is a significantly higher incidence of anastomotic dehiscence in the former group ($\chi^2 = 5{\cdot}422$, $P<0{\cdot}02$).

Table IV.—CORRELATION BETWEEN PREOPERATIVE PLASMA PROTEINS (MEAN ± S.D.) AND ANASTOMOTIC DEHISCENCE

PLASMA PROTEIN	NO ANASTOMOTIC DEHISCENCE ($n = 89$)	ANASTOMOTIC DEHISCENCE ($n = 17$)	P
Total protein (g per 100 ml)	7 2±0·76	6·6±0·53	<0 01
Albumin (g per 100 ml)	3·9±0 52	3 4±0·71	<0 001

Table V.—ANASTOMOTIC DISRUPTION IN RELATION TO PALLIATIVE OR RADICAL OPERATIONS, THE PRESENCE OR ABSENCE OF METASTASES, AND THE EXTENT OF SPREAD ON PATHOLOGICAL EXAMINATION OF THE BOWEL IN 107 CASES OF LARGE-BOWEL CANCER

	NO ANASTOMOTIC DEHISCENCE	ANASTOMOTIC DEHISCENCE	PERCENTAGE DEHISCENCE
Metastases			
None	71	10	12
Hepatic and/or peritoneal metastases	19	7	27
Palliative surgery			
Radical	61	6	9
Palliative	18	6	25
Uncertain	11	5	31
Pathology (Dukes staging)			
'A' cases	10	0	0
'B' cases	32	4	13
'C' cases	48	13	21

Fixation of Bowel.—*Table VI* shows the relationship between fixity of the bowel at operation either by tumour or inflammation and the incidence of anastomotic dehiscence. The incidence of dehiscence was significantly higher after operations for carcinoma where the bowel was adherent to the parietes or other viscera compared with cases in which fixation of the bowel did not obtain ($\chi^2 = 11{\cdot}468$, $P<0{\cdot}001$).

Bowel Preparation, Faecal Soiling, and Peritoneal Sepsis.—In *Table VII* anastomotic dehiscence is correlated with the mechanical state of the bowel and the presence of faecal soiling and peritoneal sepsis at operation. Poor mechanical bowel preparation was associated with a significantly higher incidence of anastomotic dehiscence ($\chi^2 = 10{\cdot}252$, $P<0{\cdot}01$), but there is no evidence that faecal soiling or peritoneal sepsis contributed towards anastomotic complications.

Table VI.—RELATIONSHIP BETWEEN ANASTOMOTIC DEHISCENCE AND FIXITY OF THE BOWEL BY TUMOUR OR INFLAMMATION

FIXATION OF BOWEL	NO ANASTOMOTIC DEHISCENCE	ANASTOMOTIC DEHISCENCE	PERCENTAGE DEHISCENCE
No fixation	119	11	8
Fixation by tumour	23	11*	32
Fixation by inflammation	33	6	15

* Significantly higher incidence of dehiscence compared with no fixation ($\chi^2 = 11{\cdot}468$, $P<0{\cdot}001$)

Table VII.—ANASTOMOTIC DEHISCENCE CORRELATED WITH THE EFFICIENCY OF MECHANICAL BOWEL PREPARATION AND THE PRESENCE OF FAECAL SOILING OR PERITONEAL SEPSIS AT OPERATION

	NO ANASTOMOTIC DEHISCENCE	ANASTOMOTIC DEHISCENCE	PERCENTAGE DEHISCENCE
Mechanical bowel preparation			
Well prepared	116	9	7
Badly prepared or obstructed	59	19*	24
Faecal soiling at operation			
No soiling	154	22	13
Soiling	21	6	22
Peritoneal sepsis			
No sepsis	151	24	14
Sepsis	24	4	14

* Significantly higher incidence of anastomotic dehiscence compared with well-prepared cases ($\chi^2 = 10\,252$, $P<0\,01$)

Table VIII.—INCIDENCE OF ANASTOMOTIC DEHISCENCE IN 119 PATIENTS TREATED WITH OR WITHOUT A DEFUNCTIONING COLOSTOMY

	NO ANASTOMOTIC DEHISCENCE	ANASTOMOTIC DEHISCENCE	PERCENTAGE DEHISCENCE
Colostomy	42	10	19
No colostomy	59	8	12

Drains.—Intraperitoneal drains were placed routinely in the vicinity of the anastomosis with the exception of 12 cases. Two patients in the latter category developed clinical evidence of anastomotic disruption but the numbers are insufficient to warrant critical analysis.

Defunctioning Colostomy.—*Table VIII* shows the incidence of anastomotic dehiscence in 119 patients treated by resection of the left colon or rectum with or without a temporary defunctioning transverse colostomy. A colostomy was performed in 52 cases, but the incidence of disruption in this group was similar to that encountered in the group treated without a colostomy. However, it cannot be concluded that a defunctioning colostomy afforded no protection since it was reserved frequently for cases which might be expected to do badly. Thus, the incidence of low anterior resection was significantly higher amongst colostomy patients ($\chi^2 = 41{\cdot}921$, $P<0{\cdot}001$) and the cumulative incidence of poor mechanical bowel preparation, fixed tumours, peritoneal sepsis, and faecal soiling was also significantly higher in colostomy cases ($\chi^2 = 6{\cdot}975$, $P<0{\cdot}01$).

DISCUSSION

The results of recent studies on anastomotic healing imply that a wide variety of factors may be involved in the aetiology of anastomotic disruption. Thus, the methods of preoperative bowel preparation (Rosenberg, Graham, de Dombal and Goligher, 1971), faecal loading of the bowel (Goligher, Graham, and de Dombal, 1970), the use of intraperitoneal drains (Manz, La Tendresse, and Sako, 1970), the role of faecal contamination and peritoneal sepsis (Hawley, 1970; Rosenberg and others, 1971), and the relationship between blood-loss (Whitaker and others, 1970) and anastomotic healing have all come under scrutiny as well as consideration of the nutritional status of the patient (Daly and others, 1972) and attention to surgical technique (Dunphy, 1971). The present study of 204 patients treated by a standard method of end-to-end anastomosis of the intestine has identified the relative clinical importance of several of these aspects.

We previously suggested (Goligher, Graham, and de Dombal, 1970; Rosenberg and others, 1971) that poor mechanical preparation of the bowel was associated with an increased incidence of anastomotic disruption and this impression has been confirmed in the present study which has shown a highly significant correlation between faecal loading and anastomotic dehiscence. The clinical importance of preoperative antiseptics in colonic surgery has been demonstrated previously (Rosenberg and others, 1971) and need not be considered here since all the patients undergoing elective surgery in the present study were given antiseptics in conjunction with preoperative mechanical bowel preparation.

Hawley (1970) showed that faecal soiling and peritoneal sepsis significantly impaired the healing of colonic anastomoses in experimental animals and our earlier studies on smaller numbers of patients tended to support this thesis (Goligher, Graham, and de Dombal, 1970: Rosenberg and others, 1971). The present study has not confirmed that these factors are of significance in the aetiology of anastomotic disruption, but it should be noted that prophylactic broad-spectrum antibiotics were administered routinely in cases complicated by sepsis or faecal soiling at operation, and in the latter part of the study peritoneal lavage with antibiotic solutions was employed in a proportion of such cases. Thus, it is conceivable that such measures may have prevented anastomotic complications.

Low anterior resections of the rectum were associated with a significantly higher incidence of dehiscence compared with the other operations under study and it seems that the extraperitoneal rectum is less suited for anastomosis than the intraperitoneal rectum or colon. Examination of our results shows that the high incidence of dehiscence is not explained by an unduly large number of poor mechanical bowel preparations or fixed tumours in cases treated by low anterior resection.

Palliative operations and operations for the more advanced colonic tumours were associated with an increased incidence of anastomotic breakdown, but this trend was of statistical significance only in the cases where the tumour was actually adherent to the parietes or other viscera. It is interesting to relate this association between anastomotic disruption and the surgery of fixed tumours to some recent experimental and clinical studies. Conolly, Hunt, Sonne, and Dunphy (1969) found that the incidence of wound infection in experimental animals was increased after major surgical trauma, and Hawley (1970) showed a similar relationship between surgical trauma and lysis of mature collagen in the colon of experimental animals. In man Whitaker and others (1970) found that the incidence of anastomotic disruption was increased after operations which involved major blood-loss and they postulated that intra-operative shock and intestinal ischaemia interfered with anastomotic healing. Clearly, the relationship between surgical trauma and anastomotic healing is worthy of further investigation.

The significance of age as an aetiological factor in anastomotic disruption is uncertain. A significantly higher incidence of disruption was found in patients over the age of 60 years, but this may reflect merely the higher incidence of fixed tumours and low anterior resections in this age-group.

There seems little doubt that the nutritional status of the patient is relevant in the healing of intestinal anastomoses. A significant correlation was shown in the present study between hypoproteinaemia and anastomotic disruption, and Daly and others (1972) found that protein depletion in experimental animals significantly impaired the healing of colonic anastomoses.

The results of the present study amply confirm the common impression that a number of factors are involved in the aetiology of anastomotic dehiscence and the practical implications are considerable. Inadequate mechanical bowel preparation is involved in a significant proportion of cases and it seems likely that improved methods of mechanical preparation of the colon would result in a reduced incidence of anastomotic disruption. Our results have clearly shown that the presence of a defunctioning colostomy does not completely remove the threat of anastomotic dehiscence, but the precise value of a proximal colostomy needs to be evaluated in a randomized prospective trial. Improvement in the nutritional status of patients undergoing intestinal anastomoses may also prove worth while, but this too must be evaluated and further investigations are necessary to determine the factors which compromise anastomotic healing after extensive surgical procedures.

Now, to simplify treatment of pseudomonas chest infections:

Pyopen infusion

In the published papers, Pyopen's success rate in chest infections is 65% even though the majority of the patients described had severe underlying pathology.

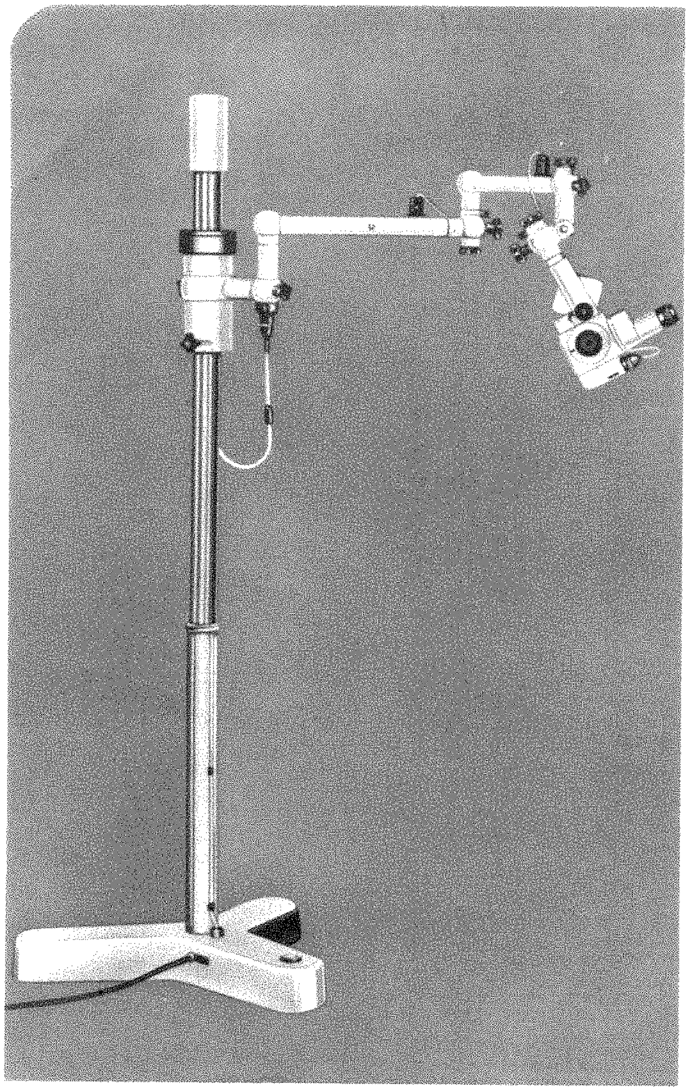
The best results have been achieved with a dosage of 20-30G. I.V. daily. Pyopen infusion makes this dosage simpler to administer by providing Pyopen in ready-to-use infusion bottles with diluent and transfer needles for the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and has proved valuable in patients with known renal impairment: in such cases, however, dosage should be reduced.

Adult dosage: 20-30G. I.V. daily.
In patients with renal impairment dosage should be reduced.
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.



SURGERY MICROSCOPE II

Another superb instrument from

CARL ZEISS JENA

This well established Surgery Microscope from VEB Carl Zeiss Jena has gained a well deserved reputation for it's reliability and all-round performance. It is extremely versatile, allowing complete freedom of movement. The working distance is 200-300 or 400mm. You'll be surprised at the competitive price of this popular microscope which incorporates optics of the highest quality. Remarkable value!

SPECIAL FEATURES INCLUDE:-

- ⁎ Individually focussing eyepieces
- ⁎ Rapid changing for two filters and five magnifications (5x, 8x, 12.5x, 20x, 32x)
- ⁎ Observer eyepiece available
- ⁎ Photographic attachments available.

Write or telephone for literature or demonstration on this instrument and others in the comprehensive VEB Carl Zeiss Jena Range.

CARL ZEISS JENA LTD., C.Z. Scientific Instruments Ltd.,
93/97 New Cavendish Street, London W1A 2AR. Tel: 01-580 0571

NON-MALIGNANT BREAST MASSES IN AN AFRICAN POPULATION

By O. O. AJAYI and O. ADEKUNLE
DEPARTMENT OF SURGERY, UNIVERSITY COLLEGE HOSPITAL, IBADAN, NIGERIA

SUMMARY

The clinical manifestation of non-malignant breast masses in an African population is presented. The pattern of disease is affected by many factors, among which are social habits, poverty, and ignorance. The problems of diagnosis and treatment are discussed. Ulcerating benign masses simulate advanced malignancies and no hasty conclusion should be made on the latter without histological proof or evidence of distant metastases. There may be an indication for mammary amputation in some diseased pendulous breasts.

It is generally accepted that the incidence of cancer of the breast is lower in Africa and Asia than in Europe and North America (Doll, 1969; De Waard, 1969). While the causes of breast cancer continue to elude us, a number of aetiological factors are being closely examined with conflicting conclusions. Such factors include hormonal status (Bulbrook, Hayward, Spicer, and Thomas, 1962; Bulbrook and Hayward, 1967), genetic make-up (Macklin, 1959), marital status, parity, lactational habits, social class, and nutrition (Graham, Levin, and Lilienfeld, 1960; MacMahon and Feinleib, 1960; Lilienfeld, 1963; De Waard, 1969). Whatever part these factors play in mammary carcinogenesis, relatively little attention has been paid to other pathological effects that they may have on the breast. While the lower incidence of breast cancer in Africa and the clinical pattern may be due to complex social factors unrelated to the causation of the disease it is worth while to look more closely at the pattern of non-malignant breast masses in this environment with a view to seeing if similar differences exist.

MATERIALS FOR STUDY

One hundred and fifty-two non-malignant breast biopsies examined at the University College Hospital, Ibadan, in a 3-year period between 1969 and 1971 were studied. Fifty unselected case histories were also available for detailed clinical evaluation. The nomenclatures and histological criteria were based on those recommended by the World Health Organization International Reference Centre for the Histological Definition and Classification of Breast Tumours (1968).

FINDINGS

Frequency.—In the years under review 15,706 biopsy samples were examined in the Department of Pathology of the University College Hospital. The non-malignant breast mass biopsies therefore constitute about 0·8 per cent of the total number of biopsies. This compares with 166 cases of carcinoma of the breast recorded at the Cancer Registry of the hospital over the same period.

Age and Sex.—There were 139 females to 13 males in this series. The age range of the patients was 13–72 years. The average age of the patients with benign mammary dysplasia (B.M.D. group) was 32 years, while patients with benign or apparently benign tumours (fibro-adenoma group) had an average age of 22 years. Eighty per cent of the fibro-adenoma group presented by the third decade of life as compared with 50 per cent of the B.M.D. group.

Other Clinical Features.—The majority of the patients were educated women and can be considered more sophisticated than the average Nigerian female of the same age-group. About 50 per cent of the women were married and parity ranged between 0 and 9. Sixty per cent of the women were nulliparous. The length of history varied between 1 week and 10 years and the duration of symptoms in 48 per cent of the patients was less than 6 months. Twenty-two per cent of the patients were lactating at the time of the clinical examination. The masses were equally distributed in both breasts and were bilateral in 10 per cent of cases. There were two or more lumps in one breast in 8 per cent of the cases and 12 per cent had ulceration of the overlying skin.

Pathology.—*Table I* shows the histological diagnoses in the patients studied. The size of tumour excised varied between 1 and 28 cm. in diameter and the weight range was 1–4400 g.

Table I.—HISTOLOGICAL DIAGNOSIS OF BENIGN BREAST MASSES IN 152 NIGERIANS

DIAGNOSIS	NO. OF CASES	PERCENTAGE (APPROX.)
Group A		
Benign mammary dysplasia	61	40
Group B		
Benign or apparently benign tumours	65	43
Chronic abscesses	14	9
Others (epidermal inclusion cyst, parasitic cyst, galactocele, tuberculosis, etc.)	12	8
Total	152	100

Of the 65 cases with benign or apparently benign tumours, 60 were fibro-adenomas most of which had mixed intra- and pericanalicular patterns. The weight range of the fibro-adenomas was 1–2320 g. with an average of 129 g. Ten of the 13 males had unilateral 'idiopathic' gynaecomastia.

DISCUSSION

The pathology of non-malignant breast affections in an African population has attracted little attention. The literature on them has been scanty and textbooks have, at best, been vague and often silent. By general clinical experience the foregoing analysis is a considerable underestimate of the frequency of inflammatory breast disease. This is accounted for by the fact that the majority of breast infections resolve spontaneously or respond to warm applications or self-medication of antibiotics. This, however, does not invalidate the results of the present review since our motivation was to document breast masses which are non-cancerous in a tropical environment.

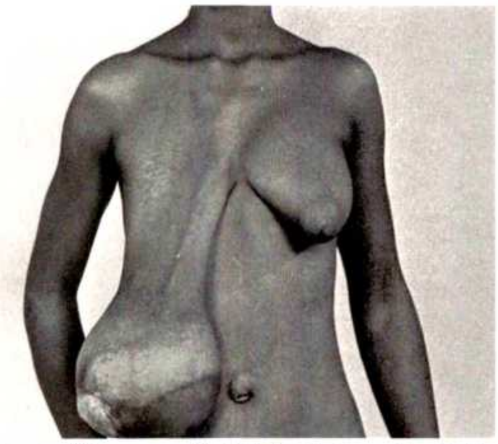

FIG. 1.—This 25-year-old girl had noticed a swelling in the right breast for 2 years. It got rapidly bigger during pregnancy and ulcerated shortly before her confinement following topical applications. She presented with a 'fungating' breast mass and ipsilateral axillary lymphadenopathy. The photograph was taken after a course of antibiotics. Lymph-node biopsy showed 'non-specific' reactive hyperplasia. Histology of the excised breast mass showed fibro-adenoma

Fibro-adenoma.—The commonest benign mammary mass was a fibro-adenoma which constituted 39·5 per cent of the total number of excised specimens. Templeton (1971) reported 56 fibro-adenomas out of 168 non-malignant histological specimens examined in Mulago Hospital, Kampala, Uganda: this was an incidence of 33·3 per cent. We agree with him that this may represent an underestimate since African women seldom attend hospitals with early, painless disease owing mainly to socio-economic reasons. It is therefore not surprising that nurses and students constituted about half the total cases reviewed from a teaching hospital in a university city. It is, however, worthy of note that Ellis (1937) examined the breasts of 140 patients in Bida, Northern Nigeria, and reported that 72 of them had 'nodularity' and 20 had cysts. No mention was made of fibro-adenomas. There are two possible reasons for this: either there were no fibro-adenomas in the cases examined or some of the 'cysts' were fibro-adenomas. It is clear that the overall incidence in this population needs further study.

The age-range of the patients with fibro-adenoma was 13–41 years, giving an average of 22·4 years. This contrasts with an average age of 30 years in 108 cases surveyed by Kinder in the United Kingdom in 1954. This is interesting as it has also been observed that carcinoma of the breast occurs about a decade earlier in Nigeria than in Europe and America (Pearson, 1963).

While 48 per cent of the cases presented within 6 months of discovering a lump in the breast, no less than 22 per cent waited for 18 months or more before seeking medical advice. It therefore is not surprising that over 70 per cent of the cases of carcinoma of the breast in Nigeria present in Stages III and IV (Manchester Classification).

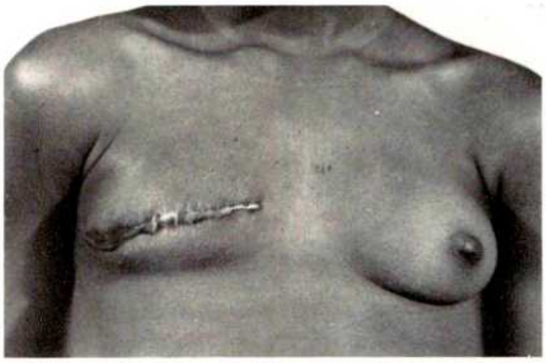

FIG. 2.—This 15-year-old girl presented with a 3-year history of progressive swelling of the right breast which had been 'treated' with topical applications. Extensive skin destruction with sloughing of the nipple made mastectomy inevitable. The tumour was thought to have totally replaced the breast at operation. Note the extent of the hypertrophy of the remnant breast 3 months later.

That fibro-adenomas in Africans are large at the time of clinical presentation has been noted before (Davey, 1968; Edington and Gilles, 1969). The diameters of the fibro-adenomas varied between 1 and 28 cm. and the weight range was between 1 and 2320 g., giving an average of 129 g. This contrasts with fibro-adenomas in the United Kingdom where tumours of more than 2·54 cm. in diameter are seldom seen (Handley, 1964). In 3 of the fibro-adenomas there were areas which examined in isolation could have been described as Brodie's tumour (cystosarcoma phyllodes). We therefore agree with Treves and Sunderland (1951) that microscopic detail and clinical behaviour are the essential criteria in the diagnosis of cystosarcoma phyllodes. Of its many synonyms, 'giant fibro-adenoma' is the most misleading.

Benign Mammary Dysplasia.—Benign mammary dysplasia accounted for 40 per cent of the present series. These were histologically confirmed, thus eliminating the guesswork of clinical examination whereby 'nodularity' is equated with mammary dysplasia. The true incidence in an African population is still unknown. Templeton (1971), by a rough calculation of the population at risk in Uganda, suggested that mammary dysplasia is about five hundred times more common in Europeans and seventy times more common in Asian women than in Africans. The studies of Ellis (1937) in Northern Nigeria in which 51 per cent of his patients had 'nodularity' have been referred to above. He concluded that in Bida 'nodularity' is about twice as common as in England. It would seem that the facts might lie between the two views, considering that of 500 British women examined by D'Abreu in 1935, 28·8 per cent had nodularity of the breast. Our proposed epidemiological survey of breast masses in a fixed village population in Western Nigeria might provide an answer.

The age-range of the patients in this group was 13–63 years, the average age being 31·7 years. This suggests that the patients with benign mammary dysplasia are about 10 years older than patients in the fibro-adenoma group. Where clinical details were

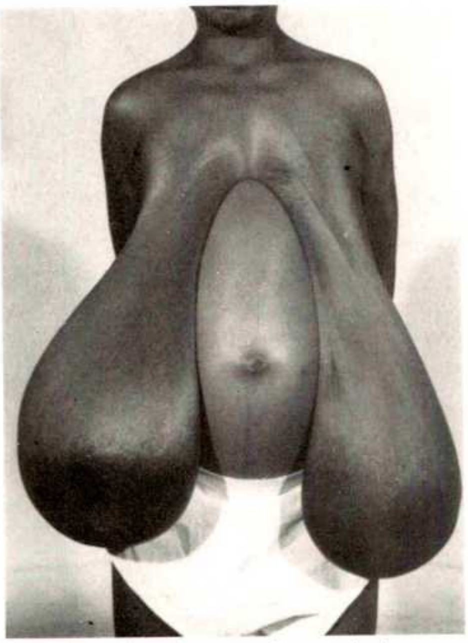

FIG. 3.—Gross bilateral mammary hypertrophy in a 22-year-old girl who was about 30 weeks pregnant. Histology confirmed bilateral benign mammary dysplasia.

available, about 30 per cent of the patients were lactating at the time of clinical presentation. No great significance can be attached to this as the cases under review are few. Although 60 per cent of all the patients in this study were nulliparous and, therefore, had presumably not lactated, about 70 per cent of the patients with benign mammary dysplasia had an average parity of 2. It would therefore seem that benign mammary dysplasia is much more common in patients who have suckled their infants since all African women breast-feed their infants. If that were true one would expect mammary dysplasia to be more common in an African population of high parity in which prolonged lactation is the rule. Since a parity of 2 cannot be considered high, perhaps prolonged lactation may be a contributory factor in the pathogenesis of some mammary dysplasias.

Other Breast Affections.—The other breast affections presenting as masses do not deserve extensive discussion except to note the rarity of tuberculosis of the breast in this series. This is surprising in an environment where tuberculosis is a common disease. In our view tuberculosis of the breast is commoner than it would seem from this series though a 'tuberculoma' of the breast is rare. Breast lesions in miliary tuberculosis are well known (Handley, 1964). While we do not wish to enter into the controversy as to whether primary or secondary tuberculosis of the breast is more frequent, we note that the commonest cause of upper limb lymphoedema in Western Nigeria is tuberculosis (Ngu, 1962). It is likely that not a few of these had lesions originating in the ipsilateral breast which eventually become oedematous following lymphatic obstruction, thus making clinical detection difficult.

DIAGNOSIS AND TREATMENT

The diagnosis of non-malignant breast masses in Nigerians can sometimes be difficult. Such difficulty often arises from late presentation at a hospital, superimposed infection commonly due to tattooing by the 'native doctor', and skin excoriations from powerful topical applications. It is therefore not unusual to see a patient with a benign ulcerating breast mass, *peau d'orange*, and palpably enlarged axillary lymph-glands on the ipsilateral side (*Fig.* 1). A clearly definable edge of the mass should raise a suspicion of a benign mass but this is sometimes not possible where sepsis is considerable. A high index of suspicion, a 'negative' axillary lymph-node biopsy, and response to a short course of antibiotics often provide an answer in a week. Subsequent histological examination of the excised lump would be confirmatory.

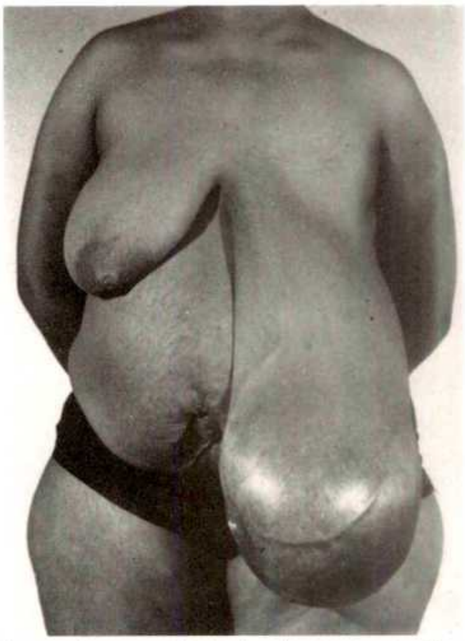

FIG. 4.—A 27-year-old schoolteacher (parity, 3) with a 12-month history of progressive enlargement of the left breast following confinement. The diagnosis was a galactocele.

The problems of treatment are accounted for by skin destruction for the reasons mentioned above. Supplementary to this is the necessity to preserve the breast not only for cosmetic reasons but also for function. The latter reason is especially important as most of the patients are young and suckling is the most satisfactory method of feeding the infant in a predominantly underprivileged society. The balance of judgement should always scale towards conservatism notwithstanding the extent of skin destruction. While 'cosmetic salvage' can often be achieved, 'functional salvage' is usually less successful, especially when the nipple has sloughed.

Large fibro-adenomas should always be shelled out. The initial clinical impression is that of total replacement of the breast by the large tumour. Careful palpation not invariably reveals a compressed rim of normal breast tissue which may quantitatively equal the normal opposite breast. *Fig.* 2 shows a young girl who had a 'mastectomy' for extensive ulceration and destruction of the right breast owing to a fibroadenoma. Note the extent of hypertrophy of the remnant breast after 3 months. Occasional difficulties may arise where the large mass turns out to be a malignant Brodie's tumour. One such case was in a 12-year-old girl in whom the tumour recurred 6 months after enucleation. This was enucleated again and it recurred 10 months later. The patient then had a sector mastectomy and has had no problems for 2 years.

Mammary hypertrophy is not uncommon in parous African women. Some are associated with obesity and others with benign mammary dysplasia (*Fig.* 3), but most are normal. There is no relation to parity, lactational histories, and degree of sophistication. Problems, however, do arise where a pendulous breast is the seat of neglected mammary dysplasia (*Fig.* 4). McIndoe and Dee Rees (1958) held the view that there is no place for amputation in benign breast lesions. Cases of this sort must be the exceptions since it is difficult to accept such breasts as satisfactory organs of lactation or as cosmetically desirable even after the excision of the breast lesions. Any form of mammaplasty in this circumstance is tantamount to amputation.

Acknowledgements.—We are grateful for the co-operation of all our colleagues in the preparation of this paper. Professor A. O. Williams of the Department of Pathology has been most kind. The staff of the University of Ibadan Medical Illustration Unit have been helpful. We thank Mr. T. Odeyale for his secretarial assistance.

STREPTOKINASE THERAPY IN DEEP-VEIN THROMBOSIS

By G. E. MAVOR, D. P. DHALL, A. A. DAWSON, J. S. DUTHIE, M. G. WALKER,
R. G. MAHAFFY, and M. ALLARDYCE
ABERDEEN ROYAL INFIRMARY

SUMMARY

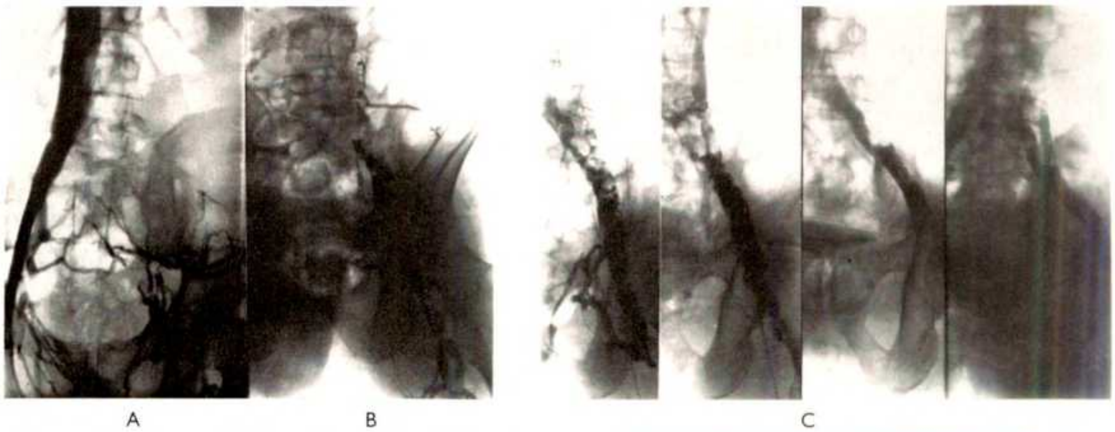
Experience with the use of streptokinase in the treatment of iliofemoral venous thrombosis is described. Streptokinase in a dose sufficient to induce systemic controlled defibrination was administered via an indwelling cannula which was used for repeated phlebography during the course of lysis and for several days afterwards. Of 40 patients treated, 10 had complete clearance and 24 partial clearance of the thrombus with the establishment of an iliofemoral channel. In 5 patients lysis did not occur and in 1 it was followed by early rethrombosis.

Thrombectomy under phlebographic control remains the treatment of choice for non-occlusive iliofemoral venous thrombosis (Mavor, 1971). However, experience suggests that where occlusion is present and of some duration complete operative clearance is more difficult and the incidence of post-thrombectomy rethrombosis rises (Mavor and Galloway, 1969). In this respect in many cases of occlusive iliofemoral venous thrombosis non-occlusive clot has been present for a considerable time before the appearance of symptoms of venous occlusion, so that thrombectomy is inevitably a late procedure in these cases. The use of streptokinase in doses sufficient to induce systemic fibrinolytic activity in the management of rethrombosis following iliofemoral venous thrombectomy has been encouraging (Mavor, Bennett, Galloway, and Karmody, 1969). This has led us to use the drug in the primary treatment of iliofemoral venous thrombosis in selected patients.

This report covers the results of the use of streptokinase both in rethrombosis after venous thrombectomy and for the primary treatment of iliofemoral venous thrombosis.

PATIENTS AND METHODS

A total of 40 patients were given streptokinase: 39 for iliofemoral venous thrombosis (1 bilateral) and 1 for axillary vein thrombosis. Of the 40 patients (16 males and 24 females), 19 had post-thrombectomy rethrombosis. In all these patients an indwelling saphenofemoral catheter had been inserted at the conclusion of thrombectomy; regular follow-up phlebograms through this cannula had shown rethrombosis. The remaining 21 patients (1 with bilateral iliofemoral venous thrombosis) were treated with streptokinase as the initial treatment. Only 1 of the 40 patients had an associated pulmonary embolus. This patient had a massive pulmonary embolus associated with non-occlusive iliofemoral venous thrombosis; this was the only non-occlusive thrombus in the series which was treated with streptokinase as the initial treatment.



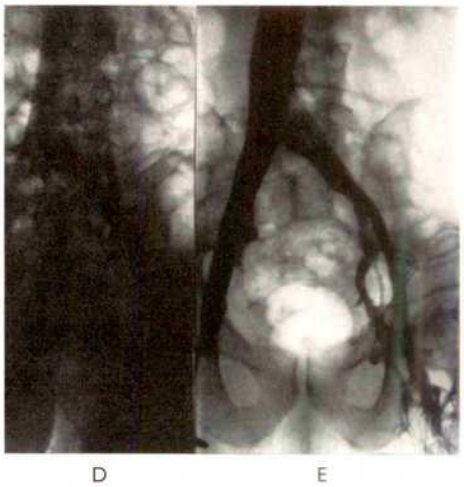


FIG. 1.—Phlebograms showing left occlusive iliofemoral venous thrombosis (A) which was treated by thrombectomy following which rethrombosis occurred (B). Streptokinase was administered and lysis was phlebographically obvious at 8 hours (C) and progressed to restore complete patency by 48 hours (D). This was maintained at the final phlebogram obtained 4 months later (E).

In patients with iliofemoral venous thrombosis streptokinase was administered through an indwelling saphenofemoral catheter by means of a constant-infusion Palmer pump (Mavor and Galloway, 1969). During the infusion of streptokinase phlebography was performed serially to determine the response of thrombus to thrombolytic therapy. After the cessation of streptokinase therapy the cannula was left in situ and heparinized saline (15,000 units in 500 ml. of normal saline in 24 hours) was instilled to maintain patency. Serial phlebograms were obtained for up to 10 days. For the administration of streptokinase and for monitoring the response to thrombolytic therapy in the patient with axillary vein thrombosis a tributary of the basilic vein was used instead of the long saphenous vein.

The titrated dose of streptokinase calculated on the basis of the streptase test was infused over a period of 40 minutes. This was followed by a fixed dose of 750,000 units over the first 4 hours and in each subsequent 8-hour period of treatment until phlebographic evidence of lysis occurred. In 15 cases this régime was modified to a 12-hour infusion with a total dose of 1·5 million units plus the initial dose. Before infusion, streptokinase (Hoechst Pharmaceuticals Ltd., Hounslow, Middlesex) was made up as a solution in 0·9 per cent NaCl at room temperature. The activity of the streptokinase was not measured and the units refer to those given by the manufacturers. It was assumed that the material was stable over the period of infusion. All the patients were given 10 mg. of prednisolone, starting on the day preceding infusion and lasting till the day after infusion was discontinued. Phlebograms were obtained in all the patients before infusion, and then 4, 8, 12, 24, 36, and 48 hours after infusion. Thereafter phlebograms were obtained daily until the cannula was removed 7–10 days after infusion. All the patients were also assessed clinically and phlebographically 4–6 months after streptokinase therapy.

The degree of lysis shown on the phlebogram at 7–10 days was used as a criterion for dividing the patients into three groups. In group 1 complete lysis had occurred (*Fig.* 1). In group 2 lysis had occurred but residual thrombus remained or recurred before the final phlebogram was taken, although a venous channel persisted (*Fig.* 2). In group 3 patients had either no lysis or initial lysis was followed by complete rethrombosis so that no channel remained in the iliofemoral segment. Patients in groups 1 and 2 had a normal leg.

Regular coagulation and fibrinolytic assays were made during and after the infusion of streptokinase to ensure that systemic excess fibrinolytic activity had been produced and that no severe coagulation defect had been induced. Plasma fibrinogen, plasminogen, euglobulin lysis time, Quick one-stage prothrombin time, and thrombin clotting times were measured serially during and for 24–48 hours after the cessation of streptokinase therapy, as described elsewhere (Mavor and others, 1969). Some patients were also given anticoagulant drugs, without apparent effect on the incidence of rethrombosis (Mavor, Dhall, Walker, Dawson, Duthie, and Allardyce, 1973).

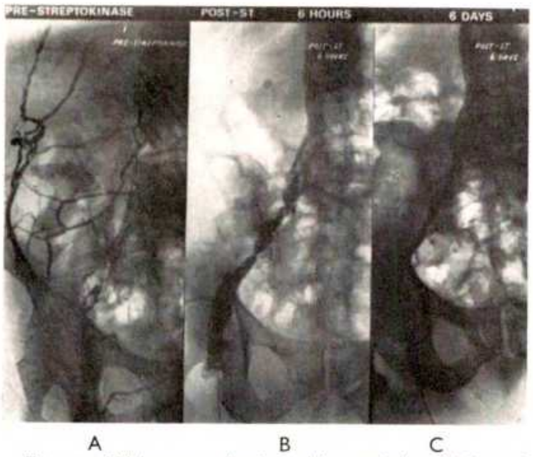

FIG. 2.—Phlebograms showing right occlusive iliofemoral venous thrombosis (A) which was treated with streptokinase following which a channel was established by 6 hours (B) which persisted. C, 6-day phlebogram.

RESULTS

The results of streptokinase therapy are shown in *Tables I–III*, corresponding to the three groups into which the patients were divided according to the final 7–10-day phlebographic assessment.

Table I shows the clinical details of the 10 patients in group 1 who initially had complete clearance of thrombus. Eight of the 10 patients had occlusive and 2 had non-occlusive thrombus at presentation. Five patients had been subjected to thrombectomy for occlusive thrombus; streptokinase was an additional measure to lyse post-thrombectomy thrombus. The details of loading dose (mean 400,000 units; range 100,000–1,000,000 units), total dose (mean 2·5 million units; range 1·6–4·2 million units), and infusion times (mean 23·5 hours; range 12–48 hours) are shown in *Table I*. Although all these patients had complete clearance of thrombus initially, 2 cases were found to have an occluded iliofemoral venous segment at the follow-up phlebogram 4 months later.

Table II shows the clinical details of the 24 patients in group 2. Of the 24 patients, 11 had had thrombectomy and in the remaining streptokinase was the initial treatment. These patients were, therefore, comparable to those in group 1 with respect to choice of initial treatment. Twenty-two cases had occlusive iliofemoral venous thrombosis and the remaining 2 had non-occlusive thrombus for which both patients had had thrombectomy initially. Details of loading dose (mean 190,000 units; range 100,000–500,000 units), total dose (3·65 million units; range 1·2–7·0 million units), and infusion times (mean 33·9 hours; range 8–83 hours) are shown in *Table II*. These patients had larger streptokinase doses over more extended periods of time than those in group 1. It is clear that streptokinase therapy was successful in establishing a patent venous channel in all the patients who presented with occlusive iliofemoral venous thrombosis. In the remaining 2 patients who had had a previous thrombectomy and had started to rethrombose this process was halted by streptokinase so that progression to occlusive thrombus was checked. Phlebographic assessment 4–6 months later showed that of the 24 patients in group 2, 12 remained with a venous channel through the iliofemoral venous segment and the remaining 12 developed occlusive thrombosis. It should be emphasized that of the 12 cases remaining with a channel 4 months later, 10 originally had had complete occlusion.

Table I.—CLINICAL DETAILS OF 10 PATIENTS WHO HAD COMPLETE CLEARANCE OF THROMBOSIS ON THE 7–10-DAY PHLEBOGRAM (GROUP 1)

CASE NO.	AGE AND SEX		STREPTOKINASE		INFUSION TIME (hr.)	COMPLICATIONS
			Loading Dose (units)	Total Dose (units × 10^6)		
1	50	F.	100,000	4·7	47	Profuse bleeding from wound
2	56	M.*	750,000	1·25	12	Nil
3	36	F.	100,000	1·6	12	Nil†
4	50	M.	250,000	2·7	22	Nil
5	63	M.*	100,000	1·6	12	Asthmatic attack requiring cessation of streptokinase
6	42	M.	1,000,000	2·5	12	Wound haematoma
7	29	F.	1,000,000	2·5	12	Nil†
8	48	M.	500,000	4·0	48	Rigors and fever
9	79	F.	100,000	2·35	32	Nil
10	68	M.	100,000	2·05	26	Nil

Cases 6–10 had post-thrombectomy rethrombosis.
* Non-occlusive iliofemoral thrombosis.
† Complete occlusion of the iliofemoral venous segment on the follow-up phlebogram at 4–6 months after streptokinase therapy.

Table III shows the clinical details of the 6 patients classed in group 3. Of these 6 cases, 4 had occlusive and 2 had non-occlusive thrombus. Three patients (2 for occlusive and 1 for non-occlusive thrombus) had had thrombectomy as the initial treatment and thrombolytic therapy was instituted to counteract post-thrombectomy rethrombosis. Five cases showed no lysis whatsoever and in 1 (non-occlusive) the lesion progressed to occlusive clot while the patient was receiving streptokinase. The details of loading dose (mean 275,000 units; range 100,000–1,000,000 units), total dose (mean 2·3 million units; range 1·4–4·6 million units), and infusion times (mean 21·1 hours; range 7–54 hours) shown in *Table III* match closely with those for group 1 patients.

Table II.—CLINICAL DETAILS OF 24 PATIENTS WHO HAD PARTIAL CLEARANCE OF THROMBOSIS ON THE 7–10-DAY PHLEBOGRAM (GROUP 2)

GENERAL CONSIDERATIONS

1. Thrombolysis and Age of Thrombus.—In patients who had undergone thrombectomy and had developed rethrombosis, the age of the thrombus was accurately known from the repeated phlebographic assessment during the postoperative period. Nineteen post-thrombectomy patients developed rethrombosis of varying degree and were treated with streptokinase. On phlebographic evidence the thrombus was less than 24 hours old in 7 patients, and in the remaining cases it had a varying age from 24 hours to 10 days. Of the 7 thrombi less than 24 hours old, 5 showed satisfactory thrombolysis, and of the remaining 12 patients with thrombi older than 24 hours, 9 showed successful lysis, 3 being failures. From these results it was apparent that within certain limits the age of thrombus was not a significant factor influencing the onset and extent of lysis.

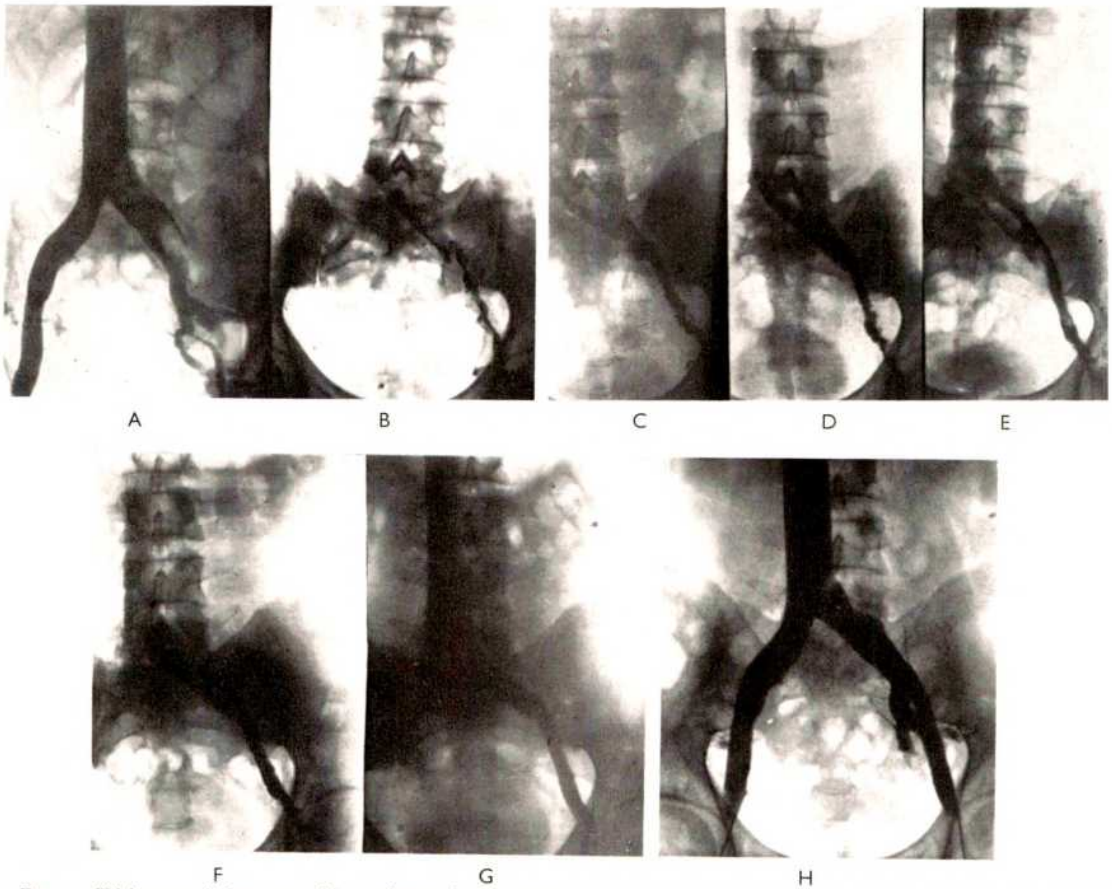

FIG. 3.—Phlebograms before streptokinase therapy by intra-osseous injection (A), and via cannula (B) showing left non-occlusive iliofemoral thrombosis. Streptokinase was administered with resultant progressive lysis at 20, 28, and 45 hours (C, D, and E). Further lysis had occurred by 3 days (F) and complete patency was achieved 11 days after streptokinase therapy (G). A check phlebogram at 4 months showed maintained patency (H).

2. Dosage and Duration of Infusion.—The duration of infusion (*Tables I–III*) was not found to bear a close relationship to the degree of lysis observed phlebographically. Of 15 patients given infusions of 12 hours or less, 5 showed complete lysis (group 1), 6 partial lysis (group 2), and 4 no lysis (group 3). In 1 of the 4 cases with no lysis the infusion was discontinued after 7 hours because the plasma fibrinogen showed a rapid decline from 784 to 183 mg. per 100 ml. In the 11 patients who showed lysis radiological changes were obvious 4 hours after the initiation of treatment. In 1 patient partial rethrombosis occurred after this time and persisted for 9 days, after which complete lysis occurred (*Fig.* 3).

In the remaining 25 patients who were given infusions with a lower initial dosage but a larger total streptokinase dosage (2·1–7·6 million units) over prolonged periods of time (16–17 hours) the maximal lysis also occurred approximately 36–48 hours after the initiation of streptokinase therapy. Thereafter the vein remained patent or rethrombosis commenced and progressed. Administration of these larger amounts of streptokinase did not guarantee eventual lysis. Furthermore, in 1 patient in group 3 complete thrombosis occurred even while the drug was being administered.

3. Complications.—The chief complication of streptokinase therapy was bleeding, usually from the cannula site; this occurred in 10 patients, necessitating the cessation of therapy in 2 cases. Apart from a haematoma in 1 patient who was given a short infusion, bleeding was related to prolonged streptokinase therapy over 12 hours and associated anticoagulant drugs. Rigors, pyrexia, and nausea complicated streptokinase administration in 3 patients, but was not severe enough to require cessation of therapy. In 1 patient an asthmatic attack was precipitated and the infusion was discontinued. Wound infection and septicaemia complicated therapy in 2 patients, requiring discontinuation of treatment in 1. This was undoubtedly due to technical difficulties with the infusion pump and cannula.

In some patients a pronounced but unexplained decrease in the haemoglobin was observed. None of the patients developed evidence of haemolysis or of blood-loss into the gastro-intestinal or genito-urinary tracts.

4. Laboratory Results.—Laboratory measurements of fibrinogen were made serially during streptokinase therapy in order to detect dangerous hypofibrinogenaemia. There was little relationship between haemorrhage and the level of fibrinogen in these 40 patients, but in 1 patient streptokinase therapy was discontinued because of a rapid decrease in fibrinogen. Although there was a rapid massive fall in plasminogen and shortening of the euglobulin lysis time (even when mixed with control plasma), these measurements did not correlate with clinical severe haemorrhage in the patients. Likewise, measurements of plasminogen and euglobulin lysis time did not show a dangerous bleeding state in any patient. The results of the haematological investigations in these patients have been critically evaluated for factors underlying thrombolysis and rethrombosis after streptokinase therapy and these will be described separately (Mavor and others, 1973).

DISCUSSION

Iliofemoral venous thrombosis is a potentially dangerous disease (Mavor and Galloway, 1969; Mavor, 1971) which poses a serious therapeutic challenge. Thrombectomy gives excellent results in the treatment of early non-occlusive venous thrombosis. However, thrombectomy is difficult in many left-sided cases and is contra-indicated in late disease, in cases where recurrent pulmonary embolism has produced severe cardiorespiratory failure, and also in post-thrombectomy rethrombosis. The need to restore venous patency to relieve venous obstruction and to avert pulmonary embolic episodes remains urgent in these patients. The use of thrombolytic therapy with streptokinase in such clinical situations is reported in this paper.

Although the aim in this study was the induction of systemic fibrinolytic activity, the administration of streptokinase via a saphenofemoral cannula takes cognizance of the clinical and experimental evidence which suggests that for its optimal action streptokinase should be delivered into the vicinity of the thrombus (Karmody and Galloway, 1969; Mavor and others, 1969). Furthermore, the in situ cannula allows a readily accessible means of phlebographic observations of the course of lysis. Such visual assessment of the iliofemoral venous segment provides an objective yardstick of success or failure of streptokinase therapy, and if a true measure of benefit of therapy is to be recorded this must be continued for a period of several days beyond the cessation of therapy.

Using such an objective control it has been found that neither preceding surgery nor the age of the thrombus is a critical factor in thrombolysis with streptokinase; in 19 patients with post-thrombectomy rethrombosis the thrombolytic response was almost identical to that in 21 patients with spontaneous venous thrombosis. In the 19 post-thrombectomy patients the age of the thrombus was accurately known from regular follow-up phlebograms. Whether the thrombus was fresh (less than 24 hours) or old (24 hours–10 days) the results of thrombolysis with streptokinase were similar. This finding is in keeping with our clinical experience in patients with iliofemoral venous thrombosis treated initially with streptokinase. In such situations one might expect that a recent thrombus, as judged by a short history, would lyse consistently and readily. However, clinically this is not always so. Conversely, occasionally patients with thrombi several days or even weeks old show rapid and satisfactory lysis; in 1 patient in this series satisfactory lysis occurred in thrombus of over 14 days' duration.

When the patients are divided according to phlebographic criteria into three groups, 34 of the 40 patients following therapy had direct venous drainage into the inferior vena cava either via a normal iliofemoral segment or one with some residual mural thrombus in it. Clinically these 34 patients had a good result. The remaining 6 failed to derive any benefit from the treatment. At present there seems to be no way of predicting the initial response or final result after streptokinase therapy. This stems from an almost complete lack of knowledge of the pharmacology of streptokinase in relationship to thrombolysis. Clearly a factor of major importance is the activity of plasmin on the surface of thrombus and within it. Yet quantitative information regarding penetration of thrombi by streptokinase, plasminogen, and plasmin is lacking. Whether the structural morphology of thrombi plays a role in their susceptibility to lysis by streptokinase is unknown, but presumably diffusion is dependent upon it. Further, the administration of streptokinase by infusion assumes that the material is stable in various vehicle solutions *in vitro* for several hours. Some preliminary studies (Walker, 1972), however, tend to cast doubt on the validity of this assumption. For the present the assessment of the dissolution of thrombi by radiological means constitutes the only clinical measurement of the degree of clot lysis in individual patients.

In comparing the three groups (*Tables I–III*) a large variation will be noted in the loading dose and the total streptokinase dose given. The loading dose was based on the streptase test. This test purports to measure the spontaneous anti-streptokinase antibody in the patient's plasma and the loading dose is adjusted to allow for the neutralization of streptokinase activity. It might have been expected that patients requiring a high loading dose would be resistant to thrombolytic therapy. However, no correlation is apparent between the susceptibility to thrombolysis and the initial titration dose. Furthermore, the final outcome in terms of restoration of complete or partial patency of the iliofemoral venous segment does not correlate with the total dose or with the duration of infusion of streptokinase. In earlier cases a large total dose of streptokinase was administered over an extended period of time in the hope that eventual lysis would occur, but experience has shown that if the thrombus is susceptible to lysis, thrombolysis begins immediately and the results are apparent phlebographically at 4–8 hours. Furthermore, lysis characteristically continues for some time after the cessation of therapy, being generally maximal at approximately 36–48 hours. In some instances complete thrombolysis may be eventually achieved several days after the cessation of therapy. After maximal lysis the vein remains patent, or in some instances where lysis is incomplete, rethrombosis of varying degree occurs, often despite continuing streptokinase infusion. As a result of these observations a smaller total streptokinase infusion dose, lasting 12 hours 40 minutes (loading dose over 40 minutes, then 1·5 million units over 12 hours), was used without compromising the incidence of good results and, when lysis occurred, the final degree of lysis. This may be related to the known adsorption by formed fibrin of plasminogen (Sherry, Fletcher, and Alkjaersig, 1959), which once activated to plasmin seems to retain its activity despite the discontinuation of its activator. On the basis of these observations it has become our practice to standardize the infusion time to 12 hours 40 minutes. This has recently been further modified to an 8-hour 40-minute infusion (40 minutes for the titration dose followed by a fixed dose of 1·5 million units over 8 hours). A short infusion time and small dosage carry important advantages in minimizing the cost. In our experience it is not possible to achieve stable anticoagulant control with drugs such as Warfarin and heparin over this short period and consequently these drugs are omitted from our current practice. Disadvantages do not result from this omission in terms of the incidence of successful lysis or rethrombosis (Mavor and others, 1973). Present evidence suggests, therefore, that streptokinase dosage schedules of 24–48 hours or more are not only unnecessary but also may be harmful in terms of complications, especially when combined with anticoagulant therapy.

That benefits accrue for the patient who has an immediate good response to streptokinase and then maintains complete or partial patency is clear. However, it is surprising that on an objective phlebographic follow-up study 2 of the 10 patients in group 1 and 12 of the 24 patients in group 2 showed complete occlusion of their iliofemoral venous segments 4–6 months after thrombolytic therapy. Certainly, from these results it would seem that the chances of insidious venous occlusion occurring subsequently is related inversely to successful thrombolysis with streptokinase. However, it is possible that the patients may have further thrombotic episodes which are unrelated to their treatment with streptokinase. Nevertheless, the incidence of late rethrombosis at 4 months after successful thrombolysis in these patients is certainly higher than in patients who have undergone thrombectomy for non-occlusive iliofemoral venous thrombosis. These findings indicate the need for further investigation into the problem of rethrombosis.

CONCLUSIONS

1. Streptokinase has been shown to be useful in the treatment of occlusive iliofemoral venous thrombosis.
2. The saphenofemoral catheter technique allows the administration of the drug in the vicinity of the thrombus and also facilitates phlebographic assessment of lysis as required.
3. Lysis of the thrombus starts immediately and is usually maximal 36–48 hours after the initiation of infusion.
4. A short infusion period of 12 hours 40 minutes during which 1·5 million units plus the loading dose are given has been shown to be as effective as an extended infusion period with larger doses. In all cases the streptase test was used to calculate the loading dose.
5. Bleeding was the chief complication and occurred in patients in whom the duration of infusion exceeded 12 hours and in whom anticoagulant drugs had also been administered.

Acknowledgements.—We acknowledge the valuable co-operation of the physicians and surgeons of Aberdeen General and Special Hospitals in referring these patients to us for study and treatment. We are also indebted to Hoechst Pharmaceuticals Ltd. for financial assistance and research grants to one of us (M. G. W.) and for the supply of streptokinase. We would also like to acknowledge the financial assistance of Aberdeen General Hospitals, and the co-operation of the Department of Pathology, Aberdeen University.

VOLVULUS OF THE CAECUM: CAECOPEXY BY POLYVINYL ALCOHOL SPONGE

By Y. EL-KATIB
FACULTY OF MEDICINE, CAIRO UNIVERSITY

SUMMARY

Six cases of caecal volvulus were encountered. In one, with a gangrenous caecum, a right hemicolectomy was carried out. In the other five, with a viable caecum, caecopexy using a strip of polyvinyl alcohol sponge was carried out. No complications or recurrences have followed this form of treatment.

CAECAL volvulus is a rare but serious type of intestinal obstruction. It comprises less than 1 per cent of all cases of intestinal obstruction. The early diagnosis of volvulus of the caecum is essential to the success of surgical treatment, because delay has the danger of allowing gangrene to occur and thus mortality rises with delay (Villet, 1959; Wolf and Wilson, 1966).

Six cases of caecal volvulus have been encountered. In the first case the caecum was gangrenous and a right hemicolectomy was done. In the subsequent 5 cases caecopexy was performed using a strip of polyvinyl alcohol sponge. No complications or recurrences have followed this form of treatment.

In this paper a method of caecopexy using polyvinyl alcohol sponge is described and the importance of early diagnosis and treatment in volvulus of the caecum is stressed.

CASE REPORTS

Case 1.—A woman aged 48 years presented with severe generalized abdominal pain of 24 hours' duration. She had also vomited and was constipated. She had had a hysterectomy for a fibroid uterus 8 years before. On examination the patient had a distended abdomen with generalized tenderness. On auscultation there were increased intestinal sounds. A plain radiograph of the abdomen showed dilated loops of small intestine. A preoperative diagnosis of intestinal obstruction of unknown nature was made.

Operation was carried out through a right paramedian incision and revealed a volvulus of the caecum. The torsion was in a clockwise direction. Detorsion of the volvulus was carried out. The caecum was gangrenous and therefore a right hemicolectomy with ileotransverse anastomosis was performed. There were no postoperative complications.

Case 2.—A woman aged 30 years in the 28th week of pregnancy presented with abdominal cramping pains, vomiting, and constipation of 2 days' duration. On examination there was generalized mild tenderness which was more marked in the right lumbar region.

A diagnosis of acute appendicitis was made and a laparotomy was performed. A volvulus of the caecum was found. The torsion was in a clockwise direction. Treatment consisted of detorsion and caecopexy with polyvinyl alcohol sponge.

The postoperative course was uneventful and the pregnancy was continued to full term.

Case 3.—A man aged 35 years presented with continuous abdominal pain in the right iliac fossa of 8 hours' duration. Initially the pain had been intermittent and colicky but later it had become continuous. The patient also had nausea and vomiting but he had passed a motion the morning before the onset of the pain. He had had an appendicectomy 3 years earlier.

On examination, the right iliac fossa was distended and somewhat tender. Auscultation of the abdomen revealed increased intestinal sounds. A plain radiograph of the abdomen showed multiple small intestinal fluid levels. A diagnosis of small intestinal obstruction was made with a possibility that it might be caused by a caecal volvulus.

At laparotomy through a right paramedian incision a volvulus of the caecum in a clockwise direction was found. Detorsion of the volvulus revealed a viable distended caecum. Caecopexy with polyvinyl alcohol sponge was carried out. The patient made an uneventful recovery. He was well and symptom-free 8 years after operation.

Case 4.—A man aged 44 years complained of pain in the right iliac fossa of 36 hours' duration with nausea and vomiting. He gave a history of chronic constipation with frequent purgation. On examination he had marked tenderness in the right iliac fossa. A tentative diagnosis of acute appendicitis was made and the abdomen was entered through a McBurney's incision; a volvulus of the caecum was found. The McBurney's incision was closed and a right paramedian incision was made. The torsion was in a clockwise direction. Detorsion and caecopexy with polyvinyl alcohol sponge were carried out. The patient was followed up for 2 years and no recurrence of symptoms occurred.

Case 5.—A woman aged 34 years presented with severe colicky pains in the umbilical region of 24 hours' duration. At first the pains were intermittent, but later they became continuous. She had vomited several times and had had no bowel motion since the onset of the symptoms. She had a history of appendicectomy 10 years before.

On examination the patient had a distended abdomen with generalized tenderness. Auscultation revealed increased intestinal sounds. The patient had had similar symptoms, but of a lesser degree, several times in the past 2 years; the symptoms had usually been relieved by an enema. On the present occasion an enema increased her symptoms markedly and therefore it was decided to perform a laparotomy.

Exploration of the abdomen revealed a volvulus of the caecum in a clockwise direction. The caecum was viable. Detorsion and caecopexy with polyvinyl alcohol sponge were carried out. The patient was followed up for 6 months with no recurrence of symptoms.

Case 6.—A man aged 30 years underwent a difficult appendicectomy, the appendix being pre-ileal and severely inflamed; the appendicectomy operation was lengthy although the caecum was freely mobile. His postoperative course was uneventful and the patient was discharged from hospital on the sixth postoperative day. On the same day the patient complained of severe abdominal colic and vomiting and on examination it was found that he had a distended abdomen with severe tenderness in the right iliac fossa. He was kept under observation for a few hours, but aggravation of his symptoms indicated small intestinal obstruction and abdominal exploration was performed. Volvulus of the caecum was found and the torsion was in a clockwise direction. The caecum being viable, caecopexy with polyvinyl alcohol sponge was carried out. The patient was followed up for more than 1 year after the operation with no recurrence of symptoms.

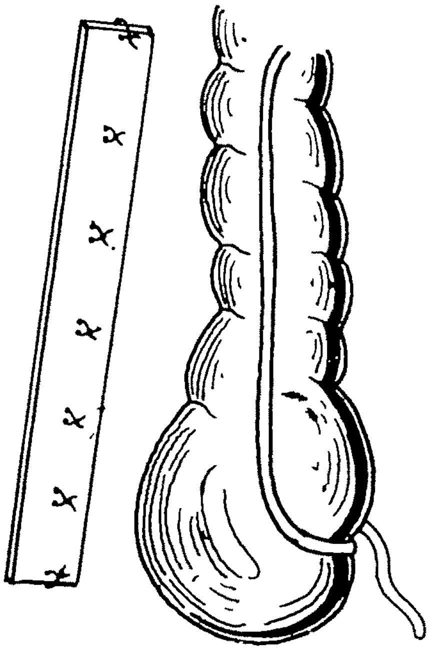

FIG. 1.—Strip of polyvinyl alcohol sponge sutured to the lateral abdominal wall.

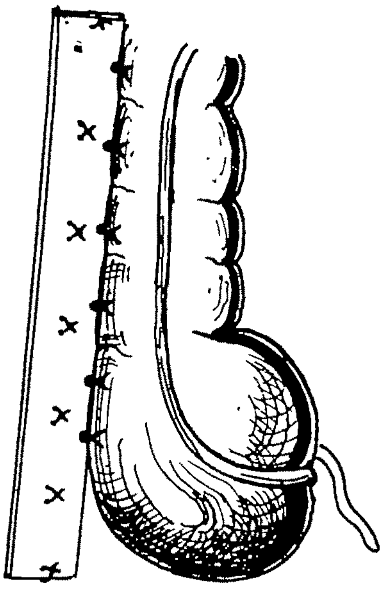

FIG. 3.—Medial layer of sutures completed.

SUMMARY OF CASES

Of the 6 cases in this series 3 were males and 3 were females. Their ages ranged from 30 to 48 years. The duration of symptoms before presentation was from 8 hours to 2 days.

One patient had a history of hysterectomy 8 years earlier and 2 patients had had an appendicectomy several years previously. In 1 case the caecal volvulus followed a few days after appendicectomy. Only 1 patient gave a history of chronic constipation and frequent purgation. One patient was in the 28t week of pregnancy. Recurrent symptoms of caecal volvulus had occurred in 1 case.

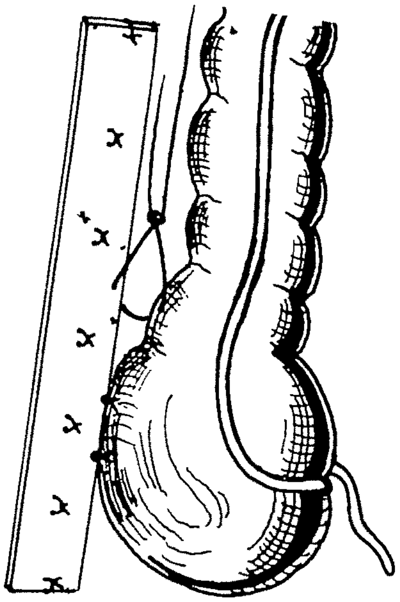

FIG. 2.—Medial layer of sutures being taken

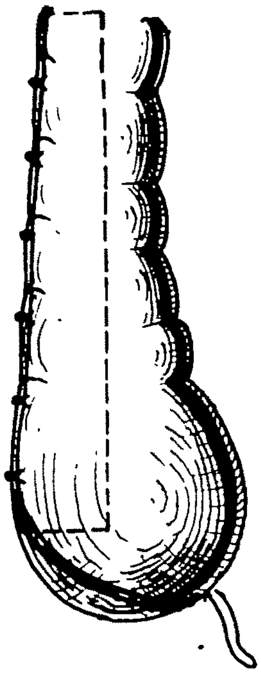

FIG 4.—Lateral layer of sutures completed. The strip of polyvinyl alcohol sponge is completely buried.

Preoperative diagnosis was small intestinal obstruction in 4 cases, with a possibility of caecal volvulus in 1 of them. In the other 2 cases the preoperative diagnosis was that of acute appendicitis.

The torsion in all 6 cases was in a clockwise direction. No distal obstruction was found in any of the cases.

One case was treated by hemicolectomy because of gangrene of the caecum and the other 5 cases were treated by caecopexy with polyvinyl alcohol sponge. None of the 5 cases treated by caecopexy had any recurrence of symptoms, 1 of them being followed for 8 years.

CAECOPEXY WITH POLYVINYL ALCOHOL SPONGE

At laparotomy when the condition of caecal volvulus is diagnosed the distended loop of bowel is decompressed by needle suction and, if the bowel wall is viable and there are no perforations, caecopexy with polyvinyl alcohol sponge is performed.

A strip of polyvinyl alcohol sponge, 4 × 15 cm., is cut, soaked in saline, and fixed along its centre with silk sutures to the lateral abdominal wall, so that it lies parallel to the line of the caecum and ascending colon (*Fig.* 1). Then, using fine silk (00), the medial edge of the polyvinyl alcohol sponge is sutured to the caecum and the proximal part of the ascending colon, including the peritoneum of the lateral abdominal wall in the stitches (*Figs.* 2, 3), with five to six sutures. The lateral edge of the strip is then sutured in the same way to the colon and caecum (*Fig.* 4). On completing this, the strip of polyvinyl alcohol sponge is completely buried lateral to the caecum and ascending colon, attaching them to the lateral abdominal wall. Closure of the abdomen without drainage terminates the operation.

DISCUSSION

Aetiology.—An abnormally mobile caecum is a necessary prerequisite for the development of caecal volvulus. This may occur as a complete malrotation (Holman, 1940; Godfrey, 1945; Butler, 1958; Armitage, 1961) or more commonly as a mobile caecum with an ileocaecal mesentery (Krippaehne, Vetto, and Jenkins, 1967) producing a volvulus by rotation about a fixed point.

Abnormal fixation of the ascending colon by a transverse band (Melchior, 1949; Krippaehne and others, 1967) or by adhesions produced by previous operations may also be predisposing factors. This was not present in any of the cases of this series.

Other precipitating factors associated with caecal volvulus are distension of the caecum by distal obstructing lesions, chronic constipation and frequent purgation (*Case* 4), pregnancy (*Case* 2), and pelvic tumours that displace the caecum upwards. Jordan and Beahrs (1953) suggested that withdrawal of abdominal packs or undue manipulation of the ileocaecal region at operation might precipitate volvulus. In *Case* 6 the volvulus occurred a few days after appendicectomy.

Pathological Process.—Most cases of caecal volvulus twist in a clockwise direction, the caecum passing laterally, then upwards, and finally to the left. In fact, all the cases in this series had twisted in a clockwise direction. Closed-loop obstruction rarely occurs before 180° of torsion, which may be considered physiological provided that there are none of the aetiological factors present. When torsion exceeds 180° two types of rotation may be noted in the included loop of bowel (Gerwig, 1969): twisting of the two segments of bowel one on the other as well as twisting of each part on its longitudinal axis. These two factors combine to effect a closed-loop obstruction. It is not the number of rotations but the tightness of the twist that produces vascular occlusion. As the torsion tightens the first circulatory impairment to the walls of the intestine is venous. The thin walls of the veins in contrast to the thick walls of the arteries are more easily compressed. Occlusion of the venous return is followed by arterial ischaemia with eventual progression to gangrene and perforation.

Clinical Picture.—Caecal volvulus occurs predominantly in the 40–60-year age-group (Meyers, Heifetz, and Baue, 1972). In the present series the ages of the patients were between 30 and 48 years with a mean of 37 years.

A review of the literature has shown that the sex ratio is variously reported as 2 : 1 in favour of females (Villet, 1959) and 3 : 1 in favour of males (Gardiner, 1947). In this series there were 3 males and 3 females.

The signs and symptoms of volvulus of the caecum are essentially the same as those of small-bowel obstruction. The onset is rapid and is generally characterized by severe intermittent colicky pains which are initially closely spaced and then become continuous. Nausea and vomiting occur early. After the existing gas and faeces in the large bowel have been eliminated, absolute constipation ensues. Rectal bleeding is uncommon but has been recorded (May, 1966; Krippaehne and others, 1967).

Frequently a history of milder attacks of similar acute abdominal pain is elicited and suggests a recurrent form of the disease (Villet, 1959). Seventy-three of the 100 patients reviewed by Donhauser and Atwell (1949) had a history of previous subacute or chronic symptoms. These episodes may have been aborted by a change in position or an enema, resulting in forceful elimination of gas or faeces per rectum with dramatic relief of symptoms. One case in the present series (*Case* 5) had this recurrent form of the disease.

The majority of patients on examination have a distended abdomen with tenderness which is most marked in the right lower abdomen. In some cases a large gas-filled loop may be palpated. The location of the segment depends upon the original location of the caecum, the length of the mesentery, and the amount of dilatation in the isolated loop (Gerwig, 1969). Often the loop migrates in the upper abdomen and may simulate gastric retention that can be excluded by passing a nasogastric tube.

A fulminating form of caecal volvulus with a short history of severe pain and tenderness has been described (Hinshaw, Carter, and Joergenson, 1959; Wolf and Wilson, 1966), and at laparotomy gangrene of the caecum is found.

Radiology.—Plain radiography of the abdomen and barium-enema examination would in some cases confirm the diagnosis of caecal volvulus. However, since all the cases present as emergencies operation should not be delayed by waiting for a barium-enema examination to be done.

McGraw, Kremen, and Rigler (1948) have documented the radiological findings, which can be summarized as follows:—

1. The caecum is greatly distended and often presents in an ectopic position. It may be possible to distinguish a caecal from a sigmoid loop by the direction of the gas shadow which faces the left lower quadrant in caecal volvulus and the right lower quadrant in sigmoid volvulus.

Frequently the distended caecum is located in the left upper quadrant of the abdomen where it may be mistaken for gastric retention, especially as both conditions have a single fluid level. Evidence that the shadow is a dilated caecum rather than the stomach may be found in the relative lack of gastric contents on aspiration and by the upright radiograph of the abdomen which usually reveals a separate air-bubble in the stomach.

2. Distended loops of small intestine which are located to the right of the caecal shadow.

3. Demonstration of the ileocaecal valve when the caecum is outlined by gas.

4. A spiral distorsion of the mucosal folds at the site of obstruction.

5. A single fluid level is seen in caecal volvulus in contrast with sigmoid volvulus which usually has two fluid levels.

6. Gas is absent from the transverse colon and beyond.

These radiological signs are not present in every case. Wolf and Wilson (1966) had radiological signs of caecal volvulus from plain radiographs in 13 out of 22 cases, and Dowling and Gunning (1969) in 2 out of 7 cases. In the present series plain radiography was done in 2 cases but in neither case was any of the radiological signs of caecal volvulus apparent.

Barium-enema examination reveals a 'bird's beak' deformity at the site of torsion in the right lower quadrant.

Management.—Emergency surgery is almost always required for all forms of caecal volvulus. The best way to treat caecal volvulus is greatly disputed in the literature. It is advisable to decompress the distended caecum by needle suction so that it can be twisted and its viability assessed.

There is general agreement that when gangrene and perforation of the bowel are present right hemicolectomy is required if the patient's general condition is satisfactory. This was carried out in the present *Case* 1. Exteriorization has been recommended for late cases and where the general condition of the patient is poor (Young, Morrison, and Wilson, 1947).

When the bowel is viable detorsion alone, caecostomy, appendicostomy, caecopexy, and right hemicolectomy have all been recommended.

Detorsion alone, caecostomy, and appendicostomy have not prevented recurrence (Melchior, 1949; Nelson and Bowers, 1956), and indeed caecostomy may provide an axis around which the caecum could rotate. In addition Krippaehne and others (1967) have reported gangrene of the abdominal wall following caecostomy, which is sometimes associated with persistent fistulas that should be formally closed.

Right hemicolectomy is an unnecessarily drastic procedure for a case with a viable bowel. However, it was advised by Melchior (1949) and Meyers and others (1972) because of the high recurrence rate after caecal fixation by sutures. Indeed, Saint (1958) found a completely mobile caecum 1 year after caecopexy by sutures to the lateral gutter. Dixon and Meyer (1948) have suggested a fixation technique whereby an incision is made in the peritoneum of the posterior iliac fossa, creating a retroperitoneal pocket into which the caecum and ascending colon are placed, and the peritoneum is sutured to the anterior taenia coli. Successful treatment by this method has been reported (Nelson and Bowers, 1956; Bell and Powers, 1962) with alleviation of symptoms and no recurrences.

The technique of caecopexy by a strip of polyvinyl alcohol sponge described in this paper is an easy procedure and allows fibrosis to develop between the caecum and ascending colon on the one side and the lateral abdominal wall on the other. No complications or recurrences have ensued in the 5 cases treated by caecopexy in this series.

CONCLUSION

Six cases of caecal volvulus have been operated upon. One had a gangrenous caecum and therefore a right hemicolectomy was carried out. The other 5 cases have been treated by caecopexy using a strip of polyvinyl alcohol sponge to initiate fibrosis between the colon and lateral abdominal wall. No complications or recurrences followed this technique. The importance of early diagnosis and treatment to prevent the development of gangrene of the bowel is stressed.

IN BRONCHITIS early optimism confirmed by further clinical experience

“On the basis of our earlier experience,[1] we said of trimethoprim that ‘we believe it to represent a major discovery and to have far-reaching therapeutic possibilities.’ Not only have we had no subsequent reason to alter this belief, but in our view some very promising possibilities have yet to be explored.”[2]

More effective than ampicillin or tetracycline

In the reduction obtained in sputum volume and purulence SEPTRIN* has been shown to be superior to either ampicillin or tetracycline.[3,4]

Highly active against both primary and secondary invaders

"... not only are the two primary pathogens *Strep pneumoniae* and *H influenzae* sensitive, but so are secondary invaders such as klebsiella which often replace them after antibiotic treatment."[2]

"It is seldom at the completion of a clinical trial that authors are inclined to classify an antimicrobial ..., but in this case, on our results, we feel that the combination of trimethoprim plus sulphamethoxazole can only be considered excellent on the criteria originally specified, namely the elimination of the infecting microorganism."[5]

TWO CASES OF IDIOPATHIC VOLVULUS OF THE SMALL BOWEL

BY J. C. POSTLETHWAITE AND P. A. DUPONT
ST. MARY'S HOSPITAL, LONDON

SUMMARY

Volvulus of the entire small bowel about its mesentery without predisposing anatomical defects is rare in the Western world but more common in less developed countries. Two cases are described, the aetiology is discussed, and a valuable diagnostic sign is highlighted. It is suggested that the high mortality is avoidable by prompt diagnosis and early surgery.

VOLVULUS of the small intestine about its mesentery is a well-known complication of congenital defects of gut rotation in both children and adults (Devlin, 1971).

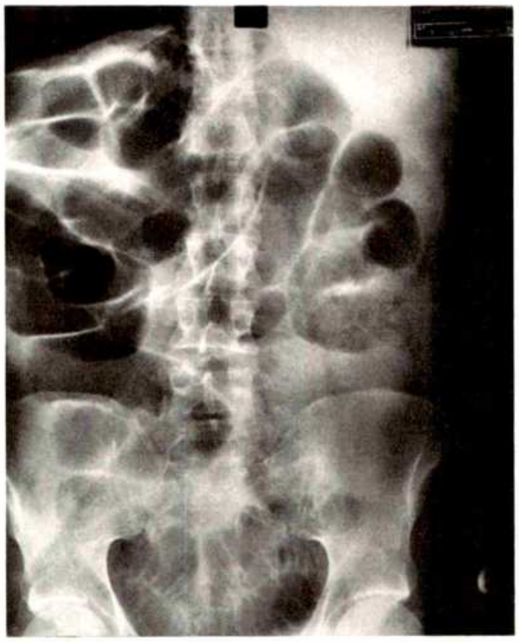

FIG. 1.—*Case* 1. Supine radiograph of the abdomen, demonstrating jejunal bowel pattern in the pelvis.

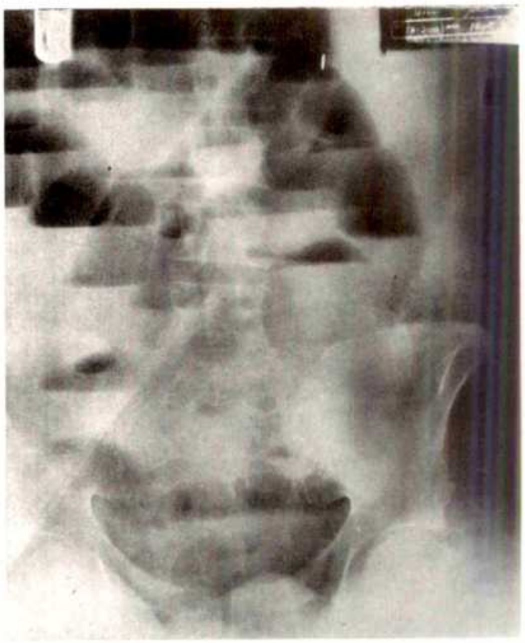

FIG. 2.—*Case* 1. Erect radiograph of the abdomen, demonstrating multiple small-bowel fluid levels.

Primary volvulus occurring without any obvious predisposing cause is rare and is probably decreasing in incidence in Europe and America (Vick, 1932; Walker, 1960), although it is common in India (Agarwal and Singh, 1966), Africa (Kerr and Kirkaldy-Willis, 1946), and Iran (Vaez-Zadeh, Dutz, and Nowrooz-Zadeh, 1969). The cases of primary small-bowel volvulus described here occurred in previously fit Englishmen.

CASE REPORTS

Case 1.—A 31-year-old white Englishman presented as an emergency with a 12-hour history of severe colicky and generalized abdominal pain of sudden onset, accompanied by bilious vomiting. Shortly before the onset of the pain he had consumed 6 pints of beer, as was his habit most evenings. He had a past history of a single hospital admission as a child for undiagnosed abdominal pain.

On examination the patient was distressed, shocked, apyrexial, and in obvious pain. His abdomen, which bore no scars, was distended and uniformly tender, and bowel-sounds were obstructive in type. There were no herniae present, and rectal examination revealed a few soft faeces.

A full blood-count, erythrocyte-sedimentation rate, plasma urea, and electrolytes were all within normal limits. A chest radiograph was normal. Abdominal radiographs (*Figs.* 1, 2) showed distended loops of small bowel and numerous fluid levels. Loops with a jejunal mucosal pattern were seen to lie in the lower half of the abdomen, and the featureless small-bowel pattern occupied the upper half. A clinical diagnosis of acute small-bowel obstruction with probable strangulation was made, and after a short period of intravenous fluid therapy and gastric aspiration the patient underwent laparotomy. He was found to have an 180° anti-clockwise volvulus of the small bowel about its mesentery. The jejunal segment was heavily loaded with fluid and hung down into the pelvis, its mesentery being drawn tautly downwards across the origin of the rest of the small-bowel mesentery. The distal small bowel was displaced upwards into the upper abdomen. There was free blood-stained fluid, and the small bowel was distended and plum-coloured, but viable. The small bowel was deflated and the volvulus was reduced. The anatomy of the small-bowel mesentery was normal. The abdomen was closed without any attempt at enteropexy.

The patient's recovery was marred only by a pneumococcal chest infection, which responded quickly to treatment with antibiotics. He was discharged 10 days postoperatively and has had no further symptoms. A barium-meal and follow-through examination has demonstrated no congenital defects of the alimentary tract.

Case 2.—A 30-year-old white Englishman presented in the Casualty Department, St. Mary's Hospital, London, with a 2-hour history of very severe generalized abdominal pain with colicky exacerbations, the maximal pain being umbilical and to the right of the umbilicus. After admission he had vomited copiously, the vomit being mainly bilious. The patient stated that for the week prior to these severe symptoms he had had vague abdominal pains but no other symptoms. He had no previous medical history or hospital admission.

On examination the patient appeared to be in considerable pain and was obviously in agony during the colicky exacerbations, when he curled up in the left lateral position or in the knee–elbow position. The abdomen was a little distended; there were no scars or herniae. On palpation there was generalized tenderness with an impression of a vague mass to the right of the umbilicus. Bowel-sounds were reduced and obstructive in type. Rectal examination was non-contributory. Haematological investigation revealed haemoconcentration, with a haemoglobin of 22·6 g., packed-cell volume of 71·5 per cent, and blood-urea of 56 mg. per 100 ml. Radiographs of the chest were normal, whilst those of the abdomen revealed dilated obstructed small-bowel loops, mainly to the right of the umbilicus. After rapid rehydration and nasogastric aspiration the patient was submitted to laparotomy 6 hours after the onset of his acute symptoms. A 180° volvulus of the small bowel about its mesentery was found which after reduction revealed that 90 per cent of the small bowel, from a few centimetres from the duodenojejunal flexure to a few centimetres from the ileocaecal region, was distended, black, and gangrenous. No arterial pulsation was found and no other bowel or mesenteric abnormality was noted. Improvement was attempted by conservative methods only and after an hour only minimal improvement was obtained. The abdomen was closed routinely. The patient gradually deteriorated over the next 4 days and died on the fourth day after surgery.

A post-mortem examination was carried out, the pathologist noting irregular ulceration and membranous exudates of the small bowel which he postulated might have predisposed to the volvulus.

DISCUSSION

The aetiology of primary volvulus of the entire small intestine was discussed by Wilms (1906), who considered that mesenteric rotation occurred frequently following food intake. Spasokukozki (1909) considered that bulky poorly digested food accompanied by hypermotility were causative factors. Vaez-Zadeh and others (1969) postulated that the heavily laden jejunum sinks into the pelvis, displacing empty distal bowel upwards, thus initiating rotation of the mesentery. The frequency of the condition in countries in which unprocessed vegetables form a large part of the diet adds strength to this theory (Kerr and Kirkaldy-Willis, 1946).

Spasmodic reports of the condition in England and the United States (McKechnie and Priestly, 1936; Weber, 1945; Walker, 1960; Renton, 1965), however, do not confirm dietary factors as a cause. In the present *Case* 1 it is possible that a high intake of alcohol led to the heavily laden jejunum prolapsing into the pelvis. Marginal abnormality of mesenteric dimension has been described (Vaez-Zadeh and others, 1969) but does not bear critical examination.

Tagart (1950) described the knee–elbow position adopted by sufferers as the 'position of relief', and considered this an important diagnostic sign; this was a prominent finding in the present *Case* 2. *Case* 1 illustrated a useful diagnostic invesgtiation, i.e., the presence of jejunal bowel pattern in the lower abdomen on a plain abdominal radiograph, while the featureless distal small bowel is seen to ride high in the upper half of the abdomen.

Most writers are agreed that the right course of action is to resect any gangrenous bowel, if it is not too extensive, and to return the decompressed intestine without enteropexy (Rowlands, 1929; Woods, 1945; Maingot, 1957). Kerr and Kirkaldy-Willis (1946) described a method of exteriorization and enterotomy to decompress and fix the bowel.

Several reports from Europe, Scandinavia, and the United States quote a high mortality due mainly to late diagnosis (Svane, 1965), which supports a 'look-and-see' policy when faced with signs of unexplained acute obstruction.

ASSESSMENT OF ACUTE BLOOD-LOSS BY DETERMINATION OF CHANGE IN RED-CELL VOLUME

By T. SMITH[*] and T. C. NORTHFIELD[†]

MEDICAL RESEARCH COUNCIL GASTROENTEROLOGY RESEARCH UNIT AND DEPARTMENT OF GASTROENTEROLOGY,
CENTRAL MIDDLESEX HOSPITAL, LONDON

SUMMARY

A method is described for the quantitative measurement of acute blood-loss from any source by determination of change in the red-cell volume. The accuracy and sensitivity of this method have been assessed in 23 patients admitted to hospital with acute gastro-intestinal bleeding. The method was sufficiently sensitive to detect a change in red-cell volume of 3 per cent. Reproducible results were obtained, duplicate measurements of red-cell volume deviating from the mean by less than 4 per cent. Completely separate daily measurements, in subjects not undergoing further haemorrhage, deviated from the mean by less than 5 per cent.

THERE is a need for a universally applicable method for the accurate quantitative measurement of blood-loss in order to study the physiological and metabolic changes occurring in patients undergoing acute haemorrhage. We have therefore developed a technique for measuring changes in red-cell volume (R.C.V.). The conventional method of carrying out a single R.C.V. determination using ^{51}Cr-labelled red cells (Sterling and Gray, 1950) has been modified in several respects in order to enable three completely separate R.C.V. measurements to be carried out at daily intervals. We have assessed the accuracy and sensitivity of this method under clinical conditions by studying 23 patients admitted to hospital with acute upper gastro-intestinal bleeding.

MATERIALS AND METHODS

Preparation of Labelled Red-cell Stock.—In order to avoid the need to repeat the time-consuming labelling process, a stock of each patient's labelled red cells was prepared and aliquots were used for daily R.C.V. estimations. Special attention was paid to the dilutions made and extra care was taken with sterile procedures, but otherwise the labelling technique was essentially the same as that described by Mollison and Veall (1955).

Approximately 35 ml. of the patient's blood were placed in a sterile 50-ml. bottle containing 10 ml. of acid–citrate–dextrose solution, and this bottle was used as the stock container. All transfers to and from it were made through a Subaseal stopper using syringes. The red cells were labelled with 120 μc. ^{51}Cr (approximately 1 μg. of Cr as sodium chromate), then washed three times with saline, and finally made up to 40 ml. in saline prior to storage at 4° C. until required for use. The efficiency of the labelling procedure was always greater than 90 per cent.

Subsequent dilutions and volumes taken for injection were adjusted so that the amounts of ^{51}Cr in the second and third injections were respectively about two and four times larger than that in the first injection; the total amount administered in three such injections did not exceed 100 μc. ^{51}Cr. This improved the sensitivity of measuring the radioactivity in circulating red cells following the second and third injections, in the presence of radioactivity from the prior injection, while ensuring that the total body radiation dose was small (<30 mrad).

First R.C.V. Determination.—Five ml. of the stock of labelled red cells (15 μc. ^{51}Cr) were injected using a glass syringe, care being taken to ensure efficient entry of red cells into the circulation. The actual volume injected was later accurately determined by weighing the volume of water required to fill the syringe to the same mark as that used for the red-cell suspension, the average volume being calculated from at least three such calibrations. In order to determine the amount of radioactivity injected, an aliquot (2 ml.) was withdrawn from the stock of labelled red cells for duplicate haematocrit and counting measurements. For the latter, aliquots (0·1 ml.) were diluted to 4 ml. with water, after which the remainder of the 2-ml. sample was centrifuged and aliquots (0·1 ml.) of the supernatant were similarly diluted. Venous blood samples (10 ml.) were withdrawn from the patient at 15, 25, and 30 minutes after the injection and collected in heparinized tubes. On account of the small amount of radioactivity injected the red cells of these samples were concentrated by centrifugation prior to counting. A 4-ml. aliquot of the packed red-cell fraction was taken for counting and samples were also removed for haematocrit determination.

All the radioactivity measurements were made using a well-type NaI scintillation counter (Ekco type N550A) set to accept the ^{51}Cr photopeak. A small amount of solid Saponin was added to all the counting samples which contained blood in order to lyse the red cells and so avoid variations in counting efficiency due to sedimentation. Counting times were adjusted to reduce the counting error to less than 2 per cent for all the samples except the supernatant of the injected red-cell suspension. The correction which allowed for supernatant radioactivity was found to be so small that this degree of accuracy was unwarranted.

Haematocrit determinations were made using the microhaematocrit technique. Plain capillary tubes containing blood were sealed with Critoseal vinyl plastic putty (Biological Research Inc.). These were centrifuged for 5 minutes in a Hawksley centrifuge, after which measurements were made using a Hawksley Microhaematocrit Reader.

---

[*] Present address: M.R.C. Department of Clinical Research, University College Hospital Medical School, London, W.C.1.

[†] Present address: Gastroenterology Unit, Mayo Clinic, Rochester, Minnesota 55901, United States.

R.C.V. was calculated for each of the blood samples taken 15, 25, and 30 minutes after injection, using the following formula:—

$$\text{First R.C.V. (ml.)} = \frac{{}^{51}\text{Cr in injected red cells}}{{}^{51}\text{Cr per ml. red cells in withdrawn blood sample}},$$

$$= \frac{(C_1 V/0{\cdot}1) - [C_2 V(1-H_1)/0{\cdot}1]}{C_3/4 \cdot H_3}$$

$$= \frac{40 H_3 V}{C_3}[C_1 - C_2(1-H_1)],$$

where C_1 is the radioactivity (counts per second) in a 0·1-ml. aliquot of the injected red-cell suspension; C_2 is the radioactivity (counts per second) in a 0·1-ml. aliquot of the supernatant of the injected red-cell suspension; C_3 is the radioactivity (counts per second) in a 4-ml. aliquot of the packed red-cell fraction of a blood sample withdrawn from the patient; H_1 is the haematocrit of the injected red-cell suspension (expressed as a fraction); H_3 is the haematocrit of the packed red-cell fraction of a blood sample withdrawn from the patient (expressed as a fraction), and V is the volume (ml.) of the injected red-cell suspension. The second term in the numerator of the above expression is the correction for residual ^{51}Cr in the fluid fraction of the injected red-cell suspension. This correction factor was always less than 1 per cent and confirmed that the cells had been efficiently washed prior to injection.

Second and Third R.C.V. Determinations.—A second R.C.V. determination was carried out about 24 hours after the first. Immediately before the second injection a 10-ml. sample of blood was withdrawn from the patient for counting as previously described, in order that the concentration of radioactivity remaining in the circulating red cells as a result of the first injection could be measured and corrected for. After a single washing with sterile saline the stock of labelled red cells was resuspended in saline to a volume of 40 ml., and 10 ml. (25 μc. ^{51}Cr) were injected. The calibration of the syringe and the subsequent procedure were essentially the same as described for the first R.C.V. determination. The second R.C.V. was calculated from the following formula:—

$$\text{Second R.C.V. (ml.)} = \frac{40V[C_1 - C_2(1-H_1)]}{(C_3/H_3) - (C_4/H_4)},$$

where C_1, C_2, C_3, H_1, H_3, and V have their previous notation as referred to the second injection. C_4 is the radioactivity (counts per second) in a 4-ml. aliquot of the packed red-cell fraction of a blood sample withdrawn from the patient immediately before the second injection and H_4 is the haematocrit value of this fraction. The second term in the denominator of the above equation represents the correction for the amount of ^{51}Cr present in circulating red cells at the time of the second injection as a result of the first injection.

For the third R.C.V. determination, which was carried out after a further 24 hours, the stock of red cells was washed as before and resuspended in sterile saline to a volume of 25 ml. After a 10-ml. sample of blood had been taken from the patient in order to measure the amount of residual radioactivity from the first and second injections, 20 ml. (55 μc. ^{51}Cr) of the labelled red-cell suspension were injected. The subsequent procedure and calculations were the same as those used for the second R.C.V. determination.

RESULTS

Reproducibility of the 15-, 25-, and 30-minute Values in Individual R.C.V. Determinations.—Repeated R.C.V. determinations, as described above, were made on 23 patients with acute gastro-intestinal haemorrhage. Three successive R.C.V. measurement were made on 7 patients and two measurements only were made on the remainder, giving a total of 53 R.C.V. determinations. For all except 1 patient three values were obtained at each R.C.V. determination, based on the measurement of blood samples taken 15, 25, and 30 minutes after the injection of labelled red cells.

In *Fig.* 1 the R.C.V. values calculated from the 25-minute blood samples have been plotted separately against those based on the 15- and 30-minute samples. In each case there is a high degree of correlation with the 25-minute values ($r > 0{\cdot}99$) and the regression lines are both very close to the 45° line, representing perfect agreement. It is apparent, however, that the calculations based on the measurement of blood samples taken at 15 minutes gave lower estimates of R.C.V. than those based on the 25- and 30-minute samples in some of the patients with relatively large red-cell volumes. These results suggest that mixing of labelled red cells within the total circulating red-cell mass had not been completed within 15 minutes in such patients. For this reason all R.C.V. estimations were taken as the mean of the two values based on the measurements of the 25- and 30-minute blood samples.

Reproducibility of Separate, Successive R.C.V. Determinations.—In 10 of the patients investigated no loss of blood occurred after the first injection of labelled red cells, as shown by the absence of radioactivity in the faeces collected during the investigation and for 10 days afterwards. Three R.C.V.s were measured in 4 of these patients and only 2 in the other 6 patients. The results of these determinations are shown in *Fig.* 2, in which the first R.C.V. is plotted against the second and third R.C.V.s. Taking the second and third R.C.V.s together as a single group, the regression on the first R.C.V. is very close to the 45° line, representing perfect agreement, and the correlation coefficient is $+0{\cdot}98$. When the first and second R.C.V.s and the first and third R.C.V.s were considered as pairs of measurements, individual values differed from the mean of paired values by less than $+3$ per cent in 12 out of 14 cases, and by less than $+5$ per cent in all the cases.

Sensitivity of the Method.—In 13 patients whose faeces contained radioactivity there was a mean fall in R.C.V. of 42 per cent, whereas in 10 patients whose faeces contained no detectable radioactivity there was a mean rise of 2·3 per cent ($P < 0{\cdot}01$ by Wilcoxon's rank test). There was no overlap between the two groups with the exception of 1 patient who had a rise in R.C.V. of 94 ml. (4·1 per cent) despite the presence of radioactivity in his faeces (*Fig.* 3). This result is probably misleading, however, because the patient almost certainly had an episode of bleeding after the completion of the final R.C.V. determination, since he had a sudden episode of breathlessness, followed by a fall in the haemoglobin level from 14·6 to 7·3 g. per 100 ml. over the course of the next 2 days.

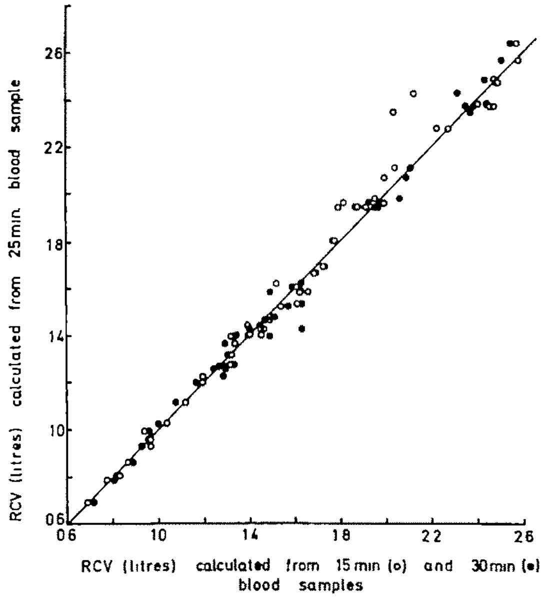

FIG. 1.—Relationship between the R.C.V. calculated from a blood sample taken 25 minutes after the injection of ^{51}Cr-labelled red cells and the R.C.V.s calculated from blood samples taken 15 and 30 minutes after the injection. The 45° line representing perfect agreement is shown.

Prior to completion of the final R.C.V. measurement he had shown no evidence of haemorrhage, and hourly measurements of pulse-rate, blood-pressure, and central venous pressure had remained steady.

If the latter result is ignored, radioactivity was detectable in the faeces of all the patients who had a fall in the R.C.V. of 3·1 per cent or more, but was not detectable in the faeces of those who had a fall in the R.C.V. of 1·3 per cent or less. Thus on the evidence of the present results a fall in the R.C.V. of about 3 per cent indicates the sensitivity of the method for detecting blood-loss. For a 70-kg. man this represents about 150 ml. of whole blood.

DISCUSSION

Methods currently available for the quantitative measurement of blood-loss all have disadvantages. Measurement of faecal radioactivity following the injection of ^{51}Cr-labelled red cells gives no indication of the timing of any episode of haemorrhage (Hughes and Burkinshaw, 1962), and is only applicable to gastro-intestinal bleeding. Although successive measurements of blood-volume based on plasma-volume determination using ^{125}I albumin can now be made quite easily by semi-automatic methods (Williams and Fine, 1961; Hobbs, 1965), plasma volume is affected not only by haemorrhage but also by the passage of fluid into and out of the extracellular space. Furthermore, calculation of blood-volume from plasma volume involves assumptions about the relationship between venous and total body haematocrit that are not necessarily valid under conditions of acute haemorrhage (Hope and Verel, 1955). Although red-cell survival is reduced in patients having recurrent haemorrhage (Tudhope, 1958), this does not give an accurate quantitative assessment of the size of the haemorrhage. Whole-body counting methods in which ^{59}Fe is used to label haemoglobin

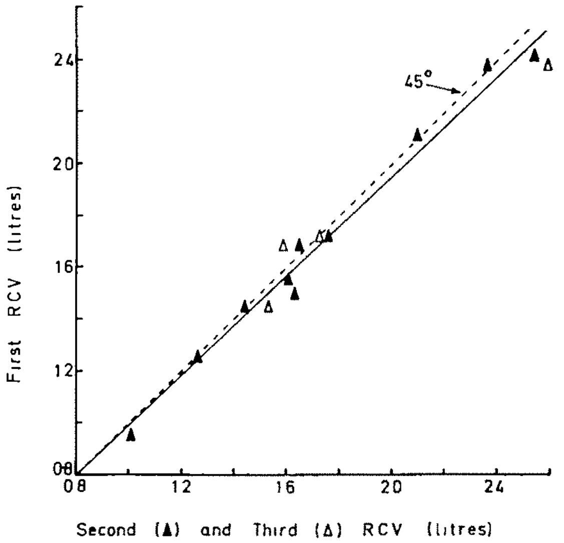

FIG. 2.—Relationship between the first R.C.V measurement and the second and third measurements (made at intervals of 1 and 2 days respectively) in patients who did not re-bleed. The regression of the second and third R C V.s on the first R.C.V. and the 45° line representing perfect agreement are shown.

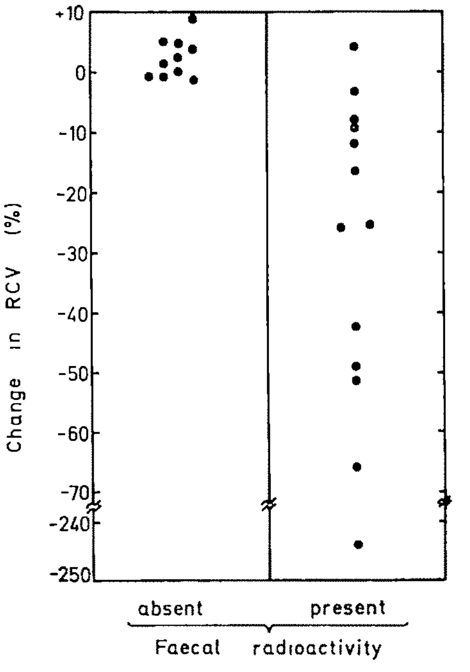

FIG. 3.—Percentage change in R.C.V. in 13 patients who re-bled and 10 patients who did not, as indicated by the presence or absence of ^{51}Cr in the faeces.

(Stack, Smith, Jones, and Fletcher, 1969) require an initial delay period of several days to allow incorporation of the tracer, and only measure blood-loss if the shed blood has been completely eliminated from the body by the time of the measurement.

Successive measurements of R.C.V. provide a more direct and specific assessment of blood-loss and are not affected by haemodilution or haemoconcentration. They also give an indication of the timing of any episode of haemorrhage. The method is reasonably sensitive, being able to detect a fall in R.C.V. of about 3 per cent of the total R.C.V. The accuracy of this technique for measuring changes in R.C.V. is best assessed from the reproducibility of individual R.C.V. measurements, under circumstances in which the R.C.V. can be expected to remain constant. Separate measurements based on the 25- and 30-minute blood samples deviated from the mean of the two measurements by less than ± 4 per cent in 98 per cent of cases, although slightly less consistent results were obtained using the 15-minute samples, probably because of incomplete mixing of the tracer during the first 15 minutes. Separate daily R.C.V. measurements in patients undergoing no further haemorrhage, as indicated by the absence of faecal radioactivity, showed a mean daily rise in R.C.V. of 38 ml. This can probably be attributed to the release of new red cells from the bone-marrow. The average rate of red-cell production in normal subjects is 14–20 ml. per day but this may be increased three to four times in severe haemorrhage (Tudhope, 1958). Despite this, daily measurements of the R.C.V. were reproducible, successive measurements on an individual patient deviating from the mean of two or three values measured in that patient by less than ± 5 per cent in all the patients with no recurrent haemorrhage.

This method of measuring the change in the R.C.V. has been found of value in correlating blood-loss with change in the central venous pressure (Northfield and Smith, 1970). It is probably applicable to the quantitative measurement of acute blood-loss from any source.

Acknowledgements.—We are grateful to Sir Francis Avery Jones and Dr. T. D. Kellock for allowing us to study patients admitted under their care.

These studies formed part of a M.D. thesis submitted to the University of Cambridge by one of the authors (T. C. N.).

THE EFFECT OF INTESTINAL PREPARATION ON FLUID AND ELECTROLYTE BALANCE

By T. T. IRVIN, C. J. HAYTER, K. E. WARREN, and J. C. GOLIGHER

THE UNIVERSITY DEPARTMENT OF SURGERY AND THE DEPARTMENT OF NUCLEAR MEDICINE, THE GENERAL INFIRMARY AT LEEDS

SUMMARY

It has been suggested that circulatory instability in elderly patients after the induction of anaesthesia is frequently accounted for by undiagnosed hypovolaemia, particularly in cases of intestinal cancer when preoperative mechanical bowel preparation has been used.

In the present study measurements were made in 25 patients undergoing mechanical bowel preparation for large-bowel cancer surgery.

Blood-volume measurements remained within normal limits after bowel preparation, and in 5 patients no change was found in total body exchangeable sodium, extracellular fluid volume, and plasma volume measured before and after bowel preparation.

Fluid and electrolyte balance studies in 11 cases showed that renal conservation of sodium occurred in the 24 hours preceding surgery and this is probably accounted for by diminished dietary intake. Circulatory instability after the induction of anaesthesia was commonly encountered but in most cases this was not the result of preoperative dehydration.

It has been suggested that dehydration and occult hypovolaemia are commonly present in elderly patients submitted to elective surgical operations (Beling, Bosch, and Carter, 1972; Waltemath and Harkness, 1963). These factors are held to be at least partly responsible for the high incidence of arterial hypotension encountered in this age-group after the induction of anaesthesia, particularly in malnourished patients and patients with intestinal carcinoma (Scott, 1961).

In our experience significant arterial hypotension is a common finding after the induction of anaesthesia in patients with large-bowel cancer and it seemed probable that a significant degree of dehydration might obtain in such patients since they are all subjected to a vigorous schedule of mechanical bowel preparation and intestinal antisepsis. Accordingly, we have studied the effects of intestinal preparation on the fluid and electrolyte balance in patients with carcinoma of the colon and rectum, and also the circulatory response to the induction of anaesthesia.

Table I.—PROTOCOL FOR THE 5-DAY COURSE OF INTESTINAL PREPARATION

DAY	APERIENT	ENEMAS OR SUPPOSITORIES	BOWEL ANTISEPTIC	DIET
1	Magnesium sulphate, 1 g. t d.s	Soap-and-water enema or 2 Dulcolax suppositories in evening	Sulfathaladine, 2 g 4-hourly during day	Ordinary
2	Magnesium sulphate, 1 g. t d.s	Soap-and-water enema or 2 Dulcolax suppositories in evening	Sulfathaladine, 2 g 4-hourly during day	Ordinary
3	Magnesium sulphate, 1 g t d.s	Soap-and-water enema or 2 Dulcolax suppositories in evening	Sulfathaladine, 2 g 4-hourly during day	Ordinary
4	Magnesium sulphate, 1 g. t.d s.	Soap-and-water enema or 2 Dulcolax suppositories in evening	Sulfathaladine, 2 g 4-hourly during day + kanamycin, 1 g 4-hourly	Ordinary
5	Castor oil, 2 oz. at 6.00 a m	Soap-and-water enema or 2 Dulcolax suppositories in evening	Sulfathaladine, 2 g. 4-hourly during day + kanamycin, 1 g. 4-hourly	Liquid
6 (day of operation)	None	None	Sulfathaladine, 2 g 4-hourly + kanamycin, 1 g up to 4–5 hours before operation	None

MATERIAL AND METHODS

Twenty-five patients undergoing preparation for elective large-bowel surgery were studied; informed consent was obtained in each case. Details of the 5-day course of intestinal preparation are shown in *Table I*. Mechanical bowel preparation was achieved with magnesium sulphate, enemata, suppositories, and castor oil, and intestinal antisepsis was obtained with sulphonamides and kanamycin. Diet was withheld during the 24-hour period prior to surgery and no oral intake, apart from the intestinal antiseptics, was permitted within 10 hours of operation.

Group 1.—In 14 patients (8 males and 6 females) plasma volume measured a few hours prior to surgery was the only investigation performed. The average age of these patients was 60 years (S.D. ± 9). Twelve of the patients were found at operation to have carcinoma of the colon or rectum, 1 patient was found to have Crohn's disease of the colon, and in the remaining case the pathology was diverticular disease of the sigmoid colon.

Group 2.—In 11 cases of large-bowel cancer (8 males and 3 females) fluid and electrolyte balance, changes in body-weight, and the haemodynamic response to surgery were measured. The average age of the patients in this group was 71 years (S.D. ± 7). In 5 cases plasma volume, total body exchangeable sodium, and extracellular fluid volume were also determined.

Patients were weighed to the nearest 100 g. on a metabolic scale each day. The haemoglobin and haematocrit, plasma and urinary sodium, potassium, urea, and osmolarity were also estimated daily. The haemoglobin and haematocrit were measured electronically on a Coulter counter and the urea and electrolytes were determined on an Autoanalyzer. Osmolarity was measured by freezing-point depression on an advanced osmometer.

Radio-isotopic studies were made prior to the 5-day course of intestinal preparation and again in the 24-hour period preceding surgery, in the latter case plasma-volume measurements being made within a few hours of operation. In group 1 patients plasma volume (P.V.) was measured using ^{125}I-labelled human serum albumin (H.S.A.). Plasma activity was assayed using a well-type scintillation counter in blood samples taken 20, 40, and 60 minutes after injection and the plasma volume was obtained by retrapolation of the dilution curve to zero time. The total blood-volume was estimated from the venous haematocrit after correction for the body : venous haematocrit ratio (Chaplin, Mollison, and Vetter, 1953).

In group 2 patients P.V., 24-hour total exchangeable sodium (Na^{e+}), and bromine 'space' (as a measure of extracellular fluid volume) were measured on two occasions. ^{125}I- or ^{131}I-labelled H.S.A., ^{24}Na sodium chloride, and ^{82}Br ammonium bromide (in doses of 5, 40, and 40 μc. respectively) were given as a single intravenous injection and blood samples were collected (*see above*) for P.V. measurement. All the urine was collected in the following 24 hours and a pooled aliquot was assayed for activity lost during equilibration. A plasma sample was obtained at 24 hours for assay of ^{24}Na and ^{82}Br activity and for the measurement of plasma sodium on the Autoanalyzer.

The plasma and urine activities due to the different radio-isotopes were separated by pulse-height analysis using a well-type sodium iodide scintillation counter and ^{24}Na and ^{82}Br standards. Radio-iodine, which was excluded in this procedure in order to obtain good physical separation of ^{24}Na and ^{82}Br, was assayed after a period of 7 days, thus taking advantage of the differential decay rates. For the first plasma volume ^{125}I was used, and for the second ^{131}I. A pulse-height setting which excluded ^{125}I was used for assay of the samples comprising the second P.V. measurement. The dilution 'spaces' for ^{24}Na and ^{82}Br were calculated in the usual way from the administered dose (less the activity lost in urine) and the 24-hour plasma activity. The Na^{e+} was calculated from the sodium space and the specific activity of ^{24}Na.

A minimum of 10,000 pulses was collected for each count, and duplicate counts were carried out on all the assay samples. Duplicate counts did not vary one from the other by more than 2 per cent.

In group 2 cases blood-pressure, pulse, and central venous pressure were recorded before the administration of the anaesthetic premedication and again after the induction of anaesthesia. Central venous pressure was measured with a saline manometer after the insertion of a catheter via an antecubital vein into the superior vena cava under radiographic control. The sternal angle was used as the zero reference point. Opiate and atropine were administered intramuscularly 45–60 minutes before the induction of anaesthesia. Thiopentone was used for the induction of anaesthesia and was given slowly by intravenous injection until the loss of the eyelash reflex occurred. A dose of 6–8 mg. of pancuronium was administered as a muscle relaxant, intermittent positive-pressure ventilation was commenced with a 50 per cent nitrous oxide/oxygen mixture, and the various circulatory parameters were then measured.

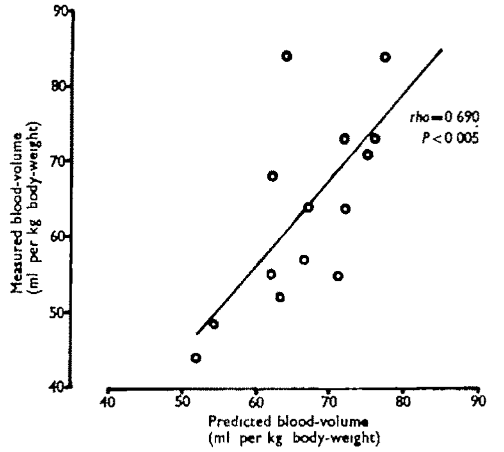

FIG. 1.—The highly significant correlation between the measured blood-volume and the predicted results based on body-weight and height in 14 patients in group 1.

Table II.—CORRELATION BETWEEN PREOPERATIVE WEIGHT-LOSS, CENTRAL VENOUS PRESSURE, AND BLOOD-PRESSURE CHANGE ON THE INDUCTION OF ANAESTHESIA IN 11 PATIENTS IN GROUP 2

AGE AND SEX	SYSTOLIC BLOOD-PRESSURE (mm. Hg)			CENTRAL VENOUS PRESSURE BEFORE PREMEDICATION (cm H_2O)	PLASMA VOLUME (ml. per kg body-weight)		WEIGHT-LOSS IN 24 HOURS BEFORE OPERATION (percentage of body-weight)
	Before Premedication	Before Induction	After Induction		Before Bowel Preparation	Before Premedication	
66 F	140	142	90	−4·0	38·7	39·5	1·3
75 F.	130	135	70	+2·5	—	—	0·8
59 F.	135	135	115	+3·5	44·7	46·1	1·3
65 M.	145	105	90	−4·0	—	—	1·6
67 M.	140	120	75	−4·0	54·4	62·8	0·6
75 M	140	130	90	−4·0	—	—	3·9
83 M	150	170	80	−4·5	49·5	48·2	0·6
68 M.	140	140	115	−1·0	—	—	2·6
66 M.	155	160	140	−4·0	—	—	2·5
71 M.	145	160	90	−9·5	—	—	4·9
81 M.	150	170	135	−5·5	52·3	59·4	3·0

It quickly became apparent that the important preoperative changes in body-weight occurred within the 24-hour period prior to surgery and two further groups of patients were studied during this period to determine the relative effects of intestinal preparation and fluid and dietary restriction on preoperative weight-loss.

Group 3.—Nine patients (7 males and 2 females) were weighed at the beginning and end of the 24-hour period prior to haemorrhoidectomy. The average age of these patients was 60 years (S.D. ± 6). Intestinal preparation was not used in this group but oral intake consisted of fluids only during the period of study. As in the group 2 cases, no oral intake was permitted during the 10 hours preceding operation.

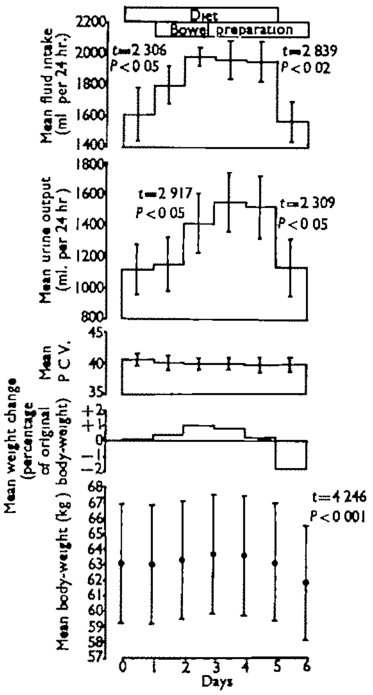

FIG. 2.—The mean fluid intake, urine output, haematocrit, and body-weight in 11 patients in group 2 undergoing a 5-day course of bowel preparation. There was a statistically significant increase in fluid intake and urine output during the course of bowel preparation until the 24-hour period preceding surgery when a significant reduction in fluid intake and urine output occurred. Haematocrit did not change significantly but there was a significant reduction in body-weight during the 24-hour period preceding surgery.

Group 4.—Nine patients (7 males and 2 females) were similarly studied prior to operation for groin hernia, peptic ulcer, or cholelithiasis. The average age of the patients in this group was 59 years (S.D. ±

13). Diet was not restricted in this group except during the 10-hour period prior to surgery when no oral intake was permitted.

RESULTS

Group 1.—*Fig.* 1 shows the statistically significant correlation between the blood-volume measured in 14 patients at the end of the 5-day course of intestinal preparation and the predicted value derived from height and body-weight using the method of Nadler, Hidalgo, and Bloch (1962). The average measured blood-volume was 63·7 ml. per kg. (S.D. ± 12·2), which was not significantly different from the expected value of 66·5 ml. per kg. (S.D. ± 7·5).

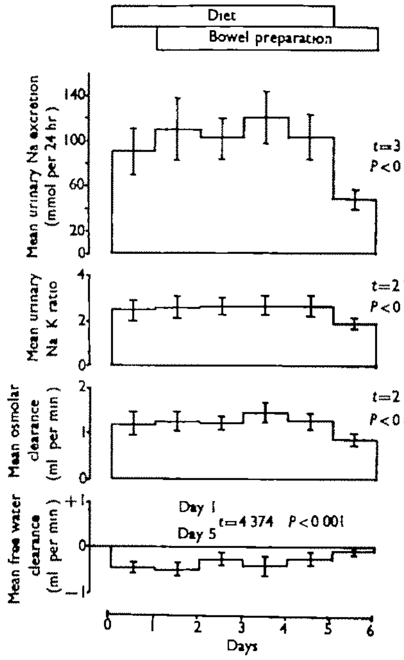

FIG. 3.—Mean urinary sodium excretion, sodium : potassium ratio, osmolar clearance, and free-water clearance in 11 patients in group 2 undergoing a 5-day course of bowel preparation. There was a statistically significant reduction in urinary sodium excretion, sodium : potassium ratio, and osmolar clearance during the 24-hour period preceding surgery. Free-water clearance remained negative but there was a statistically significant trend towards positive values during the course of bowel preparation.

Group 2.—*Fig.* 2 shows the fluid-balance measurements in 11 patients during the 5-day course of intestinal preparation. It can be seen that the average fluid intake increased significantly during the course of the study, as did the urine flow, until the 24-hour period prior to surgery when there was a statistically significant reduction in the fluid intake, urine flow, and body-weight. There was no significant change in the haematocrit during the period of study.

The data on urinary solute and water excretion in group 2 patients are shown in *Fig.* 3. Little change was observed until the 24-hour period preceding surgery when there was a statistically significant reduction in the urinary sodium excretion, the urinary sodium : potassium ratio, and osmolar clearance. Although free-water clearance remained negative, there was a significant trend towards positive values during the course of intestinal preparation.

Fig. 4 shows the plasma volume, total body exchangeable sodium (Na^e+), and extracellular fluid volume (E.C.F.) measurements obtained in 5 of the group 2 patients before and after the 5-day course of bowel preparation. No definite trend is apparent and there is no significant difference between the results before and after bowel preparation.

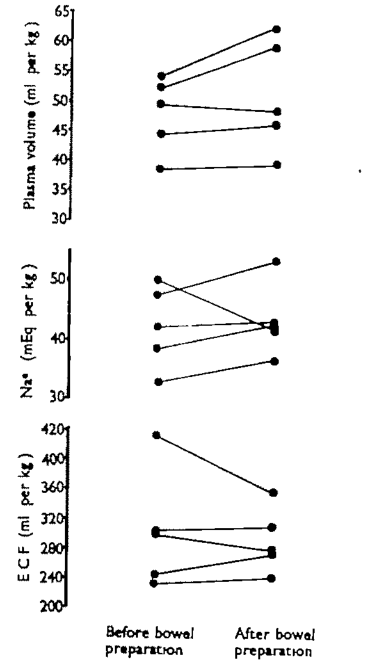

FIG. 4.—Plasma volume, total body exchangeable sodium (Na^e+), and extracellular fluid volume (E.C.F.) measurements in 5 patients in group 2 before and after bowel preparation.

Table III—COMPARISON OF AVERAGE WEIGHT-LOSS DURING THE 24-HOUR PERIOD BEFORE OPERATION IN GROUPS 2, 3, AND 4

GROUP	NO. OF PATIENTS	WEIGHT 24 HOURS BEFORE OPERATION (kg.)	WEIGHT BEFORE OPERATION (kg.)	WEIGHT-LOSS	
				kg.	Per cent
2. Bowel preparation and dietary restriction	11	63·1 ± 3·8	61·9 ± 3·6	1·3 ± 1·0	1·9
3. Dietary restriction. No. bowel preparation	9	72·0 ± 5·2	70·5 ± 5·1	1·5 ± 0·2	2·0
4. No dietary restricton. No bowel preparation	9	65·3 ± 4·0	64·3 ± 4·0	1·0 ± 0·2	1·5

Systolic blood-pressure changes resulting from premedication and the induction of anaesthesia in group 2 patients are correlated with the preoperative central venous pressure, plasma-volume, and body-weight measurements in *Table II*. The combined effects of premedication with opiates and the induction of anaesthesia with thiopentone produced a fall in the systolic blood-pressure of 50 mm. Hg or more in 7 of the 11 patients but, with the exception of 1 case, there was no obvious difference between the venous pressure, body-weight, or plasma-volume measurements in hypotensive and normotensive subjects. In 1 patient anaesthetic hypotension was associated with a preoperative central venous pressure of -9.5 cm. H_2O and a weight-loss amounting to almost 5 per cent of the body-weight.

Groups 3 and 4.—*Table III* shows the average change in body-weight of patients in groups 2, 3, and 4 during the 24-hour period preceding surgery. Group 2 cases were permitted fluids only by mouth whilst the 5-day course of intestinal preparation was completed. Patients in groups 3 and 4 had no bowel preparation but group 3 cases were permitted fluids only by mouth, whereas no dietary restriction was imposed on group 4 cases apart from the usual preoperative overnight fast. There was no statistically significant difference between the weight-loss of patients in groups 2, 3, and 4. The average weight-loss expressed as a percentage of body-weight was 1·9 per cent in group 2, 2·0 per cent in group 3, and 1·5 per cent in group 4.

DISCUSSION

It is alleged that dehydration and hypovolaemia are commonly present in elderly patients and, when unrecognized, may result in circulatory instability during anaesthesia (Beling and others, 1952; Scott, 1961; Waltemath and Harkness, 1963). It has been suggested that such problems are magnified in certain diseases including large-bowel cancer, and certainly one might expect dehydration to result in such cases from intensive preoperative mechanical bowel preparation. There is a lack of clinical data on the subject, however, and it appears that the diagnosis of dehydration or hypovolaemia is often based on subjective impressions alone rather than the results of objective measurement. Indeed, in the only previous study of the effects of intestinal preparation Trinkle, Fisher, Ketcham, and Berlin (1964) found no significant difference between the blood-volume measurements in 5 patients before and after a 5-day course of intestinal preparation.

In the present study we have found no conclusive evidence that a significant degree of hypovolaemia obtains in patients undergoing operation for large-bowel cancer (*Figs.* 1, 4), and there is no indication that intestinal preparation has a significant effect on the fluid and electrolyte status of such cases until the 24-hour period preceding surgery, when there is significant weight-loss and a reduction in urinary sodium excretion (*Figs.* 2, 3). Associated with the renal conservation of sodium, probably as a result of increased aldosterone secretion, there is a reduction in urine osmolarity and an increased clearance of free water. It appears, however, that intestinal preparation plays a small part in such changes since similar changes in body-weight were found in patients who had no bowel preparation but who were also subjected to dietary restriction (*Table III*). It seems probable, therefore, that the altered pattern of urinary salt and water excretion results largely from dietary restriction of salt.

Circulatory upset occurred in a proportion of patients during the induction of anaesthesia, but it could not be correlated with hypovolaemia or dehydration with the possible exception of 1 case. In this instance, anaesthetic hypotension was associated with a preoperative weight-loss amounting to almost 5 per cent of the body-weight and a central venous pressure of -9.5 cm. H_2O. Absolute measurements of the central venous pressure must be interpreted with extreme caution or perhaps not at all (Ryan and Howland, 1966), but it seems probable that significant dehydration obtained in this case although there was no evidence of azotaemia or change in the venous haematocrit. There are many other possible explanations for circulatory upset, of course, such as the depressant action of opiates and barbiturates, the vasodilator properties of anaesthetics or muscle relaxants, or pathological changes in the blood-gases (Jenkins and Beck, 1963), but nitrous oxide and pancuronium should have little effect on the blood-pressure (Eisele, Trenchard, Stubbs, and Guz, 1969; Kelman and Kennedy, 1971) and it seems likely that arterial hypotension in our patients resulted from the central effects of opiate premedication and thiopentone induction and the mechanical effects of positive-pressure ventilation.

It is concluded, therefore, that there is little evidence that intestinal preparation results in significant fluid and electrolyte imbalance in cases of large-bowel cancer or that such patients are hypovolaemic when anaesthetized. Nevertheless, circulatory upset on the induction of anaesthesia is frequently encountered. These patients respond well to fluid administration but it would be incorrect to assume that the majority are dehydrated.

THE RESPONSE OF THE LOWER OESOPHAGEAL SPHINCTER TO A TEST-MEAL STIMULUS

BY A. ROSZKOWSKI, P. GUILLOU, AND G. R. GILES
UNIVERSITY DEPARTMENT OF SURGERY, LEEDS (ST. JAMES'S) UNIVERSITY HOSPITAL, LEEDS

SUMMARY

The response of the lower oesophageal sphincter to test meals has been assessed using two manometric techniques. Tests in which the sphincteric pressures were continuously monitored proved to be the most satisfactory and test meals which were predominantly meat extract provided the greatest stimulus. Normal subjects increased the sphincteric pressure 86·7 per cent above the basal levels within 30 minutes of the introduction of the test meal, whereas patients with symptomatic hiatus hernia had diminished responses with pressure increases of only 30 per cent above basal levels. Patients with peptic ulceration or stricture of the oesophagus failed to respond to any form of test meal.

THERE is a great deal of evidence that the function of the lower oesophageal sphincter determines competence at the gastro-oesophageal junction (Cohen and Harris, 1971). Though the study of the lower oesophageal sphincter by intraluminal manometry has been undertaken for a number of years its value in the clinical situation has proved somewhat limited. In this report we have assessed the effect of test meals on sphincteric function using two techniques in an attempt to improve the clinical value of this type of investigation. The results suggest a possible role for test meals for the investigation of patients with symptoms of gastro-oesophageal reflux.

MATERIALS AND METHODS

Manometric investigation of the lower oesophageal sphincter area was performed using water-filled polyethylene tubes (external diameter, 1·4 mm.; internal diameter, 1·2 mm.) each with a side-hole (1·2 mm. diameter) at 5, 10, and 15 cm. from distal end respectively. These tubes were constantly perfused with water at 0·6 ml. per minute and were connected via strain-gauge transducers (Statham PEA D 300) to an amplified electromanometer (Cardiac Recorders Ltd.), the deflexions being recorded on moving photographic paper. Respiratory movements were monitored simultaneously from a pneumograph strapped around the chest.

In the first series of experiments intraluminal pressures in the oesophagus and stomach were determined by the technique described by earlier workers (Fyke, Code, and Schlegel, 1956; Atkinson, Edwards, Honour, and Rowlands, 1957). A triple-lumen tube was swallowed into the stomach and then withdrawn at 0·5-cm. intervals with pressure measurements being made from two tubes at each point for at least five full respiratory cycles. This technique results in a profile of the intraluminal pressures exerted by the lower oesophageal sphincter. The pressure tracings obtained in this way were measured using the end-inspiratory and end-expiratory excursions. The latter gave the more consistent reading and are, therefore, reported in this paper. After recording the sphincteric pressure profile under resting conditions, the test meal was introduced into the stomach through the most distal side-hole of the third tube. Sphincteric profiles were repeated after 15, 30, 60, 120, and 180 minutes.

In the second series of tests a quadruple-lumen tube was constructed using polyethylene tubing of similar dimensions to that described previously, with a cross-section diameter of 0·5 cm. One of these tubes was used to introduce the test meal into the stomach. The second tube had a side-hole (1·2 mm. diameter) 15 cm. from the distal end and was used to record pressures exerted in the upper part of the stomach. Five centimetres above this level the side-hole of the third tube measured pressure in the lower oesophageal sphincter. The fourth tube had a side-hole 5 cm. higher and recorded pressures in the lower oesophagus. The protocol for this technique called for the measurement of the sphincteric profile in the way outlined above, and then the tube system was fixed to the nose so that pressures could be continuously and simultaneously recorded from the stomach, lower oesophageal sphincter, and the lower oesophagus. Particular care was necessary in the fixation of the tube system in patients with hiatus hernia because of the frequent displacement of the cardia into the thoracic cavity. In all the subjects it proved important that the side-hole recording the sphincteric pressure was situated at the point of maximum sphincteric pressure. The pressure tracings were analysed by measuring the mean pressure recorded from any one side-hole over a period of at least 1 minute before the introduction of the test meal and for 2 hours afterwards.

Two types of test meal were used. The majority of the meals consisted of a commercial meat-extract preparation in which three cubes of desiccated meat extract (Oxo) were crumpled and dissolved in 200 ml. of water at 37° C. The other test meal consisted of 25·2 g. of skimmed-milk powder, 27·6 g. of glucose, and 14·8 g. of corn oil (Lundh, 1962). This mixture was easily homogenized in 200 ml. of water at 37° C. The test meals were introduced into the stomach via the tube system and with the subject's knowledge of their content.

Sphincteric profile test meals were carried out in 12 normal subjects (6 tests with the meat extract, 6 tests with the Lundh test meal). Continuous pressure-monitoring tests were performed in 8 normal subjects with the meat-extract test meal. Two groups of patients with gastro-oesophageal reflux were studied. Nine patients with hiatus hernia had symptoms of heartburn and regurgitation severe enough to warrant surgery. Another group of 5 patients had, in addition, severe dysphagia and were found to have an early stricture in the lower oesophagus or severe oesophagitis with peptic ulceration. The mean age of the normal subjects studied was 42 years and of the patients with hiatus hernia 54 years (range, 42–75 years). All the pressure values are presented as the mean plus 1 standard error of the mean.

RESULTS

1. Sphincteric Profiles following the Meat-extract Test Meal.—

a. Effect on Sphincteric Pressure.—From each sphincteric pressure profile the maximum pressure was noted. *Fig.* 1 shows the mean maximum sphincteric pressure under resting conditions and for 3 hours following the meat-extract test meal. The mean resting pressure of 20·3 ± 3·4 cm. H_2O reached a peak of 28·2 ± 3·3 cm. H_2O at 60 minutes after meat-extract stimulation and thereafter fell towards resting levels.

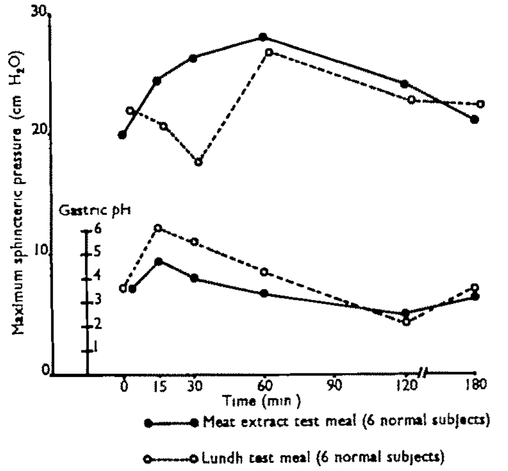

FIG. 1.—The mean lower oesophageal sphincteric pressures and mean gastric *p*H in normal subjects following stimulation with meat-extract (6 tests) or a Lundh (6 tests) test meal using the withdrawal technique.

Assuming a rise in sphincteric pressure of at least 5 cm. H_2O to be a positive response to meat extract, 4 of the subjects tested showed measurable changes in sphincteric tone. The 2 remaining subjects showed minor decreases in pressure.

A comparison of the sphincteric pressures measured by the two recording tubes in the same individual often showed a poor correlation, with maximum sphincteric pressures often varying up to 5 cm. H_2O at the same point of time after meat-extract stimulation.

The changes in sphincteric pressure were appreciated most easily by noting the percentage change in maximum sphincteric tone compared with the resting pressure. Thus the mean maximum percentage increase in sphincteric pressure within 30 minutes of meat-extract stimulation was 20·0 ± 9·0 per cent and within 60 minutes 32·4 ± 8·1 per cent (*Table I*).

b. Length of Sphincteric Area.—The mean sphincteric length of 4·2 ± 0·36 cm. was unaltered by meat-extract stimulation and was similar in the recordings of both tubes. There did not seem to be any change in the position of the sphincteric pressure area in relation to the point of respiratory reversal and thus it was assumed that the test meal did not cause alterations in anatomico-spatial relationships of the cardia.

c. Gastric Pressure and Pressure in the Lower Oesophagus.—The mean fundal pressure of 12·2 ± 0·68 cm. H_2O showed only minor changes in pressure following meat-extract stimulation. No significant changes were recorded in oesophageal pressures.

Table I.—MEAN MAXIMUM PERCENTAGE INCREASE IN SPHINCTERIC PRESSURE OVER RESTING LEVELS

	TIME AFTER MEAT EXTRACT GIVEN (min.)		
	30	45	60
Withdrawal technique			
Normal subjects	20·0 ± 9·0	—	32·4 ± 8·1
Continuous technique			
Normal subjects	86·7 ± 29·0	86·7 ± 29·0	88·3 ± 29·4
Hiatus hernia	29·8 ± 9·9	33·0 ± 11·7	36·8 ± 11·7
Hiatus hernia with stricture	0	0	0

d. pH Changes in the Gastric Aspirate.—Since routine radiological screening of the position of the tube system was not undertaken it is not certain from which gastric site the aspirate was sampled, though it was likely to be from the main body of the stomach. The *p*H of the samples under resting conditions varied from 1·8 to 6·4 with a mean of 3·6 ± 0·7. Following the introduction of meat extract (*p*H 5·8) the *p*H of the gastric aspirate became slightly more alkaline (*Fig.* 1) for 30 minutes but remained at about a mean of *p*H 3·0 for the remainder of the test.

2. Sphincteric Profiles following the Lundh Test Meal.—

a. Effect on Sphincteric Pressure.—*Fig.* 1 shows the mean sphincteric pressure under basal conditions and for the 3 hours following the Lundh test meal. Pressures observed during the first 30 minutes of the test showed a mean decrease in pressure to 17·6 cm. H_2O at 30 minutes. This decrease was seen in 4 of the 6 tests. Eventually 4 of the 6 subjects had distinct increases in maximum sphincteric pressures and the mean resting pressure rose from 22·0 ± 2·8 to 26·8 ± 3·0 cm. H_2O.

b. Length of Sphincteric Area.—The mean sphincteric length for the 6 subjects was 3·56 cm. The mean length at 120 and 180 minutes was 4 cm. but this was not taken to be indicative of any change in the length of the sphincteric area.

c. Gastric Pressure and Pressure in the Lower Oesophagus.—The mean fundal pressure for these tests was 13 ± 0·8 cm. H_2O under resting conditions and only minor changes were observed over the course of 3 hours. Similarly, the pressures exerted in the lower oesophagus were unaffected by the test meal.

d. pH Changes in the Gastric Aspirate.—The *p*H of the Lundh test meal was 6·2. Thus, the *p*H of the gastric aspirate immediately following the introduction of the meal rose to 6·0 and then gradually declined as the stomach became more acidic over the next 2 hours (*Fig.* 1).

3. Continuous Pressure Monitoring of the Sphincter following a Meat-extract Test Meal.—

a. Responses in 8 Normal Subjects.—The sphincteric pressure increased within 5–10 minutes after the introduction of the meat extract, reaching a peak at 20 minutes and then slowly declining towards the basal level over the next hour (*Fig.* 2). All the normal subjects showed a sphincteric pressure increase of 5 cm. H_2O or more and the mean sphincteric pressure rose from 29·4 ± 2·7 cm. H_2O to a mean maximum of 45·4 ± 4·1 cm. H_2O some 20 minutes after the meat-extract stimulation. All except 1 subject reached the peak of sphincteric pressure increase by 30 minutes and thereafter the mean sphincteric pressure declined. The pressure recorded by the gastric tube also showed minor increases following the meat extract which paralleled the changes seen in the sphincteric pressure (*Fig.* 2).

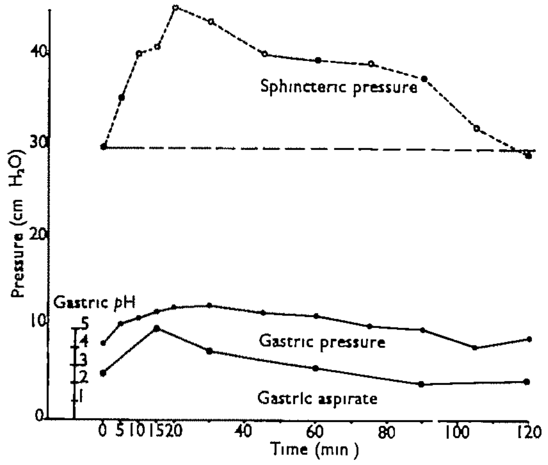

FIG. 2.—The mean sphincteric and gastric pressures and the mean *p*H of gastric aspirate in 8 normal subjects following stimulation with meat extract and using the continuous recording technique.

The mean gastric *p*H rose from 2·6 ± 0·3 to a mean maximum of 5·1 ± 0·2 (range 4·2–6·2) at 15 minutes after the meat extract (*Fig.* 2). Thereafter the gastric contents became more acidic and very little contamination of the gastric aspirate by meat extract was found after 45 minutes.

b. Responses in 9 Patients with Symptomatic Hiatus Hernia.—The mean pressure recordings of the 9 patients are shown in *Fig.* 3. The mean basal sphincteric pressure was 28·4 ± 2·4 cm. H_2O, which was similar to that in the group of normal subjects. Two of the patients had no pressure increase following the test meal and the remainder all showed increases in excess of 5 cm. H_2O. The mean sphincteric pressure for the group reached a maximum of 33·6 ± 2·4 cm. H_2O and then declined towards basal levels by 75 minutes. The timing of the peak pressure response was more variable and delayed than that in normal subjects. At 120 minutes after stimulation 6 patients still showed a sphincteric pressure elevated above resting levels (*Fig.* 3). The mean gastric pressure in these patients rose slightly from a mean of 12·5 ± 1·8 cm. H_2O to a mean maximum of 15·2 ± 2·1 cm. H_2O at 30 minutes after the test meal and then declined to basal levels (*Fig.* 3). No changes were noted in the oesophageal pressure with meat extract stimulation. The mean *p*H of the gastric aspirate rose from 3·0 ± 0·3 to 4·9 ± 0·2 at 15 minutes.

c. Sphincteric Responses in 5 Patients with a Symptomatic Hiatus Hernia and Evidence of a Peptic Stricture.—Some difficulty was experienced in defining the lower oesophageal sphincter in this group of patients. The mean sphincteric pressure was 8·6 ± 1·2 cm. H_2O. None of these patients showed any variation in this low resting sphincteric pressure with meat-extract stimulation.

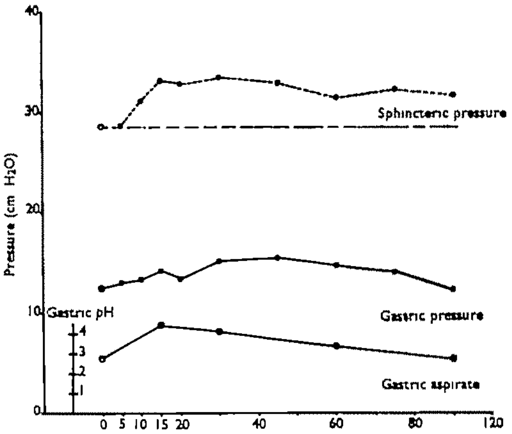

FIG. 3.—The mean sphincteric and gastric pressures and the mean *p*H of the gastric aspirate in 9 patients with a symptomatic hiatus hernia following stimulation with meat extract and using the continuous recording technique.

d. Percentage Change in Sphincteric Pressure.—In *Table I* the mean percentage increase in sphincteric pressure above the resting tone is shown for the three groups. It can be seen that normal subjects respond to the meat extract more quickly and to a greater degree than the patients with an uncomplicated but symptomatic hiatus hernia. In normal subjects the mean percentage increase within 30 minutes of stimulation was 86·7 ± 29·0 per cent, compared with 29·8 ± 9·9 per cent in patients with a symptomatic hiatus hernia. Since some patients reached the peak of sphincteric pressure later than 30 minutes the mean percentage increase within 60 minutes of the test meal rose to 88·3 ± 29·4 per cent in normal subjects and 36·8 ± 11·7 per cent in the patients with hernia. The differences between these two groups are significant at 30 minutes ($P < 0·05$). Patients with a complicated hiatus hernia had no response to the test meal.

DISCUSSION

The basic technique of oesophageal manometry demands a tube system of low volume with open end or side-holes and a constant flow of fluid along the tubes (Pope, 1970). The high pressure zone of the lower oesophageal sphincter is well shown by the withdrawal technique and demonstrates the position, shape, length, and the level of resting tone of the sphincter. The use of this technique has been criticized by Kaye and Showalter (1971) on the grounds of poor reproducibility in the same individual. This is a criticism with which we would concur and would add that it has proved to be a relatively insensitive method of detecting changes in the lower oesophageal sphincter pressure following a test meal. The static tube system with a side-hole continuously monitoring the lower oesophageal sphincter pressure is more convenient for both the patients and the investigators, and this method proved a highly sensitive method of detecting change in the lower oeosophageal sphincter pressure following a test meal. However, it is not always easy to site the tube so that the point of maximum sphincteric pressure is monitored, nor can it be certain that changes in position of the side-hole do not occur, particularly in patients with hiatal hernia in whom the sphincteric pressure is very low or where severe oesophagitis and fibrosis are present.

The meat-extract test meal has previously been used to assess antral function in patients with peptic ulceration (Welbourn and Burns, 1964; Giles and Clark, 1966). Since the lower oesophageal sphincter has been shown to respond to both endogenous and exogenous circulating gastrin (Giles, Mason, Humphries, and Clark, 1969; Castell and Harris, 1970), the meat-extract test meal may also be useful as a natural and physiological stimulus for assessing sphincteric function. The stimulus to the gastric antrum for gastrin release is probably a direct chemical one. However, it may be related, in part, to alkalinization of the gastric antrum, since the *p*H of the meat extract and the gastric aspirates for 1 hour following the meal remain relatively alkaline.

The effect of the meat-extract test meal in normal subjects was to produce an immediate and marked rise in the lower oesophageal sphincter pressure, with a mean rise of 86·7 per cent above the resting levels within 30 minutes of the stimulus. The initial pressure increase could no doubt be attributable to gastrin release from the antrum. However, since the *p*H of the gastric contents always declined below 3·0 within 60 minutes of the stimulus, it is unlikely that the gastric antrum continued to release gastrin. The persistent elevation of pressure in some subjects at 2 hours after meat extract had been given may be due to low levels of circulating gastrin or to some other mechanism. It is clearly advantageous that the sphincter maintains an elevated tone for an extended period of time following a meal, though it must be admitted that previous experience with the meat-extract test meal, under slightly different conditions, suggested that the stimulus to gastric acid secretion had completely waned by 60 minutes (Giles and Clark, 1966).

Routine use of the Lundh type of test meal was precluded by the fact that 4 of the 6 normal subjects tested showed significant falls in the lower oesophageal sphincter pressure during the early part of the test. Pressure increases were ultimately seen, though less than after meat extract. The decreases in the lower oesophageal sphincter pressure with this test meal may be related to the corn-oil content, which has previously been reported to produce inhibition of the lower oesophageal sphincter pressure (Castell and Nebel, 1971). The mechanism for this inhibition must be speculative, but it is probable that it is produced by release of secretin from the duodenum or is due to the action of enterogastrone.

Cohen and Harris (1971) have been able to correlate closely the occurrence of gastro-oesophageal reflux to the resting tone of the lower oesophageal sphincter and have questioned the relevance of the clinical diagnosis of hiatus hernia, the implication being that the function of the lower oesophageal sphincter and its response to various forms of physiological stress are the main determinants of gastro-oesophageal competence. Previous workers (Lind, Warrian, and Wankling, 1966; Cohen and Harris, 1971) have used physical stress in the form of Valsalva manœuvres and raised intra-abdominal pressure as a test of lower oesophageal sphincter function. Significantly reduced sphincteric responses to these stimuli were found in patients with gastro-oesophageal reflux. The response of the lower oesophageal sphincter to a test meal is also an appropriate stimulus since it produces the situation in which reflux is liable to occur over a longer period. The differences demonstrable between normal subjects and patients with reflux may therefore have more significance.

The patients presented in this study are by no means representative of the majority of patients with hiatus hernia since they all had symptoms severe enough to be referred for surgery. One group of these patients was found on investigation to have a lower oesophageal sphincter which was barely identifiable by manometric means and was associated with very severe oesophagitis and with early stricture or peptic ulceration. These patients with a poor sphincter tone had no increase in the pressure of the lower oesophageal sphincter on stimulation with the meat-extract test meal. It is uncertain whether this lack of response is attributable either to a primary defect of the lower oesophageal sphincter or to damage resulting from the gastro-oesophageal reflux.

The second group of patients was characterized by severe symptoms and a radiologically demonstrable hiatus hernia and had a lower oesophageal sphincter resting pressure not significantly different from that seen in normal subjects. The sphincteric response to meat extract in this group of patients was variable. Two of the patients had no response at all, but pressure increases were seen in the remaining 7 patients. The response seen in these patients differed from that in normal subjects in several respects. The mean amplitude of the pressure increase at 30 minutes was only 35 per cent above the resting tone compared with 86·7 per cent in the normal subjects. Thus, although the resting tone of the lower oesophageal sphincter in these patients was not abnormally low, an apparent defect in the response to a normal food stimulus was demonstrated. This defect might permit a gastro-oesophageal reflux to occur in response to food, both immediately after the meal and for several hours afterwards. The cause of this defective sphincteric response can only be conjectured since it might result from a failure of the gastric antrum to release gastrin on stimulation, or from a relative non-responsiveness of the lower oesophageal sphincter to gastrin in these patients, or be the direct result of anatomical displacement of the sphincter into the thoracic cavity.

It is not yet clear whether the meat extract sphincter test will be of additional diagnostic value in patients with gastro-oesophageal reflux, since a full spectrum of these patients has yet to be studied. However, the tests may provide some help in deciding upon the type of operative procedure to be employed in the surgical management of these patients. It may be possible to identify those patients in whom the lower oesophageal sphincter is completely defective and who require a procedure which creates a new valve at the gastro-oesophageal junction (Nissen, 1961; Skinner and Belsey, 1967). Conversely, patients with a lower oesophageal sphincter which is still responsive to meat extract might achieve equally satisfactory results with simpler operative procedures, such as simple repair of the hiatus or gastropexy. The test of this hypothesis will require a long-term clinical study.

THE EFFECT OF HYPOPHYSECTOMY ON THE CORTISOL SECRETION IN 4 PATIENTS WITH ADVANCED METASTATIC BREAST CANCER

By A. A. M. LEWIS and N. DESHPANDE

DEPARTMENT OF SURGERY, ROYAL FREE HOSPITAL, LONDON, AND DEPARTMENT OF CLINICAL ENDOCRINOLOGY,
IMPERIAL CANCER RESEARCH FUND, LONDON

Summary

A raised cortisol production rate is found in patients with advanced breast cancer. The cortisol production rate was estimated before and after hypophysectomy in 4 patients with metastatic disease and was found to fall to one-sixth of the original level. It is concluded that the high preoperative cortisol production rate was dependent on pituitary function and was not due to the production of corticotrophin by the tumour cells.

It is now generally accepted that the estimation of the urinary metabolites of androgens and cortisol forms a useful measurement for predicting the response of a patient with advanced breast cancer to endocrine ablation (Bulbrook, 1965). Similar information can be obtained by measuring the plasma levels of these two groups of compounds (Deshpande, Hayward, and Bulbrook, 1965). The measurement of plasma titres of these steroids indicated that in metastatic breast cancer the plasma levels of cortisol are raised and this is mainly due to a higher production rate of the hormone as no other variables, such as the half-life of cortisol, its metabolic clearance or distribution, showed any differences when compared with those in normal control subjects (Jensen, Deshpande, Bulbrook, and Doouss, 1968a, b). It was felt that the raised cortisol production might be due to gross production of corticotrophin by tumour tissue such as that reported in patients with lung cancer and other neoplasms (Liddle, Givens, Nicholson, and Island, 1965). If so, the elimination of pituitary adrenocorticotrophic hormone (ACTH) by complete hypophysectomy would allow the effect of tumour corticotrophin to be demonstrated. The proposition was tested by estimating the production rate of cortisol in patients before and after hypophysectomy. The results obtained in 4 patients are reported.

METHODS AND RESULTS

The patients were admitted to hospital 3 weeks prior to surgery and all steroid therapy was terminated. Two weeks after admission the prehypophysectomy production rate was estimated from the specific activities of three urinary metabolites of cortisol, as described by Deshpande, Jensen, Carson, Bulbrook, and Lewis (1969). The patients were then treated by transfrontal hypophysectomy followed by the insertion of six 3·8-m.c. pure gold grains into the pituitary fossa. Following hypophysectomy the patients were stabilized on cortisone acetate, 25 mg. per day, and a further 2 weeks were allowed to elapse. Dexamethasone, 0·75 mg. per day, was then substituted for cortisone acetate. Five days later the production rate of cortisol was again determined. The results obtained for the production rate of cortisol are shown in *Table I*.

Table I.—PRE- AND POSTHYPOPHYSECTOMY PRODUCTION RATE OF CORTISOL IN PATIENTS WITH ADVANCED BREAST CANCER

PATIENT	AGE (yr.)	CORTISOL PRODUCTION RATE (mg per 24 hr)						TOTAL URINARY CORTICOIDS (mg. per 24 hr)	
		Cortisol		*Tetrahydrocortisone*		*Tetrahydrocortisol*			
		Pre	Post	Pre	Post	Pre	Post	Pre	Post
1	53	16·0	—	28·5	2·6	22·7	3·0	6·9	—
2	68	24·2	—	26·2	2·1	27·4	1·6	8·3	0·6
3	63	21·6	—	23·5	3·0	23·3	2·7	6·9	—
4	50	20·3	—	18·6	3·7	16·8	4·0	10·6	0·13
Range in normal control subjects (Deshpande and others, 1969)	—	1·98–6·0	—	3·55–16·2	—	3·3–12·4	—	3·44–9·11	—

Cortisol, tetrahydrocortisone, and tetrahydrocortisol represent the production rate of cortisol based on the specific activities of urinary cortisol, tetrahydrocortisone, and tetrahydrocortisol.

CONCLUSIONS

Preoperatively the cortisol production rate in all 4 patients was raised to levels similar to those previously reported in cases of metastatic breast cancer (Jensen and others, 1968a). Although the number of cases studied is small the results clearly show that following hypophysectomy the cortisol production rate fell to one-sixth of the original rate. This indicates that the high prehypophysectomy cortisol production is not due to production of corticotrophin by tumour tissue, but depends on the presence of functioning pituitary cells. Abnormal prehypophysectomy cortisol production may be due to either excess pituitary ACTH or increased sensitivity of the adrenal cortex. Although the dependence of such abnormal cortisol production on the pituitary–adrenal feedback mechanism is not known, there is evidence that patients with advanced breast cancer respond normally to ACTH (Schubert, Bacigalupo, and Frankenberg, 1961).

The residual secretion of cortisol (approximately 3 mg. per 24 hours) is difficult to explain. The combination of open operation and local irradiation should completely destroy all the hypophysial tissue. Furthermore, the postoperative dexamethasone medication will suppress ACTH production from any residual hypophysial cells. It is unlikely, therefore, that the residual cortisol secretion is dependent on pituitary ACTH control, but may be the result of intrinsic adrenal production. There remains the possibility that the residual secretion of cortisol is due to the production of corticotrophins by tumour cells, and it is not possible to discount this on the basis of these figures. This small residual secretion is, nevertheless, quite inadequate to explain the raised cortisol production rate found before hypophysectomy.

SHORT NOTES OF RARE OR OBSCURE CASES

A CASE OF EMPHYSEMATOUS PYELONEPHRITIS

BY JOHN G. MOSLEY

DEPARTMENT OF MEDICINE, MANCHESTER ROYAL INFIRMARY

EMPHYSEMATOUS pyelonephritis is an unusual condition in which there is gas within the renal parenchyma, or sometimes within the pyelocaliceal collecting system. The diagnosis is made radiologically (Bliznak and Ramsey, 1972). Thirty-five cases have been reported in the literature, all of whom had diabetes mellitus or an obstruction to urinary outflow (Costas, 1972).

The present fatal case illustrates this condition and demonstrates the rapid way in which it may develop.

CASE REPORT

J. H., a 42-year-old woman, was admitted as an emergency in a semiconscious state. The relatives gave a history of several months' duration of malaise, urinary frequency, and intermittent burning pains in the feet. Five days prior to admission she had had rigors and nausea; she had become increasingly weak. Immediately before admission she had become disorientated and confused.

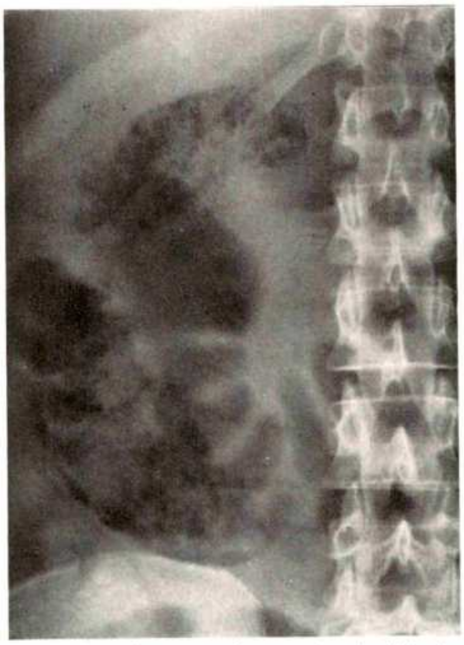

FIG. 1.—Right renal tomogram demonstrating air within the renal substance.

There was no family history of diabetes mellitus or renal disease. The patient had had an operation on the left kidney at the age of 7 years. She had been treated for syphilis when she was 26 years old.

The patient looked dehydrated and was drowsy and disorientated, though able to obey simple commands.

There was a left paramedian scar. A large tender mass was present in the right renal area. The oral temperature was 37·8° C., sinus tachycardia 140 per minute, and blood-pressure 70/50.

Laboratory data on admission included: blood-urea, 185 mg. per 100 ml.; serum sodium, 130 mEq./l.; serum potassium, 5·4 mEq./l.; serum chloride, 85 mEq./l.; blood-sugar, 650 mg. per 100 ml., with a metabolic acidosis; haemoglobin, 11·2 g. per 100 ml.; white-blood count, 10,000 per mm.^{3} Blood and urine cultures taken on admission both grew *Escherichia coli*. The patient was rehydrated and started on kanamycin at a reduced dosage in view of her renal failure (Mawer, Knowles, Lucas, Stirland, and Tooth, 1972; Mawer, Lucas, and McGough, 1972). The diabetes was controlled with soluble insulin.

The day after admission the patient remained severely hypotensive and had become anuric with a rapidly rising blood-urea, which was now 380 mg. per 100 ml. She had developed neck stiffness and a positive Kernig's sign. Cerebrospinal fluid obtained by lumbar puncture contained 180 polymorphonuclear cells per mm.^{3} Plain abdominal radiographs showed multiple gas shadows in the right renal area, and many small opacities in the gluteal region.

An abdominal tomogram 3 days after admission (*Fig.* 1) showed evidence of a considerable amount of gas within the right kidney.

Peritoneal dialysis was commenced to control the uraemia, and blood was transfused to maintain a central venous pressure of +4 cm. The haemoglobin had dropped to 9·3 g. per 100 ml., with a platelet count of 18,000 mm.^{3}, and coagulation studies demonstrated intravascular coagulation.

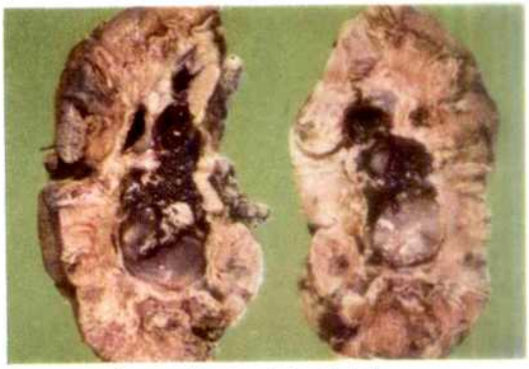

FIG. 2.—Interior of the right kidney.

The patient's general condition remained grave although the blood-sugar and blood-urea were satisfactorily controlled. The blood-pressure remained low (about 90 mm. Hg systolic pressure) and there was evidence of a continuing shock state. It was felt that surgery was essential if the patient was to survive. At operation a grossly necrotic right kidney was found and removed (*Fig.* 2). A swab from the right kidney at operation subsequently grew the same strain of *E. coli* that had been grown from the blood and urine. No left kidney was felt during the operation. The patient remained very ill and died 8 hours after the operation.

The resected right kidney was extensively destroyed by acute inflammation. Grossly, there was complete loss of the normal distinction between the cortex and the medulla. Microscopically, small ulcers were seen scattered throughout the kidney; in addition there was interstitial inflammatory infiltration and many of the tubules contained pus. There were extensive areas of coagulative necrosis in many of the small vessels. There were also areas of healthy renal parenchyma which showed no abnormality.

At post-mortem examination no left kidney was found and it was concluded that this had been resected at the earlier operation, when the patient was 7 years old.

DISCUSSION

There have been 35 reported cases of emphysematous pyelonephritis (Costas, 1972). Uncontrolled diabetes mellitus without urinary obstruction was the most common predisposing factor; in this group the mortality-rate was 40 per cent. All the patients with emphysematous pyelonephritis who did not have diabetes had an obstructing lesion in the urinary tract; in this group the mortality was 14 per cent.

In the group of patients with diabetes, the diabetes is usually out of control (Porter and Wright, 1961). Females are more frequently afflicted than males and the mean age of occurrence is 46 years (Schainuck, Foulty, and Culter, 1968). The left kidney is more often affected than the right (Stokes, 1966). *E. coli* is usually cultured (Olson, 1957; Costas, 1972), although other coliforms have been found occasionally (Schultz and Klorfein, 1962). Most coliform organisms are capable of metabolizing glucose to acid and carbon dioxide, and the raised blood-sugar and urinary sugar in diabetics may contribute to the aetiology (Gillies and Flocks, 1941). This is in contrast to the gas-producing infections of the gall-bladder, where clostridia are the usual causative organisms and only about 25 per cent of the patients have diabetes (Bigler, 1960; May and Strong, 1971).

Pathological findings are available in 11 diabetic patients. In the involved kidney a severe necrotizing pyelonephritis involving the cortex and medulla was present in every case and multiple abscesses were common (Schainuck and others, 1968).

Most authors feel that nephrectomy is not indicated (Stokes, 1966). In the present case, however, as the patient's condition continued to deteriorate in spite of antibiotic therapy it was felt that surgery was essential, and at operation the surgeon thought that nephrectomy offered the only means of a cure. Had the patient recovered she would have been placed on a long-term haemodialysis programme.

Acknowledgements.—I should like to thank Dr. N. P. Mallick for his permission to report this case and for his advice in the preparation of this paper, and Dr. H. Fox for the histological examination.

MENINGIOMA FOLLOWING TRAUMA

By W. J. WHATMORE* and E. R. HITCHCOCK
DEPARTMENT OF SURGICAL NEUROLOGY, WESTERN GENERAL HOSPITAL, EDINBURGH

Summary

A case report is given of the development of an intracranial meningioma at the site of an authentic head injury incurred 21 years previously. The available literature on the subject is reviewed. The criteria satisfying the concept of trauma being a significant aetiological factor in the production of such tumours are stated and it is shown that the meningioma reported in this paper fulfils all these criteria. The aetiology of such tumours is discussed in further detail.

It is well recognized that there is a causal relationship between the irritative effects of prolonged trauma and the development of neoplastic changes in the affected tissue. Much more controversial is the question of whether a single non-recurrent traumatic episode can be aetiologically significant in the production of neoplasia. The criteria which must be satisfied before any malignant growth can be attributed to trauma have been summarized by Austen (1961).

1. The site of injury must correspond to the region in which the tumour develops.
2. The trauma must be authentic and of sufficient importance.
3. The previous integrity of the wounded part must not be in doubt and there must be proof that neither primary nor metastatic malignant disease was present before injury.
4. The time interval between injury and the development of the neoplasm must be significant.

---

* Present address: Department of Neurosurgery, Walsgrave Hospital, Coventry.

5. There must be continuity in the pathological changes or symptoms in the wounded part from the time of injury to the appearance of the tumour.

6. There must be microscopic proof of the existence of the tumour, its character, and structure.

The most plausible evidence of this type of trauma–neoplasia relationship is available in the study of intracranial meningiomas.

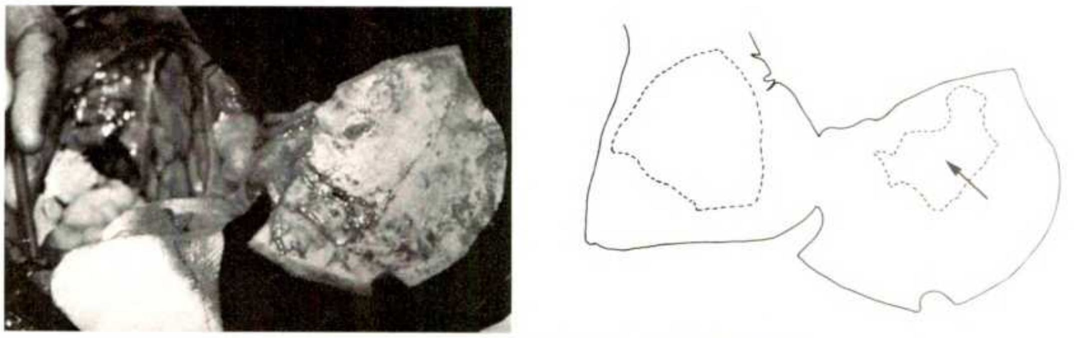

FIG. 1.—Hyperostosis of the bone-flap surrounding the old fracture site.

In his Cavendish lecture of 1922 Cushing, discussing his series of 85 verified meningiomas, stated: 'In so many of the cases in the series has a tumour been found at the exact situation where a stunning blow has been received on the skull years before, that this must represent something more than a mere coincidence.' In the large series described by Cushing and Eisenhardt in 1938, 20 out of 65 cases (31 per cent) of parasagittal meningioma had a previous history of local trauma.

Walshe (1961), in discussing head injuries as a factor in the aetiology of intracranial meningiomas, drew attention to Cushing's series and added a further 4 cases in support of the theory. He concluded: 'It is therefore submitted that the positive evidence available does not allow us to reject the existence of an aetiological relationship between a local skull injury and the subsequent development of a meningioma in a significant proportion of instances of this tumour, particularly when such an injury is related to a cranial suture and the trauma is found immediately subjacent to it.' More recently, Turner and Laird (1966) reviewed the literature and reported a case similar to the one described in this paper.

We believe that the tumour reported here, although not malignant, fulfils all Austen's (1961) criteria outlined above.

CASE REPORT

A 32-year-old, right-handed regular soldier suffered a right frontal to right parieto-occipital through-and-through machine-gun bullet wound on 8 Feb., 1945. He was admitted to the Brain Injuries Unit, Bangour Emergency Military Services Hospital, Edinburgh, and on 9 Feb. both entry and exit wounds were excised, and a craniotomy was performed with débridement and haemostasis of the missile track. Despite insufflation of penicillin and sulphamethazine powder he developed meningitis which ultimately responded to oral and intrathecal antibiotics. Postoperatively he retained a complete left homonymous hemianopia, hemiplegia, and hemianalgesia. By 8 Sept. he could walk 1 or 2 miles with the aid of a stick.

In the initial postoperative period the patient suffered six discrete left-sided motor fits associated with impairment of consciousness for which he received phenobarbitone until 1948. He had no further attacks until June, 1954, when he again suffered from left-sided motor fits. Anticonvulsants were resumed and continued up until the present time. Examination in 1954 revealed no new findings.

On 13 July, 1965, the patient complained of accentuation and persistence of the right frontal headaches from which he had suffered intermittently for 20 years. Examination at that time revealed no change. In February, 1966, his headache became so severe that he was forced to cease work. During the week prior to his readmission he became drowsy and confused and on 22 Feb. he was admitted to the Edinburgh Royal Infirmary with a history of vomiting and incontinence of urine of 1 day's duration. On examination he was conscious but confused and apathetic and only obeyed simple commands. His previous neurological deficits were more marked but he did not have papilloedema. An echo-encephalogram showed a marked shift of the midline structures from the right to the left, as did a right carotid angiogram, which also indicated the presence of a large frontal space-occupying lesion. Biopsy through the old entrance wound revealed a fine, gritty, vascular tumour instead of the cyst that had been suspected. A diagnosis of meningioma was made.

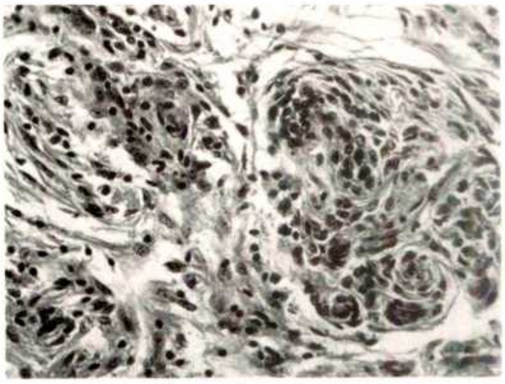

FIG. 2.—Section of the tumour. (× 116.)

The following day a large right frontal craniotomy was performed (E. R. H.). There was considerable vascularity of the diploë and on turning the bone-flap an area of hyperostosis was seen surrounding a portion of the old fracture line (*Fig.* 1). The dura below this was highly vascular with a large, middle meningeal blood-supply. On opening the dura a large meningioma was exposed, the origin of which was directly below the old fracture line and the hyperostosis. The tumour, which occupied most of the anterior half of the cranial cavity, was removed in its entirety. It measured 12·5 × 12·5 × 10 cm. and weighed 170 g. Pathological examination of the specimen confirmed the diagnosis of meningioma (*Fig.* 2).

Postoperatively the patient made good progress and was walking without help by March, 1966. He still, however, retains his left-sided deficits, which have persisted and were noted in his latest examination in March, 1972.

DISCUSSION

No one would deny that a penetrating gun-shot wound was authentic and significant and the subsequent tumour in this case developed directly beneath the old fracture site. As this future tumour site was inspected at the time of the original post-traumatic operation there is positive evidence that no tumour existed then. It is fortunate for the purposes of this case report that not only did the original and final surgery take place in the same neurosurgical unit but also that between these times the patient was reviewed in the unit as an out-patient. Thus by studying the complete case records it is apparent that there was continuity of symptoms and signs relating to the process of initial recovery from trauma and the subsequent development of new pathology. It is interesting to note that the original post-traumatic epilepsy, presumably related to the immediate effects of cortical damage, ceased without anticonvulsant drugs for 6 years from 1948 until 1954. The fits then recurred, requiring anticonvulsant suppression, and it seems likely that this recurrence was due to the new tumour growth attaining a significant size.

Cushing (1922) reviewed the evidence indicating that meningiomas originate from the islands of endothelial cells found between the layers of dura in close proximity to the arachnoid villi. In illustrating the intracranial areas of dural attachment of the meningiomas in his series he showed their frequent relationship to the dural sinuses and emphasized that these are the sites where arachnoid villi and the associated cell clusters abound. He stated that widespread occlusion of the arachnoid villi by either injury or disease will lead to stasis of the cerebrospinal fluid and hydrocephalus, and that with stimuli of this nature the cell clusters are prone to hypertrophy, a change which in turn may become permanent and lead to neoplastic tendencies.

The majority of patients with severe head injuries do not subsequently develop related meningiomas nor do the majority of patients suffering from intracranial meningiomas give a previous history of local trauma, and thus there must be other factors concerned in the aetiology of meningioma formation. Additional neoplastic agents may include infection, the irritative and occlusive effects of blood and tissue debris, the foreign-body effect of bone particles, and in the case of penetrated or explored wounds the contamination with extraneous matter or the introduction of antibiotic powder or sprays.

There is no evidence in the available literature of the development of meningiomas after surgical interference to the meninges or dural sinuses. It may be that the development of the meningioma in this case was precipitated by the gross trauma to these structures in much the same way as epithelial tumours of the skin arise from the scars subsequent to severe burns.

ACUTE DIFFUSE PHLEGMONOUS GASTRITIS

By B. L. WILLIAMS and D. I. BEEBY

ROYAL PORTSMOUTH HOSPITAL

SUMMARY

Phlegmonous gastritis is a rare inflammatory disorder of the stomach and is thought to have first been described by Galen in 1600; its recognition as a bacterial cellulitis of the submucosa and muscularis is attributed to Cruveilhier in 1820. Three hundred and ninety cases were described in the world literature up to 1969. This case is of interest because the patient displayed a number of the typical features of the disease, and also because from a search of the literature of the past 12 years she appears to be only the second of the proven cases to have resolved with conservative management.

PHLEGMONOUS gastritis is a rare inflammatory disorder of the stomach and is thought to have first been described by Galen, although its recognition as a bacterial cellulitis of the submucosa and muscularis is attributed to Cruveilhier in 1820. Since the late 1950's a number of fairly comprehensive reviews of this condition have appeared in the American literature, based on the 390 cases described in the world literature up until 1969. These categorize predisposing causes and clinical and histological features, and indicate which form of management has been most effective.

The case described here is of interest because she displayed a number of the typical features of the disease, and also because from a search of the literature of the past 12 years she appears to be only the second of the proven cases to have resolved with conservative management.

CASE REPORT

A 67-year-old retired female factory worker from East London, who was holidaying on the South Coast under an old peoples' welfare scheme, was admitted to hospital on 1 March, 1972, with peritonitis. She had suffered from severe rheumatoid arthritis for many years and was currently on treatment with Brufen. She had never undergone steroid therapy. Apart from a recent severe upper respiratory infection which had necessitated hospital admission, there was no significant past history.

Her immediate history was of 48 hours' general malaise, abdominal discomfort, vomiting, and pyrexia. She had been seen by a general practitioner 24 hours before admission, and at that stage he had been unable to elicit any abnormal abdominal signs, except for a slight degree of hepatic enlargement. Cyclizine and Septrin were prescribed. In the course of the next 24 hours her condition had worsened, and she was admitted to hospital toxic and dehydrated. She then had a pyrexia of 37·3° C., a pulse of 110 per minute, and a blood-pressure of 100/60. Abdominally she had generalized tenderness and guarding, which appeared maximally in the lower quadrants. Bowel-sounds were absent. Radiography demonstrated two fluid levels in the right iliac fossa, but no other features of note in the abdomen. An incidental finding was of bone infarcts in the upper right humerus and upper left femur.

On admission her haemoglobin was 13·7 g. per cent and the white-cell count was 7000, being predominantly neutrophils with a shift to the left. The blood-urea and electrolyte estimations were compatible with a moderate degree of dehydration and salt depletion.

Intravenous rehydration and nasogastric aspiration were commenced, and laparotomy was undertaken through a right paramedian incision. The peritoneal cavity contained approximately 1 litre of dark-yellowish brown turbid

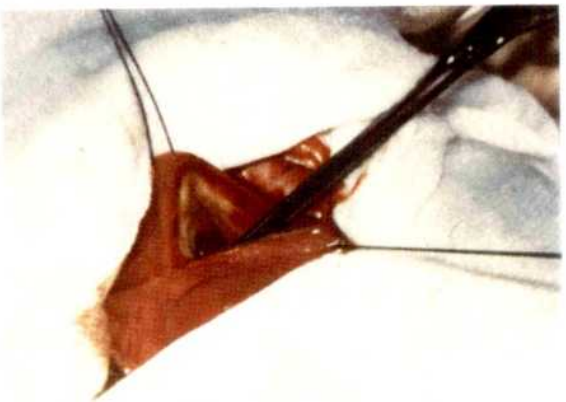

FIG. 1.—Opened stomach at operation.

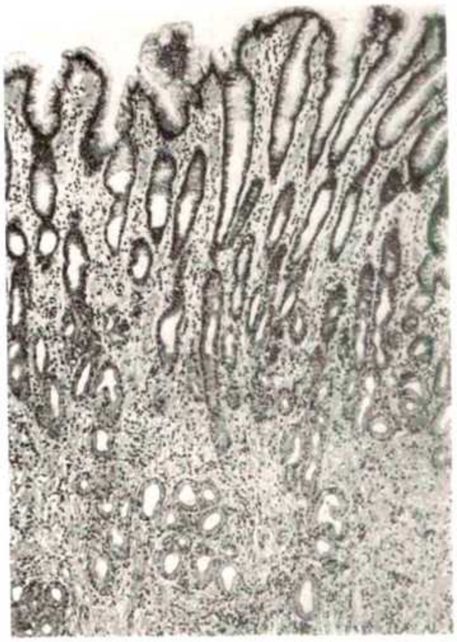

FIG. 2.—Gastric mucosa and submucosa.

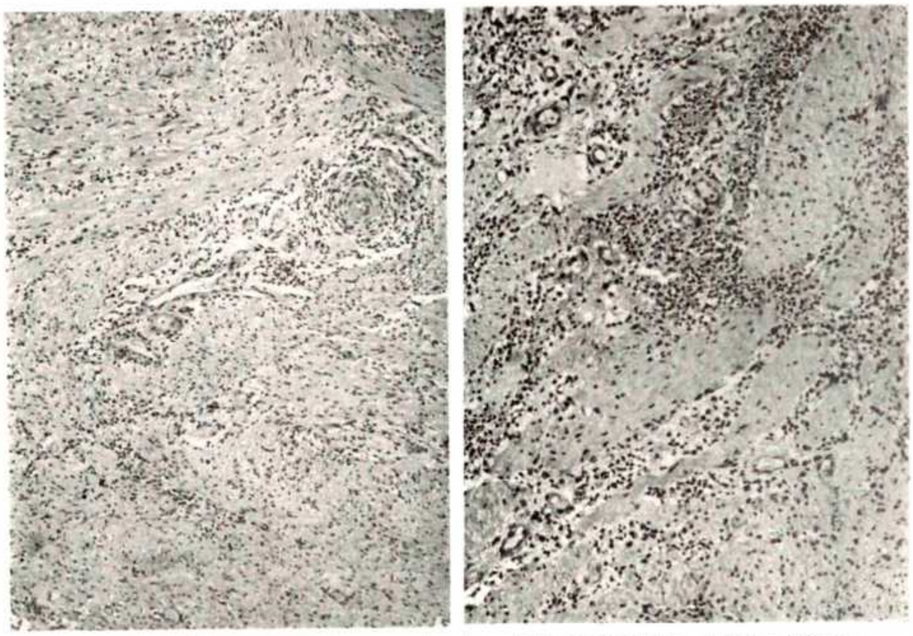

FIG. 3.—Muscularis externa showing separation of muscle bundles by polymorphonuclear infiltrate.

fluid, a specimen of which was sent for bacteriological investigation but with a negative result. The entire stomach was thick-walled and oedematous, and displayed serosal congestion from the cardia to the pylorus. In contrast the duodenum appeared relatively normal. The liver was uniformly pale and unusually firm in texture. The gall-bladder was oedematous but did not contain stones. The pancreas was exposed by opening the lesser sac through the gastrocolic omentum, and this also appeared mildly oedematous.

Anterior gastrostomy was performed as a means of obtaining clinical confirmation of the diagnosis and of providing a specimen for histological examination. On incision the appearances of the stomach wall were those of serosal and mucosal congestion, with considerable widening of the intervening layers by thick pus, as illustrated in *Fig.* 1. Inspection of the interior of the stomach revealed no additional pathology. Full-thickness biopsy was taken before closure of the gastrostomy. A wedge of liver tissue was also taken for histological purposes. No further procedure was undertaken, and after peritoneal toilet the abdomen was closed without drainage.

Histological examination of the stomach specimen showed an intact mucosa, which was oedematous and lightly infiltrated with inflammatory cells. There was heavy infiltration of the submucosa and muscle coats with acute and chronic inflammatory cells (*Figs.* 2, 3).

The liver biopsy showed slight oedema of the portal tracts which were heavily infiltrated with lymphocytes and plasma cells. There was mild fatty infiltration of periportal liver cells, which were normal elsewhere. Immediately postoperatively intensive antibiotic therapy was instituted, using an initial 5-day course of penicillin and streptomycin, followed by oral ampicillin.

Continuous gastric aspiration was maintained for 4 days postoperatively before graded oral fluids were permitted. The patient made a steady recovery, eventually being mobilized with difficulty owing to her extensive arthritis. She left hospital to finish her holiday on 12 April.

Other investigations were as follows:—

Repeat blood-counts indicated that she maintained her haemoglobin, although she had a persistent leucopenia in the region of 3000.

Serial biochemical profiles showed serum-albumin levels persistently between 2 and 2·5 mg. per cent, although her total protein levels remained within normal limits. All other estimations were normal except for a marginally raised lactic dehydrogenase.

The Wassermann reaction was anticomplementary, and the VDRL slide test was negative.

An auto-immune profile showed an atypical reaction by immunofluorescence with all tissues. This was thought to be due to the high rheumatoid titres.

The pentagastrin stimulation test yielded an 83-ml. specimen, with a *p*H of 4·3, and a free HCl content of 1·2 mEq. per specimen.

DISCUSSION

Eighty per cent of the reported cases of phlegmonous gastritis have been between the ages of 30 and 60 years. Earlier papers have suggested that the condition was commoner in females, but in the series of Stephenson, Yasrebi, Rhatigan, and Woodward (1970) the sex incidence was equal.

In over 70 per cent of cases in which organisms have been isolated from the pus a pure culture of a haemolytic streptococcus has been obtained. Other cases have yielded growths of pneumococci, staphylococci, proteus, and, rarely, gas-producing organisms which produce characteristic radiological appearances. Nevin, Eakins, Clarke, and Carson (1969) used Brown's stain to demonstrate bacteria in the submucosal layers of 3 cases. Smith, Garrett, and Herrick (1962) listed the predisposing causes as chronic gastritis, gastric trauma, alcoholism, hypo-acidity, infection elsewhere in the body, and hard work. Stephenson and others (1970) added malnutrition and low socio-economic status to this list.

Clinically, phlegmonous gastritis may be classified as localized or diffuse, and acute or chronic. In the diffuse form the entire stomach is involved, whilst in the localized variety infective changes are confined to a portion of the stomach—almost always the distal region.

Acute cases usually present with a short history of general malaise, vomiting, pyrexia, and abdominal pain. Characteristically the pain commences in the epigastrium and is completely relieved by sitting up (Deininger's sign).

The most common complication is rapidly developing peritonitis (70 per cent), but pericarditis, pleurisy, bronchopneumonia, and haemorrhage have also been recorded.

Starr and Wilson (1957) classified the condition as chronic if symptoms had been present for more than a few weeks. In these cases the clinical and radiological features often mimic linitis plastica or gastric outlet obstruction.

The macroscopic appearances of the stomach in phlegmonous gastritis are as described in this case, but occasionally there is a fibrinous exudate over the serosal surface, and rarely there is ulceration of the gastric mucosa.

Microscopically it is usual to see infiltration of all the layers of the gastric wall with inflammatory cells, but this is always maximal in, and may be confined to, the submucosa and muscularis.

The treatment of this condition has evolved over a period of many years into an aggressive surgical approach complemented by vigorous antibiotic therapy. In 1938 Eliason and Murray-Wright recorded a 16 per cent survival rate following gastrostomy and transmural drainage. By 1957 Starr and Wilson were able to record a 52 per cent survival rate and found that gastric resection with antibiotic therapy gave the best results. The recent analysis of the world literature by Stephenson and others (1970) provides a convincing testimonial for radical gastric resection, even in the diffuse type of phlegmonous gastritis. Of the 24 cases reviewed, there were 14 known survivors and the outcome in 3 cases was not known. Thirteen of the survivors had undergone either total or subtotal gastrectomy, and 8 of these had also received antibiotics. Of the 7 who died, 4 had received antibiotic therapy, 1 following subtotal gastric resection. The remaining 3 cases had neither received antibiotics nor undergone gastric resection.

DEMONSTRATION OF SIMPLE URETEROCELE PROLAPSING INTO THE URETHRA OF AN ADULT MALE

By C. A. PARSONS and C. P. MALPASS

PRINCESS MARY'S ROYAL AIR FORCE HOSPITAL, HALTON, AYLESBURY, BUCKS.

SUMMARY

A case is reported of a simple ureterocele descending into and obstructing the urethra during micturition in a 30-year-old male who had symptoms for only 6 months. This was demonstrated and recorded by a simple technique using conventional radiographic apparatus.

CASE REPORT

A 32-year-old pilot, who had previously enjoyed excellent health, presented with a 6-month history of dysuria. On starting to micturate he would pass 10–20 ml. of urine normally then the stream would stop abruptly. After a further minute, without straining, the stream would start again and continue until voiding was completed. The symptoms at first had only occurred during a diuresis, e.g., after alcohol, but more recently had become constant. The only other symptom was perineal discomfort during micturition.

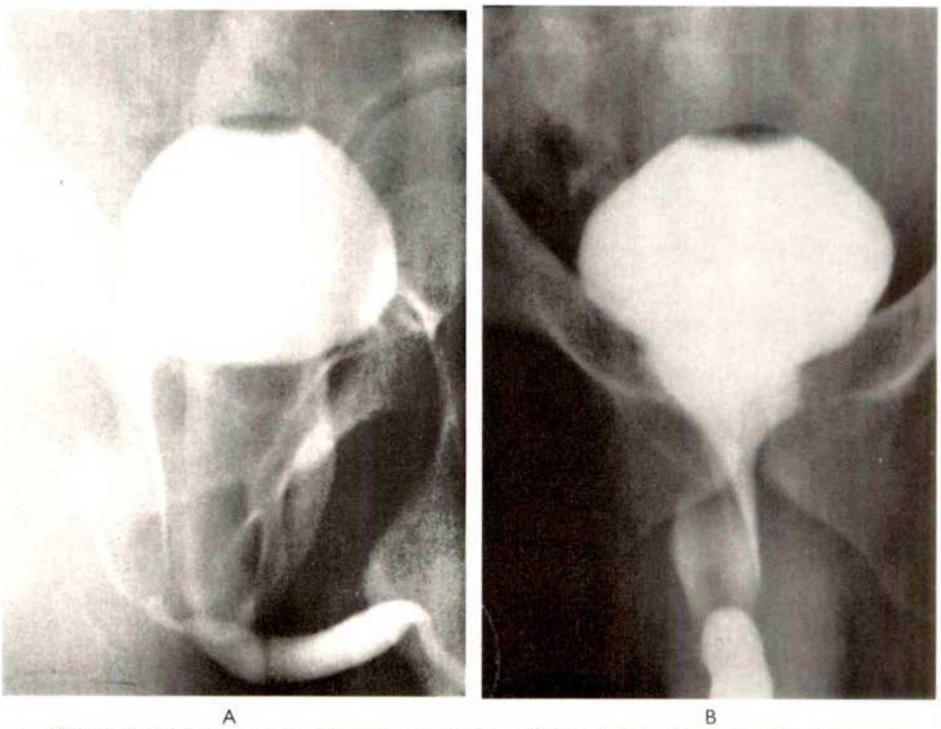

FIG. 1.—Oblique (A) and postero-anterior (B) cystograms showing widening of the bladder-neck and posterior urethra with a finger-shaped filling defect projecting downwards.

A micturating cystogram was carried out using conventional image-intensifier fluoroscopy and spot films. The bladder was filled retrogradely with 500 ml. of 17·5 per cent Diodone. The bladder was smooth in outline with a very faintly visible filling defect, 2·5 cm. in diameter, lying posteriorly on the left. Voiding was commenced and after 20 ml. of urine had been passed there was sudden cessation of the stream. The oblique view recorded at that stage (*Fig.* 1 A) showed widening of the bladder-neck and posterior urethra with a finger-shaped filling defect projecting downwards from the left and posteriorly. *Fig.* 1 B shows similar appearances on a postero-anterior film. These changes persisted throughout voiding and the filling defect appeared to remain in the urethra when the bladder was empty. With this investigation alone, differentiation could not be made from a prolapsing vesical polyp, urethral polyp, foreign body, non-opaque calculus, or ectopic ureterocele.

An intravenous pyelogram showed a moderately large ureterocele at a normally sited left ureteric orifice, with dilatation of the lower third of the left ureter. Otherwise the urinary tracts appeared normal, with no obstructive signs on the right (*Fig.* 2).

At cysto-urethroscopy a contracting ureterocele was found overlying the left side of the bladder base. The right ureteric orifice was normal and no other abnormality was found. A hole was made in the ureterocele by fulguration. Postoperatively the patient has been asymptomatic for 12 months.

DISCUSSION

Symptoms of bladder-neck obstruction are not uncommon in children with ureteroceles at normally sited ureteric orifices. Thompson and Kellalis (1964) reported interruption of the stream, overflow incontinence, or acute urinary obstruction in 20 of the 29 children with ureterocele who presented at the Mayo Clinic prior to 1963. Prolapse of a ureterocele along the female urethra and its presentation outside the external urinary meatus has been reported many times. Emmett and Logan (1944) found 37 recorded cases.

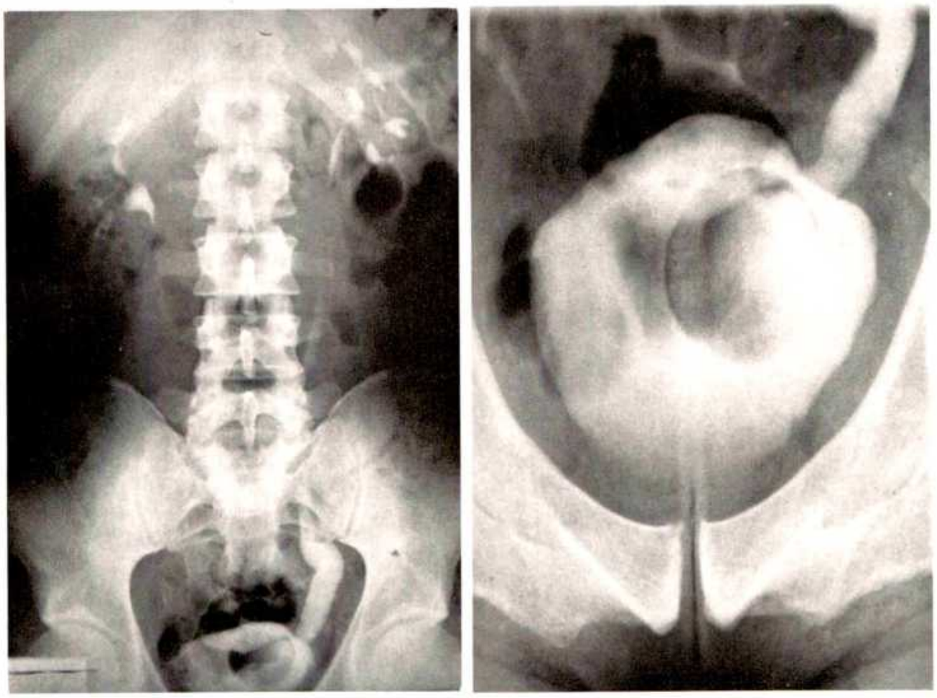

FIG. 2.—Intravenous pyelograms showing a moderately large ureterocele at a normally sited left ureteric orifice with dilatation of the lower third of the left ureter.

However, demonstration of a simple ureterocele prolapsing into the adult male urethra is extremely rare. We are aware of only 1 recorded case, that of Poznanski, Reynolds, and Johnson (1968). Their patient was aged 15 years and had a 2-year history of interruption of the urinary stream. Kinescopic cine-radiography, spot films from the image-intensifier phosphor, and videotape recording were used and the prolapsing ureterocele was recorded only on the cine-film.

In the present case we used conventional image-intensifier fluoroscopy and spot films. Using this simple technique the ability to record dynamic changes occurring during urine flow is lost. However, these can be observed on the television monitor and excellent detail can be recorded on spot films taken at appropriate intervals and angles. This technique is particularly suitable for a case such as this in which there is a slow rate of urine flow.

REVIEWS AND NOTICES OF BOOKS

Pathology of Injury. Edited by A. C. HUNT, M.D., F.R.C.Path., Plymouth General Hospital. 9½ × 7 in. Pp. 129. 1972. London: Harvey Miller & Medcalf Ltd. £2.

THIS is a short, concise, and most inexpensive report from a working party of pathologists, describing 'current knowledge and future development'. The editor and his contributors have carried out an admirable and most valuable review of the pathology, biochemistry, metabolism, endocrinology, etc., of injury, including special subjects such as bacterial infection, uraemia, fat, and thrombotic embolism. However, the views of the obviously expert contributors about research and future development are not nearly so challenging. Even so, as a synopsis this should be background reading for all surgeons, especially those in training. This publication appears to have been written in order to highlight the recommendations of the working party of pathologists about numerous programmes on education and research for medical schools, colleges, Department of Health and Social Security, Medical Research Council, etc. One of the main recommendations is that major accident departments should be designated as centres of research in trauma and its pathology. This would be most acceptable to many surgeons and indeed has been recommended for a long time by the surgeons responsible for such accident departments. If more and more interested groups would press for support to develop research programmes this would help greatly in the battle against the 'modern devastation' of trauma.

Angiographie und ihre Fortschritte. Edited by Dr. K. E. LOOSE, Itzehre/Holst. 9½ × 6½ in. Pp. 308 + xx. Illustrated. 1972. Stuttgart: Georg Thieme Verlag. DM.98.

THIS book is an account of a congress which took place on 7–9 May, 1970, showing the progress of angiography, in which radiologists and vascular surgeons from Germany, Austria, Sweden, the Netherlands, and other countries took part. The scope of angiography has widened on such a scale that the book should be of universal interest.

This book includes contributions on many aspects of angiography. Angiography of the vessels of the limbs has been popular for many years, and the technical refinements such as cinematography and the use of amplifiers detailed in this book are interesting. Selective arteriography of the abdominal organs, for instance, in the case of suspected pancreatic carcinoma or abdominal haemorrhage, should prove to be one of the most important diagnostic aspects. Microradiography demonstrates calcification of the elastica and media of vessel walls, which are apparently different processes. Pharmaco-angiography is useful in showing vessels not visible by orthodox renal arteriography. It is doubtful whether phlebography should be performed in every case of uncomplicated varicose veins as argued by one of the participants. Lymphography has an important place in surgery and some surgeons do not perform rectal amputations without lymphography in order to determine the condition of the regional glands. Interesting communications deal with the vascularization of fractures (the periosteum is less important in this respect than was assumed previously) and the haemodynamics of venous grafts. One may express the hope that Professor Loose and his colleagues will continue to publish the results of future congresses.

Gynaecology Illustrated. By MATTHEW M. GARREY, M.B., D.P.H., F.R.C.O.G., Royal Samaritan Hospital for Women, Glasgow; A. D. T. GOVAN, M.D., Ph.D., F.R.C.P. (Glas.), F.R.C.Path., Royal Samaritan Hospital for Women, Glasgow; C. H. HODGE, M.B., F.R.C.S. (Edin.), F.R.C.O.G., Larkfield Hospital, Greenock; and ROBIN CALLANDER, F.F.Ph., M.M.A.A., A.I.M.B.I., Medical Illustration Unit, University of Glasgow. 9½ × 7½ in. Pp. 492 + xi. Illustrated. 1972. Edinburgh: Churchill Livingstone. £3.

THIS book has been produced in a style similar to that of *Obstetrics Illustrated*, the immediate popularity of which has no doubt prompted the publication of this sister volume.

The emphasis is on simple line-drawings interspersed with a minimum of text. The result is an excellent summary of the essentials of gynaecology, giving a very friendly and readable effect.

There is little to criticize. The ubiquitous 'diverticulae' appears on p. 349 although it is correctly spelt 'diverticula' on p. 125. It is possible that in a book for undergraduates there is a slight imbalance between the information on diagnosis and that on operative and other techniques, for example, there are 6 whole pages devoted to the physics of radiotherapy as compared with a total of 4 pages on the diagnosis of fibroids, endometriosis, and tubal pregnancy.

This book is assured of a wide circulation, especially at its modest price.

The Neuropathology of the Alimentary Tract. By BARBARA SMITH, M.D., Ph.D., F.R.C.S., St. Bartholomew's Hospital, London. 9 × 6 in. Pp. 118 + ix. Illustrated. 1972. London: Edward Arnold (Publishers) Ltd. £4.

THIS is an important monograph describing the abnormalities of the myenteric plexus of the alimentary tract and is written by an acknowledged expert. The normal anatomy and the changes induced by pathological conditions are described in detail. The author points out that previous work has been hampered by inappropriate histological methods and she describes in detail her preparation of the specimens. The book maintains a balance between clinical abnormalities resulting from damage to the autonomic nerves and experimental work which has been done in this field, together with experimental work done by the author. The important feature common to all conditions in which there is myenteric plexus damage, whether congenital or acquired, is hypertrophy and probably hyperplasia of the smooth muscle. This thickening of the muscle is much more severe than that seen as a result of work hypertrophy behind an organic obstruction and is a macroscopic hall-mark of the condition.

There are chapters dealing with achalasia of the cardia, juvenile and adult hypertrophic pyloric stenosis, and Chagas's and Hirschsprung's diseases of the large bowel. Perhaps of particular interest is a discussion of the difficult problem of acquired megacolon and cathartic colon. There is also an important chapter on drugs which cause damage to the myenteric plexus. Although rather expensive, this book is well illustrated by photomicrographs and contains a bibliography of over 300 references. It should be read by everyone with an interest in gastroenterology.

Medical Care in the U.S.S.R. Report of the U.S. Delegation on Health Care Services and Planning. U.S. DEPARTMENT OF HEALTH EDUCATION AND WELFARE. NATIONAL INSTITUTE OF HEALTH. 1972. 50 cents.

IN May and June, 1970, a team of distinguished American doctors visited the Soviet Union to study health services and medical education. This was at the time of inception of a new health code legislation which at first sight would remind British readers of the reorganization of our own N.H.S. which is due to take place in 1974. However, the differences are considerable: the Soviet plan has as its stated aims the improvement of facilities, specialization, a more even standard of care in town and country, and an improvement in the first-line care offered by the polyclinic out-patients' system. Our own plan is for management and monitoring, perhaps with the same objectives as the U.S.S.R. but also, some suspect, motivated by the need for economy in an open-ended consumer demand for a necessary commodity which is free. The table of the organization plan on p. 7 of the U.S. booklet is reminiscent of the exhibits in our own Grey Book. The main part of the text concerns the powerful medical collectives that, like most things in Russia, do everything on a large and categorical scale, with less concern for individual needs except in so far as these fall under the procedural headings of the polyclinics, sanatoria, and hospitals. Emergency medical care, the 'Scoraya' (meaning = quick), has an overriding power of accident and emergency care and allocation with all the priority needed to carry this out. One can imagine the appeal to U.S. health workers in this. The service in Leningrad, Moscow, and Kiev was inspected and detailed information and examples are cited which are of great interest to Western readers. However, no judgement is passed on the standards. There are some amusing local cartoons and some interesting photographs of places visited. The Western medical tourist in the U.S.S.R., who may see little more than the sights and amusements of the lay visitor, will find this booklet of considerable interest, though like most such publications it still does not answer the basic question: 'What was it like?'

Bone Tumors. Fourth Edition By LOUIS LICHTENSTEIN, M.D., San Francisco. 9½ × 6¾ in. Pp. 441 + xviii, with 496 illustrations. 1972. London: Henry Kimpton. £11.

To those of us with a particular interest in bone tumours a new edition of Lichtenstein's book is quite an event, for it has for many years enjoyed a high reputation amongst the standard textbooks on the subject.

Knowing the author to be a clinical professor of pathology, one must expect this aspect to be stressed. Clinical features such as radiographs and treatment are, however, fully covered, although not in such detail. However, the reviewer must confess to some surprise at the very high standard of these purely clinical passages. Had they been written by a most experienced clinician in this field he could justifiably be proud of his work. This is not to say that one agrees with all that is written. The apparent trans-Atlantic bias against radiotherapy is evident and perhaps unjustified. Indeed, no reference could be found to the excellent work on osteosarcoma that has since come from Westminster Hospital by Sir Stanford Cade and others. In spite of this the bibliography is impressive and reasonably up to date.

Costing £11·00 in this country, this book is expensive Nevertheless, the reviewer considers it to be amongst the three best textbooks on the subject, being authoritative concise, and yet readable. Obviously most pathologist will wish to have access to it. I would also strongly recommend it to clinicians as one of the best reference books for them on the subject.

BOOK NOTICES

[*The Editorial Committee acknowledge with thanks the receipt of the following volumes. A selection will be made from these for review, precedence being given to new books and to those having the greatest interest to our readers.*]

An Atlas of Surgical Anatomy and Techniques of the Temporal Bone. By RALPH J. CAPAROSA, M.D., Pittsburgh. 11 × 8½ in. Pp. 124 + xiii, with 111 illustrations. 1972. Springfield, Ill.: Charles C. Thomas. $18.

General Urology. By DONALD R. SMITH, M.D., San Francisco. 10¼ × 7¼ in. Pp. 436. Illustrated. 1972. London: Blackwell Scientific Publications. £4·15.

Die Behandlung der hämatogenen und der traumatischen Osteomyelitis. By STOJAN POPKIROV, Fruhjahr. 9½ × 6½ in. Pp. 408. Illustrated. 1971. Berlin: Veb. Verlag Volk und Gesundheit. DM.172.40.

A Nurse's Guide to the X-ray Department. By MYER GOLDMAN, M.B., Ch.B., D.M.R.D., Consultan Radiologist, North Merseyside, Ormskirk, and Southport Hospitals. 8½ × 5½ in. Pp. 87 + xv, with 47 illustrations. 1972. Edinburgh: Churchill Livingstone £1.

Unfall Begutachtung. By Dr. E. GUNTHER, Köln, and Assessor R. HYMMEN, Köln. 9½ × 6½ in. Pp. 158 + xi Illustrated. 1972. Berlin: Walter de Gruyter & Co DM.42.

Unfall Praxis. By Professor Dr. WALTHER EHALT 9 × 6 in. Pp. 233 + xviii, with 297 illustrations. 1972 Berlin: Walter de Gruyter & Co. DM.42.

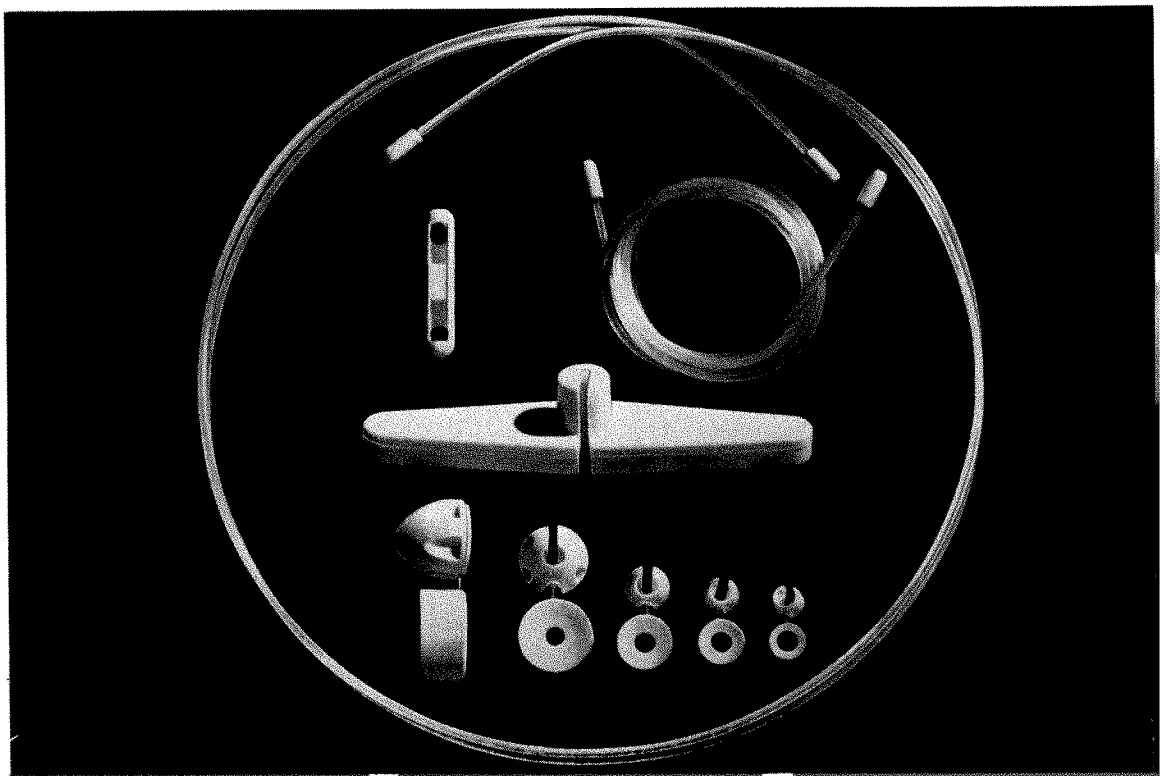
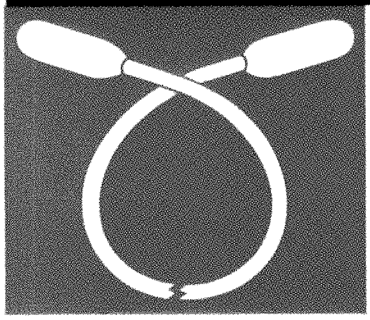
Armour Vein Stripper

Sterile, disposable, non-toxic and pyrogen-free

Eliminates time-consuming preparation and cleaning

Sterilised by irradiation



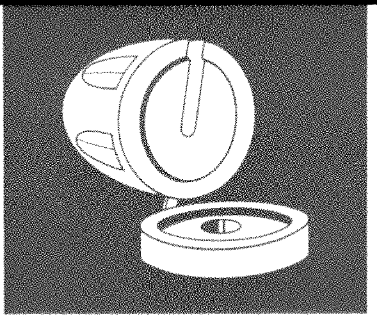


Nylon Cable

Has optimum handling quality.

Every end stop individually tested for firmness of attachment.

Breaking load of cable in excess of 150 lb.

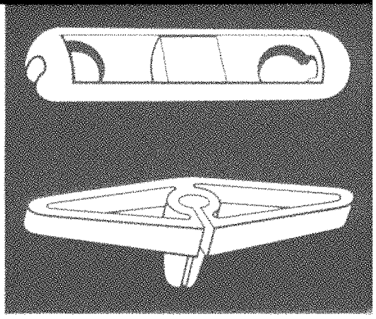


Nylon Olives

Snap fit for convenience of assembly.

Clean, well-defined cutting edge.

Hole without edge access prevents cable detachment.



Nylon Coupler and Draw Handle

Smooth, compact, coupling, ensures security of union.

Light, strong, well shaped.

EDITORIAL NOTICES

Editorial Communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

Reprints can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

No. of Pages	Number Required							
	50	100	150	200	250	300	400	500

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

Business Communications should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

Binding.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

Back Numbers.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

Advertisements.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House, 159 Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

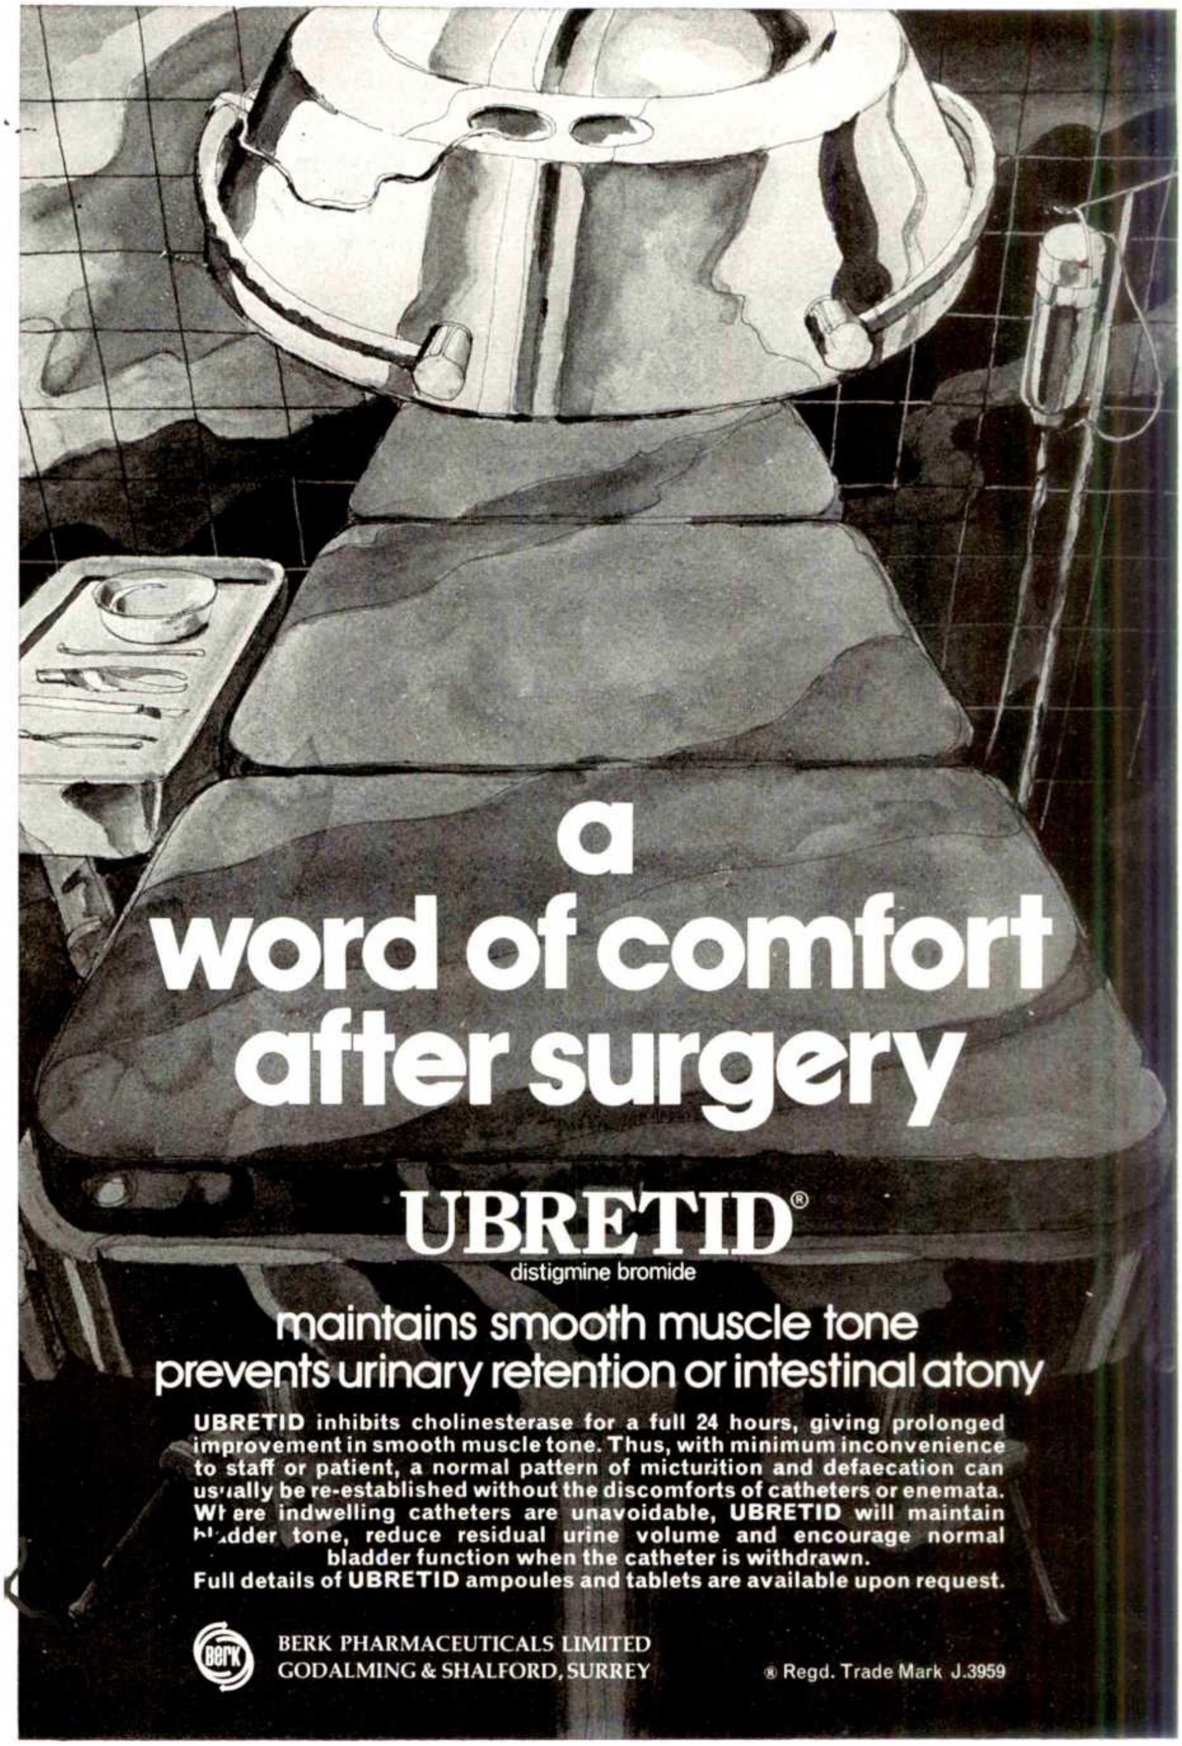
Preparation of MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

Tables and Illustrations.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

References.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "World List of Scientific Periodicals" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.



UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND

1974 MOYNIHAN FELLOWSHIP

The Association of Surgeons of Great Britain and Ireland invite applications for the Moynihan Fellowship up to the value of £1,000.

The object of the Fellowship is to enable the holder (usually of the status of a young consultant or senior registrar) to broaden his surgical education by visiting clinics at home and abroad.

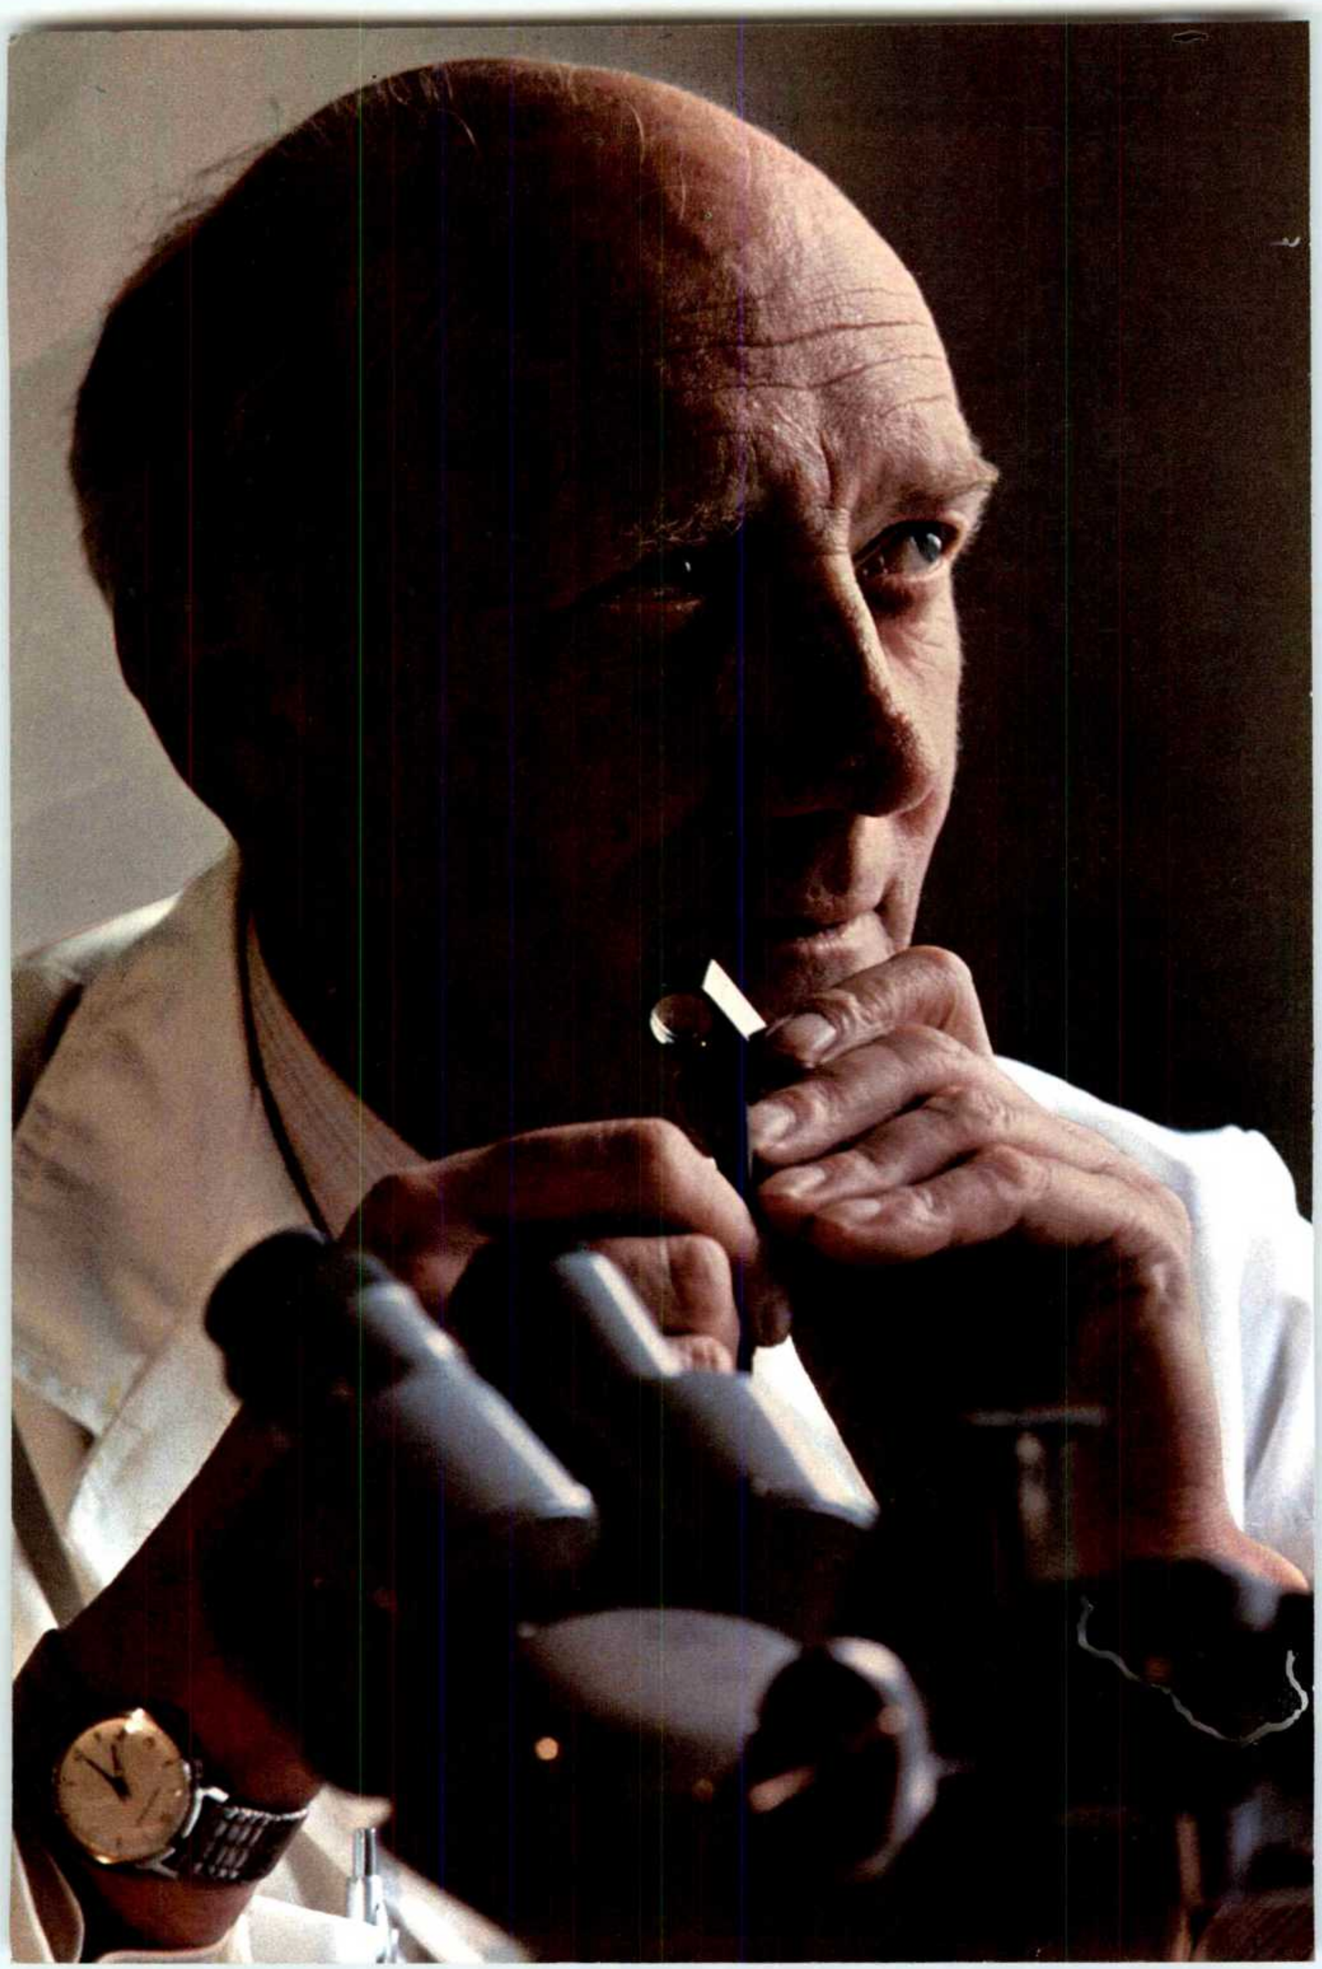
Candidates, who must be resident in the United Kingdom or Eire, but who need not be either Fellows or Associate Fellows of the Association, should state clearly in their application their programme and what they hope to achieve. If they intend holding the Fellowship in conjunction with any similar grant they should give details. They should also give short accounts of their past careers and present appointments. The names of two sponsors should be given. The Council will expect a report of the visit at its conclusion.

Applications (twenty-five copies) must be submitted to the Honorary Secretary, Association of Surgeons of Great Britain and Ireland, at The Royal College of Surgeons, 35/43 Lincoln's Inn Fields, London WC2A 3PN, *by* 31 *October*, 1973. Applicants should be prepared to attend for interview if they are requested to do so.

July, 1973.

ETHICON*

...leadership
in wound repair



We've given John Mathams a big award for his smallest achievement

Recently John Mathams came out of his back room at the Sighthill plant of ETHICON to receive one of the biggest honours the company can bestow on a research scientist.

We owe him a lot.

So do surgeons. For John made an important contribution to surgery by developing a unique method of attaching micro-needles to ultra-fine materials; the type of needle scarcely visible in our picture. It has important application in ophthalmic surgery.

Behind this achievement is one man's originality and ingenuity – backed by qualities which he shares with everyone at ETHICON: determination and dedication to the highest attainable standards in the service of the surgeon.

ETHICON

ETHICON LIMITED, SCOTLAND

Tissue approximation needs ETHICON precision

Tolerances for ETHICON sutures range from 0·0002″ (for gauge conformity in natural catgut) to 0·0001″ (for 6 mm micro-surgical needles). For every ETHICON suture is shaped by the needs of the surgeon. It is our concern to meet these needs with precision.

ETHICON

Surgical Gut

Dependable strength and absorption properties. Chromic and plain gut presented for every field of surgery.

ETHICON

MERSILK*

BRAIDED SILK

Silk made to exacting surgical specifications. In many sterile presentations, including 80 MERSUTURES* Eyeless Needled Sutures.

ETHICON

Surgical Linen Suture

Specially prepared for maximum strength and knot security.

ETHICON

PROLENE*

MONOFILAMENT POLYPROPYLENE

The most inert suture known with knotting properties superior to those of any other monofilament.

ETHICON

ETHIFLEX*

PTFE COATED POLYESTER

An inert braided suture possessing both superb handling properties and excellent tensile strength.

ETHICON

ETHILON*

MONOFILAMENT POLYAMIDE 6

Considerably stronger than BPC requirements plus a smooth surface finish of very uniform diameter.

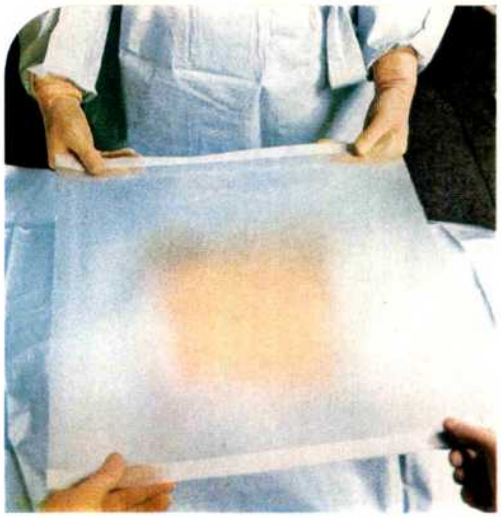
CHURCH PATH, MITCHAM, SURREY, ENGLAND

The new BARRIER* Incise Drape



BARRIER* Incise Drapes used with disposable or traditional drapes.

BARRIER* Incise Drapes in use with the BARRIER* Theatre Drape System.

The transparent drape with clear advantages

BARRIER* Incise Drapes are effective – film elasticity and the specially developed High Tack adhesive ensure adhesion at the edge of the incision even during heavy retraction and manipulation.

BARRIER* Incise Drapes are supplied sterile – the pack's heavy board reinforcement protects the sterile drape from puncture damage, and its Fibre Tear seal gives immediate visual proof of seal integrity and improves aseptic handling.

BARRIER* Incise Drapes give greater control – wide control tabs that give positive control of the drape and help prevent 'self-adhesion'.

BARRIER* Incise Drapes emphasise safety – they are glare free and inherently static safe while providing a smooth surface for organs temporarily displaced during a procedure.

ARTERIAL EMBOLUS TO THE UPPER LIMB

BY H. R. CHAMPION* AND W. GILL*
DEPARTMENT OF CLINICAL SURGERY, THE ROYAL INFIRMARY, EDINBURGH

SUMMARY

Seven cases of arterial embolus to the upper limb are presented. The cases support the current trend to management by embolectomy and the restoration of normal hand function as an important feature.

ALTHOUGH early embolectomy is the accepted treatment of choice for emboli lodged in major arteries, traditional teaching had delayed its widespread application to upper-limb emboli. This may stem from the comparative infrequency (15 per cent) of upper-limb emboli (*Table I*), and the usual absence of gangrene whatever the therapy employed. With its abundant collateral blood-supply, occlusion of the upper-limb arteries has always been viewed with less concern than comparable lesions in the lower limb.

In 1963 Fogarty introduced his catheter (Fogarty, Cranley, Krause, Strasser, and Hofner, 1963), and this significantly reduced the amputation rate in patients with lower-limb emboli (Provan and Ransford, 1970; Thompson, Sigler, Rant, Austin, and Patman, 1970). The expedient application of this technique in the upper limb promotes the main objective of treatment, namely, the complete restoration of function in a previously ischaemic hand, where subsequent fine sensation and movement are all important.

Seven cases of upper-limb embolus which presented to the Professorial Surgical Ward in the Royal Infirmary of Edinburgh in a 7-year period are reported. *Table II* shows the case summaries.

CASE REPORTS

Case 1.—C. T., a 72-year-old woman who suffered from mitral stenosis, hypertension, exertional angina, and atrial fibrillation controlled on digoxin, was admitted in December, 1965, 90 minutes after she had first felt a sudden pain in her left arm. On examination the arm was white from mid-humeral level and was pulseless. Power was markedly diminished in the forearm and hand. She had an irregular pulse-rate of 100 per minute and a blood-pressure of 210/130 mm. Hg, and an electrocardiogram showed hypertrophy of both ventricles.

Table I.—FREQUENCY OF UPPER-LIMB EMBOLI COMPARED WITH THAT OF ALL EMBOLIC EPISODES REPORTED IN THE LITERATURE

Thompson, Sigler, Rant, Austin, and Patman (1970)	188	25
	2420	364

Sixty minutes after admission a block of the brachial plexus was performed and resulted in the relief of pain but no return of the peripheral pulses. Reflex heating produced a slight improvement in the skin circulation. There was, however, no improvement in sensation or muscle power and 12 hours after admission (13½ hours after the onset) embolectomy was performed using a suction catheter through a mid-brachial arteriotomy incision.

Although the radial pulse was not palpable in the immediate postoperative period, the hand became warmer and the patient was placed on heparin (12,000 I.U. 6-hourly i.v.). Intensive physiotherapy resulted in little functional improvement of the hand and no sensory improvement or fine muscle movement was observed. The

Table II.—DETAILS OF THE 7 CASES OF UPPER-LIMB EMBOLUS IN THE PRESENT SERIES

CASE	AGE AND SEX	CONCOMITANT ILLNESS	DRUGS	CLINICAL LEVEL OF BLOCK	TREATMENT	TIME SINCE ONSET OF SYMPTOMS (hr.)	POST-OPERATIVE RADIAL PULSE	RESULT
1. C. T.	72 F	Rheumatic heart disease, mitral stenosis, atrial fibrillation, hypertension	Digoxin, chlorthiazide	Brachial	1. Brachial plexus block 2. Embolectomy, anticoagulants, physiotherapy	2½ 13½	No	Permanent loss of sensation and fine movement in the hand. Died of myocardial infarction 11 mth. later
2. C. F.	58 F.	Mitral valve disease, atrial fibrillation, previous embolus, intermittent claudication	Digoxin	Axillary	Embolectomy, heparinization, oral anticoagulants	6¾	No	Good
3 C H.	58 F.	Diabetic, and recent previous myocardial infarct	Nil	Brachial	Embolectomy, papaverine, heparinization, reflex heating, physiotherapy, oral anticoagulants	5	No	Power normal, hand cooler, sensation normal
4. M. F.	64 F.	Mitral stenosis, atrial fibrillation	Digoxin	Axillary	Embolectomy, heparin, physiotherapy, digoxin and frusemide	5	Yes	Good function
5. W. S.	65 M.	Aortic sclerosis, mitral incompetence, atrial fibrillation, chronic bronchitis, congestive heart failure, cirrhosis	Digoxin, frusemide, Aldactone-A	Brachial bifurcation	Heparinization for 1 wk., physiotherapy	6	Yes	Hand satisfactory Fatal cerebral embolus 3 mth. later
6. R. T	58 M	Previous myocardial infarct, intermittent claudication	Nil	Brachial bifurcation	Embolectomy, heparin, physiotherapy	9	Yes	Complicated by cerebrovascular accident. Good functional recovery but some fibrosis of thenar muscles
7. M. McM.	48 M.	Atrial fibrillation/flutter, myocardial infarction, ventricular tachycardia	Digoxin, practolol, Lasix, Warfarin, procainamide, lignocaine	Axillary	Heparin, embolectomy, physiotherapy	8	Yes	Good No loss of function

patient was followed up but there was no change in her upper-limb status and she eventually died 11 months later from a myocardial infarction.

Case 2.—C. F., a 58-year-old female with mitral valve disease and atrial fibrillation, experienced sudden left-arm pain accompanied by pallor 4¾ hours prior to her admission in April, 1967. The patient was obese, and had an irregular pulse of 65 per minute and a blood-pressure of 200/120 mm. Hg. On admission the arm was cyanosed beyond the elbow and sensation was absent from a point 5 cm. below the olecranon, with marked loss of power in the flexors of the wrist and in the hand muscles. No pulses were present beyond the left subclavian.

Axillary embolectomy was performed 2 hours after admission, using a suction catheter. A large amount of clot was removed both proximally and distally, which resulted in an acceptable proximal and retrograde flow of blood.

Heparin (12,000 I.U. 6-hourly i.v.) and oral anticoagulants (phenindione) were started postoperatively. The radial pulse did not return but there were good sensation and fine movement after a course of physiotherapy. Because of previous embolic episodes she was maintained on oral anticoagulants.

Case 3.—C. H., a 58-year-old female, had had angina pectoris 5 days previously with the sudden onset of pain, weakness, and numbness in her left arm 2 hours before her admission in January, 1971. She was a known diabetic controlled on dietary measures. There were no pulses distal to the axillary artery and sensation was diminished below the elbow. An electrocardiogram showed sinus rhythm and an old anteroseptal infarct with recent extension.

An embolectomy was carried out 3 hours after admission through a mid-brachial arteriotomy. Pulsation distal to the arteriotomy did not return despite bathing the vessel in 2·5 per cent papaverine. It was decided to close the wound and to reassess the arm in 6 hours, during which time reflex heating was used. The patient was heparinized using 1100 I.U. per hour by continuous infusion. The brachial pulse returned, and over the subsequent 2 days power and sensation in the hand and forearm returned to normal. Pulsation in the radial artery never returned and the left hand was always slightly colder than the right.

Case 4.—M. F., a 64-year-old female, presented in November, 1971, with a history of sudden severe pain in her right arm of 2 hours' duration. The arm became white and cold. She was known to have mitral stenosis and atrial fibrillation controlled by digoxin. On examination the right arm was cold and the hand cyanotic. There were no pulses palpable below the right subclavian. The patient was distressed and dyspnoeic, with an irregular pulse of 75 per minute and electrocardiographic evidence of left ventricular and atrial hypertrophy.

An arteriotomy in the mid-brachial artery with a No. 3 Fogarty catheter allowed much clot to be removed. The patient was heparinized postoperatively and stabilized on Warfarin by the fifth postoperative day. At the end of surgery the radial pulse was impalpable although it returned within 48 hours. Physiotherapy to the hand and forearm produced a satisfactory result with no residual disability.

Case 5.—W. S., a 65-year-old male, had a 15-year history of cirrhosis and ascites and was a known chronic bronchitic with congestive heart failure requiring digoxin, frusemide, and Aldactone-A. He developed sudden pain and loss of power and sensation in his left forearm 3 hours before his admission in December, 1971. He had atrial fibrillation and the left brachial pulse in the antecubital fossa was absent. The left forearm was cooler than the right but there was minimal loss of sensation and power.

The patient was heparinized for 5 days and given physiotherapy. At discharge 8 days later the radial pulse was palpable and the muscle power normal. Oral anticoagulants were discontinued because of cirrhosis and he died 3 months later from a cerebral embolus.

Case 6.—R. T., a 58-year-old male, was admitted in December, 1971, complaining of a gradual onset of numbness, weakness, pain, and coldness in his right forearm of 4 hours' duration. He had a history of myocardial infarction and intermittent claudication. On examination the brachial pulse was palpable in the antecubital fossa, but the radial and ulnar pulses were absent. Power and sensation in the hand were diminished. He was not fibrillating and had no evidence of cardiac failure.

Embolectomy using a Fogarty catheter was performed under general anaesthesia 9 hours after the onset of symptoms; the arteriotomy was sited just proximal to the elbow. The radial pulse returned the following day. Postoperative heparinization by constant infusion was discontinued on the second postoperative day when the patient suffered a cerebrovascular accident producing a left hemiparesis. Over the ensuing days, power and sensation in the right arm returned to normal apart from the infarcted thenar muscles which later fibrosed. Intensive physiotherapy later produced a satisfactory recovery from his cerebrovascular accident.

Case 7.—M. McM., a 48-year-old male, had atrial fibrillation of 5 years' standing controlled by digoxin. He was admitted to hospital in May, 1972, with an acute myocardial infarction and atrial fibrillation flutter, and he later developed runs of ventricular tachycardia. Anticoagulation with Warfarin was commenced.

Three days after admission it was noted that his right radial pulse was absent and then that the only palpable pulse in his right limb was the subclavian. The hand was cool, but had no loss of sensation or power. The patient had suffered no symptoms and at the time was adequately anticoagulated with a prothrombin ratio of 1·8 : 1.

Eight hours after detection a 1-cm. embolus was removed from the axillary artery using a No. 3 Fogarty catheter through a brachial arteriotomy. The radial pulse returned 10 minutes after surgery and at a later follow-up there was no functional deficit in the limbs.

DISCUSSION

The comparative infrequency of upper-limb emboli is probably due to anatomical factors. A large heavy embolus is less likely to leave the aortic stream and thus passes on to the legs. The emboli that do lodge in the upper extremity are likely to be small, 65 per cent lodging in the brachial, 30 per cent in the axillary, and 5 per cent in the subclavian arteries (Baird and Lajos, 1964). In this series four emboli lodged in the brachial artery, either at the origin of the profunda brachialis or at the terminal bifurcation of the brachial artery.

The diagnosis of upper-limb embolus presents no difficulty, though it must be emphasized that the onset is not always dramatic (Stirling, Morris, Officer-Brown, and Barnett, 1963; Young, Humphries, De Wolfe, and Lefevre, 1963; Baird and Lajos, 1964) and symptoms may develop over several hours if the embolus lodges distally, as in *Cases* 6 and 7, the latter patient being asymptomatic initially. A change in rhythm of the heart is important in the genesis of an embolus and this occurred prior to embolization in *Case* 7.

Arterial occlusion results in pain, numbness, pallor, and coldness, the degree and extent of which depend on the size and site of the embolus. Cutaneous sensation is diminished early, but some improvement may occur when the collateral flow becomes established (Deterling, 1966). Loss of motor power is a serious prognostic sign (Young and others, 1963). These symptoms and signs relate to the extent of distal and proximal propagation, and it is of interest to note the minimal upset present in *Case* 7 who was effectively anticoagulated at the time of presentation and in whom there was no evidence of propagation of the clot at operation.

The proximal extent of the embolus can frequently be identified by direct palpation, and this corresponds well with the pathological level of occlusion. Angiography is not usually necessary (Wheeler, 1968).

It has always been recognized that there is little risk to life or limb (i.e., amputation) from an embolus in the arm (Warren, Linton, and Scannell, 1954) and when death occurs it results from the primary cardiac disease (Warren and others, 1954; Stirling and others, 1963; Thompson and others, 1970). Conservative management was at one time frequently advocated (Frey and McGhee, 1957). Sympathetic blockade has been used to relieve pain and spasm (Veal and Duncan, 1951), as in the present *Case* 1. Dye, Olwin, Javid, and Julian (1955) were among the first to advocate strongly surgical treatment of upper-limb occlusion. Trumbull, Masashi, and Averbrook (1959) reported 9 cases of embolectomy, in all of which the radial pulse was restored, but early embolectomy for upper-limb emboli was not widely accepted until 1964 (Baird and Lajos, 1964; Cranley, Krause, Strasser, Hofner, and Fogarty, 1964). The procedure offers the advantage of mechanically removing the distal propagating thrombus and thus decreasing any dysfunction. Baird and Lajos (1964) analysed 102 upper-limb emboli in 95 patients; surgery produced good results in 88 per cent of the patients and conservative management in 75 per cent, but the poor results in those treated by conservative therapy were of a more serious nature than in the surgical group.

Of the 7 cases reported here, 5 were treated initially by embolectomy. Conservative treatment was used in 2 patients, failing in 1 (*Case* 1) and succeeding in the second patient who had a very distal embolus (*Case* 5). It is clear that those patients with minimal symptoms of gradual onset, absence of progressive cutaneous sensory loss, and a very distal embolus can be adequately managed on a conservative régime of anticoagulation and physiotherapy.

Late embolectomy was carried out in *Case* 1 after failure of a brachial plexus block. The hand remained viable with permanent loss of sensation and fine movement. The previously held concept that late embolectomy was of no value was challenged by Spencer and Eiseman (1964), who believed that embolectomy was worth while as long as severe muscle necrosis was absent. Cranley and others (1964) also emphasize that viability and not the duration of occlusion should determine operability. Darling (1969) suggests the use of late embolectomy in the non-viable limb to lower the level of amputation.

The brachial artery is easily exposed under local or regional anaesthesia, although this form of anaesthesia was only used in 1 of our patients (*Case* 7). Dissection of the vessels involved is relatively simple, but difficulty may be encountered negotiating the terminal bifurcation of the brachial artery and necessitates a second arteriotomy (Sachatello, 1968). 'Spasm' may prove troublesome during the operation, as in *Case* 3, and in this instance papaverine provided no help. Cranley and others (1964) stress the importance of maintaining patency at the arteriotomy site during closure and are prepared to reopen the artery as many as six times if necessary to ensure a good blood-flow. Clinical 'spasm' should alert the surgeon to the possibility of persisting debris within the artery or damage to the arterial wall. If pulsation is present 1–2 cm. distal to the site of the arteriotomy and the preoperative findings were favourable, then limb viability is guaranteed (Cranley and others 1964).

Prevention of further emboli is important and 80 per cent of the patients who have recurrent emboli are not receiving prophylactic therapy when they occur. Recurrent emboli appear to be associated with a greater mortality and morbidity (Darling, 1969). *Case* 5 in the present series who was not placed on long-term anticoagulants because of cirrhosis died of a fatal cerebral embolus within 3 months of the first embolus. Young and others (1963) advised mitral commissurotomy and auricular appendectomy in selected patients and carried out this operation in 24 of their 114 patients with peripheral emboli.

Most surgeons rely on long-term anticoagulants, and in the earlier patients in the present series simultaneous heparin and phenindione were given postoperatively. A more recent policy has been immediate heparinization on admission, continued by intravenous infusion into the postoperative 4–5 days, by which time oral anticoagulants have been started. The use of heparin preoperatively is strongly advocated by Cranley and others (1964) and Fogarty, Daily, Shumway, and Krippaene (1971).

The presence of the radial pulse after embolectomy is often regarded as important and some series report 100 per cent success in recovery of the radial pulse (Trumbull and others, 1959). This is not our experience. Moreover, it is possible to get good functional recovery without the return of radial pulsation (*Case* 3) and, conversely, for infarction of the small muscles of the hand to take place in the presence of a palpable radial pulse (*Case* 6).

With early surgical treatment, loss of the upper limb is a rarity (Rossi, Ehrenhaft, and Sensenig, 1965) but partial loss of function occurs in 10–15 per cent of cases (Baird and Lajos, 1964; Cranley and others, 1964). This is related to a delay in treatment or to atherosclerosis (Edwards, Tilney, and Lindquist, 1966). Death following embolectomy is most commonly due to concomitant cardiac disease, but whatever the physical state of the patient his condition is not improved by the presence of ischaemic muscle or a gangrenous limb (Kinmonth, Rob, and Simeone, 1962; Provan and Ransford, 1970).

The superiority of the Fogarty catheter over suction catheters for the procedure of embolectomy is well recognized. It does not require a direct approach to the site of the embolus, and can be carried out under local anaesthesia with little discomfort to the patient. Its early use to remove the embolus, and any distal and proximal propagating clot, together with preoperative heparinization to prevent such clot formation, should further reduce the incidence of disability that results from ischaemia of the small muscles and nerves of the hand.

Acknowledgements.—The authors wish to thank Professor Sir John Bruce, Professor A. P. M. Forrest, and Mr. I. B. Macleod for permission to report patients under their charge, and those colleagues contributing individual cases.

GLUCAGON THERAPY IN ACUTE PANCREATITIS

By JOHN R. CONDON
ST MARY'S AND PRINCESS ALICE HOSPITALS, EASTBOURNE

MICHAEL KNIGHT
ST. GEORGE'S HOSPITAL, LONDON

AND JOHN L. DAY
KING'S COLLEGE HOSPITAL, LONDON

SUMMARY

Thirty patients with acute pancreatitis (10 classified as severe) were treated with glucagon at an initial dose of 1 mg. intravenously followed by 1–1·5 mg. every 4 hours.

Glucagon therapy was associated with the relief of pain and clinical improvement in all the patients including 2 subjects who eventually died. In all but 1 of the patients the plasma amylase fell during glucagon infusion. Two patients died, giving a mortality-rate of 7 per cent compared with 22 per cent and 26 per cent of most published series in Britain.

ADMINISTRATION of glucagon to patients with acute pancreatitis has been reported to result in clinical improvement and the relief of pain associated with a fall in the plasma amylase (Knight, Condon, and Smith, 1971). It was suggested that the main beneficial effect of glucagon in acute pancreatitis was due to the inhibition of pancreatic exocrine secretion, thus suppressing the activity of the acutely inflamed gland.

Further studies of the use of glucagon in patients with acute pancreatitis are reported here.

MATERIAL AND METHODS

Thirty patients at seven hospitals were studied. Acute pancreatitis was confirmed at operation in 13 cases. In 17 cases the diagnosis was made on the clinical picture and a high plasma amylase. One patient (*Case* 25) developed acute pancreatitis following an operative pancreatogram. This patient had no pancreatic pain but 3 days postoperatively developed a tachycardia with increased abdominal tenderness and a marked rise in the plasma amylase from 400 to 2000 Somogyi units per 100 ml.

An initial dose of glucagon, 1 mg. intravenously, was given in all the cases. This was immediately followed by an intravenous infusion of glucagon in either 5 per cent dextrose or normal saline. The dose of glucagon given by infusion varied from 1 to 1·5 mg. every 4 hours for 24–96 hours.

Plasma calcium was measured by atomic absorption spectrophotometry, plasma amylase by the method of Babson, Tenney, and Megraw (1970), and methaemalbumin by the method of Chong and Owen (1967).

The patients were assessed before and after glucagon therapy. The degree of abdominal pain, shock, and peritonism was recorded at intervals following the administration of glucagon. Plasma amylase, plasma calcium, and methaemalbumin were measured before and approximately 12 hours after glucagon had been started.

Ten of the patients treated (*Cases* 1–10) were classified as severe because of the presence of one or more of the following features: severe clinical shock, a plasma calcium of less than 7·0 mg. per 100 ml., and haemorrhagic pancreatitis diagnosed either at operation or by the detection of methaemalbuminaemia (Lipp and Hubbard, 1950; Kirby, Senior, Howard, and Rhoads, 1955; Winstone, 1965; Trapnell, 1966). The diagnosis in 5 of these patients (*Cases* 6–10) was confirmed at laparotomy.

Twenty patients (*Cases* 11–30) were classified as non-severe in the absence of all these features. The diagnosis was confirmed at laparotomy in 8 of these patients.

RESULTS

Severe Group.—

CASE REPORTS.—

Cases 6, 1, *and* 2.—These 3 patients, aged 47, 62, and 59 years, respectively, were extremely ill when first seen. All had severe epigastric pain with vomiting, abdominal tenderness, guarding, and rebound tenderness. They were hypotensive and had raised plasma-amylase values (*Fig.* 1). The severity of the pancreatitis was reflected by the low plasma-calcium levels of 7·1, 6·2, and 6·1 mg. per 100 ml., respectively. Following treatment with glucagon there was partial relief of abdominal pain at 30 minutes to 2 hours, with complete relief at 1, 12, and 3 hours respectively. Signs of peritonism subsided over 6–8 hours and this was associated with a marked clinical improvement and a rise in the blood-pressure. Plasma-amylase levels measured 12 hours after beginning glucagon therapy fell from the pre-glucagon values by 28, 54, and 43 per cent respectively (*Fig.* 1).

Case 3.—A female aged 70 years with epigastric pain had a plasma amylase of 2000 Somogyi units per 100 ml., a plasma calcium of 9·4 mg. per 100 ml., and methaemalbuminaemia (1 mg. per 100 ml.); she was not clinically shocked. Glucagon therapy resulted in the complete relief of pain within 8 hours and a fall in the plasma amylase of 62 per cent at 15 hours (*Fig.* 1).

Case 4.—A male aged 44 years with abdominal pain was shocked and had a plasma calcium of 8·4 mg. per 100 ml. and a plasma amylase of 1560 Somogyi units per 100 ml. Partial relief of epigastric pain occurred at 4 hours and complete relief at 12 hours. The plasma amylase fell by 10 per cent over 12 hours.

Cases 10 *and* 5.—These patients (a female aged 29 years and a male aged 78 years respectively) were not shocked but had plasma-calcium values of 6·2 and 6·9 mg. per 100 ml. respectively. In *Case* 5 the plasma amylase which was 533 Somogyi units on admission fell to 90 Somogyi units when glucagon was given for persistent abdominal pain. Relief of pain occurred 2 hours after starting glucagon. *Case* 10 had a pancreatic fistula and developed acute pancreatitis while awaiting surgery. Her plasma amylase fell from 857 to 608 Somogyi units per 100 ml. following glucagon.

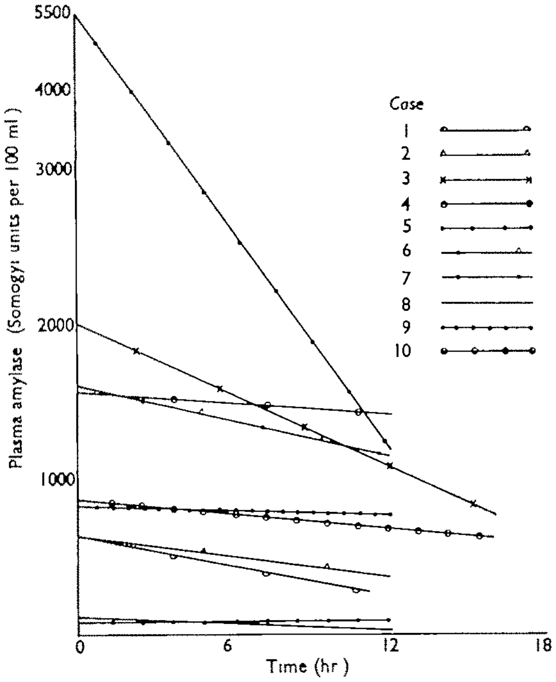

FIG. 1.—Decrease in the plasma amylase at 12 hours following the beginning of intravenous glucagon therapy in 10 patients with severe acute pancreatitis.

Case 7.—A 63-year-old female was found at laparotomy for generalized peritonitis to have acute haemorrhagic pancreatitis. Her plasma calcium was 9·2 mg. per 100 ml. and plasma amylase 115 Somogyi units per 100 ml. Glucagon resulted in the relief of the pancreatic pain at 6 hours and the plasma amylase fell to 58 Somogyi units per 100 ml. 12 hours after starting glucagon.

Case 9.—A 73-year-old female with cardiac failure and rheumatoid arthritis presented with a 5-day history of abdominal pain and vomiting. When seen she was shocked and had a rigid abdomen, and laparotomy confirmed acute haemorrhagic pancreatitis. The post-operative plasma amylase was 830 Somogyi units per 100 ml. and the plasma calcium was 6·2 mg. per 100 ml. Glucagon therapy which was started 11 hours post-operatively induced partial relief of the pancreatic pain within 6 hours. Following laparotomy the patient was anuric and she became hyperkalaemic and died. Post-mortem examination showed a necrotic area in the head of the pancreas with fat necrosis around the body and tail; the kidneys showed acute tubular necrosis.

Case 8.—A 69-year-old female presented with a 3-hour history of epigastric pain and vomiting. She was clinically shocked with a plasma amylase of 5000 Somogyi units per 100 ml. Operation confirmed the presence of acute pancreatitis. Glucagon therapy resulted in pain relief, clinical improvement, and a fall in the plasma amylase of 75 per cent. The patient appeared to be improving when 12 hours after beginning glucagon she suddenly became hypotensive and clinically ill. At this time she had no abdominal pain but rapid clinical deterioration occurred and she died. Post-mortem examination showed severe haemorrhagic pancreatitis.

Non-severe Group.—Twenty patients (11 males and 9 females, aged 23–83; average 46 years) had acute pancreatitis which was classified as non-severe.

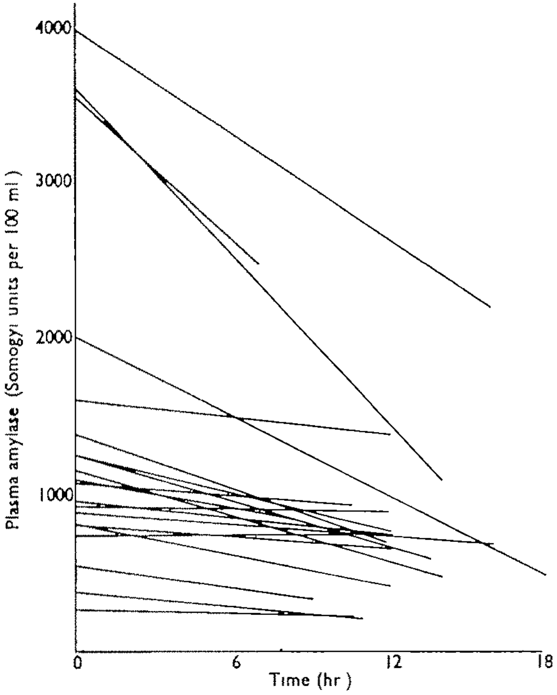

FIG. 2.—Decrease in the plasma amylase at 12 hours following the beginning of intravenous glucagon therapy in 20 patients with non-severe acute pancreatitis.

Table I.—PERCENTAGE OF PATIENTS WITH ACUTE PANCREATITIS CLAIMING PAIN RELIEF FOLLOWING GLUCAGON INFUSION

TIME (hr)	SEVERE GROUP (10 patients)	NON-SEVERE GROUP (20 patients)
0–3	30	50
3–6	60	55
6–12	90	95

All but 1 of these patients had abdominal pain, and glucagon infusion was associated with relief of pain within 1–12 hours (*Table I*) and a fall in the plasma amylase (*Fig.* 2).

DISCUSSION

Glucagon is known to suppress gastric secretion and motility (Stunkard, Van Itallie, and Reis, 1955; Dreiling and Janowitz, 1959; Quirarte, Woodward, and Dragstedt, 1966) and pancreatic exocrine secretion (Walker and Necheles, 1956; Necheles, 1957; Dyck, Texter, Lasater, and Hightower, 1970; Knight and others, 1971). These facts suggest that this hormone might be of benefit in treating patients with acute pancreatitis and our results lend some support to this concept.

In a series of 30 patients with acute pancreatitis treated with glucagon there were only 2 deaths, giving a mortality-rate of less than 7 per cent, in comparison with 22 and 26 per cent in published series in Britain (Pollock, 1959; Efron, 1966; Trapnell, 1966). Ten of the treated patients were classified as severe and in this group there were 2 deaths; a mortality-rate of 20 per cent. This compares with a mortality-rate in this country of over 40 per cent in patients with severe hypocalcaemia (Trapnell, 1966) and haemorrhagic pancreatitis (Sinclair, 1959; Northam, Winstone, and Banwell, 1965; Winstone, 1965; Trapnell, 1966). Glucagon therapy was associated with the relief of pain and clinical improvement in all the patients, including the 2 subjects who eventually died. In all but 1 patient the plasma-amylase values fell during glucagon infusion.

Glucagon is remarkably free of side-effects in man but nausea and vomiting may occur with large doses. Hypocalcaemia has been reported following its administration (Paloyan, Paloyan, and Harper, 1967; Birge and Avioli, 1969) and it is obviously important to monitor plasma-calcium levels in patients with acute pancreatitis receiving glucagon; if severe hypocalcaemia develops, intravenous calcium should be given. In our own series the maximum fall in plasma calcium did not exceed 1·1 mg. per 100 ml. following glucagon infusion and in some cases plasma calcium actually rose during glucagon therapy.

These findings are encouraging and indicate the need for a controlled trial in a large series of patients. This might well be organized on a multi-centre basis.

THE SURGICAL TREATMENT OF PEPTIC ULCER

A 15-YEAR REVIEW

By K. G. Callum* and J. E. Talbot
HAROLD WOOD HOSPITAL, ESSEX

Summary

A 15-year retrospective study of 713 patients having surgical treatment for peptic ulcer was carried out. A comparison of gastrectomy with vagotomy and drainage was made. The ways in which other factors may affect the outcome were also studied.

The results are discussed and some conclusions drawn.

This paper reports a retrospective study of patients who had surgical treatment for peptic ulcer at the Harold Wood Hospital, Essex, during the 15-year period 1952–67. Elective and emergency operations for both duodenal and gastric ulcers are included.

The main objective was to compare the results of gastrectomy with those of vagotomy and drainage. Comparison was made of operative mortality and morbidity and late complications. In addition, how other factors affected the results were noted.

Although the greatest number of operations was performed by one of the consultants specializing in gastric surgery, all the operations for peptic ulcer, many of which were carried out by registrars, are included.

MATERIAL AND METHODS

The names of the patients were obtained from the theatre operations books. A form was designed which was filled in where possible at the follow-up clinic with the help of the patient. In a large number of cases where the notes were well kept until recently the form was filled in directly from the notes. Where the notes were inadequate, questionnaires were sent to the patients, and finally if the replies to the questionnaires were unsatisfactory, new appointments were made to see the patients again in the out-patients' department.

---

* Present address: Lecturer in Surgery, St. Thomas's Hospital Medical School, London, S.E.1.

The results were analysed on punch cards.

RESULTS

The initial number of patients was 967. We were unable to contact 217 and 37 had died of other diseases, so that the total number under review was 713 (*Table I*).

The total figures are shown in *Table I*.

Table I.—TYPE OF ULCER COMPARED WITH OPERATION PERFORMED IN 713 PATIENTS

TYPE OF ULCER	TOTAL NO OF PATIENTS	GASTRECTOMY			VAGOTOMY AND DRAINAGE			GASTRO-JEJUNOSTOMY ONLY
		Total	Polya	Billroth-I	Total	Vagotomy and Pyloroplasty	Vagotomy and Gastrojejunostomy	
Duodenal ulcer	527	228	204	24	275	146	129	24
Gastric ulcer	152	129	79	50	18	17	1	5
Duodenal and gastric ulcers	34	21	16	5	12	8	4	1
Total	713	378	299	79	305	171	134	30

Table II.—PERCENTAGE DISTRIBUTION OF THE DIFFERENT TYPES OF OPERATION PERFORMED DURING THE 15-YEAR PERIOD OF THE SURVEY

TYPE OF OPERATION	1952–7	1958–62	1963–7
Total No. of Cases	313	251	149
Polya gastrectomy	70·6	27·8	5·4
Billroth-I gastrectomy	21·1	4·0	2·0
Vagotomy and pyloroplasty	0·6	21·1	77·8
Vagotomy and gastrojejunostomy	1·0	44·7	12·8
Gastrojejunostomy only	6·7	2·4	2·0

Table III.—PERCENTAGE INCIDENCE OF EARLY POSTOPERATIVE MORBIDITY

MORBIDITY	GASTRECTOMY			VAGOTOMY AND DRAINAGE		
	Total	Polya	Billroth-I	Total	Vagotomy and Pyloroplasty	Vagotomy and Gastrojejunostomy
Total No. of cases	378	299	79	305	171	134
General complications	20	—	—	10·4	—	—
Specific complications	4·7	5·0	3·8	1·9	1·7	2·2

The type of operation performed varied over the 15-year period of the series, as is shown in *Table II*. The shortest follow-up period was 18 months, but it was much longer for the majority of cases.

Operative Mortality.—This includes patients dying during or following operation and before discharge from hospital. The longest period recorded for operative mortality was 17 days after operation.

Thirteen patients died (1·8 per cent for the whole series). Of these deaths, 10 were after emergency operation, 9 of which had been for bleeding and 1 for perforation. The mortality for elective gastrectomy was 3 out of 309 cases (1·1 per cent).

Ten of the patients who died were over the age of 60 years, their operation being performed before 1958. The mortality between 1952 and 1957 was 3·8 per cent. This dropped to 0·5 per cent from 1958 to 1962, and there were no deaths in the last 5 years of the series. However, only 11 partial gastrectomies were performed for benign peptic ulcer in the last 5-year period.

There were no deaths in any of the 305 patients who had vagotomy and drainage procedures.

Table IV.—PERCENTAGE INCIDENCE OF RECURRENT ULCERATION AFTER OPERATION FOR DUODENAL ULCER

CRITERION FOR RECURRENCE	GASTRECTOMY		VAGOTOMY AND DRAINAGE		GASTRO-JEJUNOSTOMY ONLY
	Polya	Billroth-I	Vagotomy and Pyloroplasty	Vagotomy and Gastrojejunostomy	
Total No. of cases	204	24	146	129	24
Recurrence on barium-meal examination	1·5	16·7	2·7	3·9	4·2
Further operation for recurrent ulcer	2·0	29·2	2·7	2·3	16·7

Early Postoperative Morbidity.—This has been divided into general complications that occur after any operation, and those specific to gastric surgery (*Table III*). The general complications include chest infection, deep venous thrombosis and pulmonary embolism, wound infection, burst abdomen, and coronary thrombosis. The specific complications are bleeding, stomal obstruction, and anastomotic or duodenal stump leakage.

Recurrent Ulceration.—It is not easy to diagnose a recurrent ulcer with certainty. The most reliable way is at further operation, although even then it may sometimes be difficult. A barium-meal examination should be reliable, but some patients found to have an ulcer at operation had equivocal barium-meal findings. Further criteria are epigastric pain and bleeding, but these are not definite evidence of a recurrence of ulceration.

For the purpose of this review recurrence was recorded from the barium-meal examination and from reoperations (*Tables IV, V*).

Postcibal Symptoms.—In order to assess dumping, patients were asked if they suffered from attacks of sweating, dizziness, or fainting after meals. Those who had were asked whether these attacks came on soon after meals and were relieved by rest, or whether they came on 2 hours or more after meals and were relieved by taking more food.

Table V.—PERCENTAGE INCIDENCE OF RECURRENT ULCERATION AFTER OPERATION FOR GASTRIC ULCER

CRITERION FOR RECURRENCE	POLYA GASTRECTOMY	BILLROTH-I GASTRECTOMY	VAGOTOMY AND DRAINAGE
Total No. of cases	79	50	18
Recurrence on barium-meal examination	2·5	4·0	—
Further operation for recurrent ulcer	—	4·0	—

Table VI.—PERCENTAGE INCIDENCE OF POSTCIBAL SYMPTOMS

SYMPTOM	GASTRECTOMY			VAGOTOMY AND DRAINAGE		
	Total	Polya	Billroth-I	Total	Vagotomy and Pyloroplasty	Vagotomy and Gastro-jejunostomy
Total No of cases	378	299	79	305	171	134
Early dumping	10·8	12·6	5·1	4·9	2·8	8·2
Late dumping	1·1	1·3	—	1·6	2·3	0·75
Epigastric fullness	3·4	3·6	2·5	1·3	2·3	—
Vomiting	7·6	10·6	1·2	3·8	5·2	2·9
Further operations for symptoms other than recurrent ulcer	2·1	2·7	—	3·9	4·1	3·7

Table VII.—PERCENTAGE INCIDENCE OF NUTRITIONAL PROBLEMS

NUTRITIONAL PROBLEM	GASTRECTOMY			VAGOTOMY AND DRAINAGE		
	Total	Polya	Billroth-I	Total	Vagotomy and Pyloroplasty	Vagotomy and Gastro-jejunostomy
Total No. of cases	378	299	79	305	171	134
Loss of appetite	7·4	8·0	5·0	2·3	2·3	2·2
Weight-loss of more than 6·4 kg.	7·4	7·3	7·6	4·6	4·6	4·4
Iron-deficiency anaemia	11·9	12·6	8·8	4·6	1·1	10·4
Vitamin-B_{12}-deficiency anaemia	4·7	6·0	—	—	—	—

Patients were also asked if they noticed any undue feeling of fullness in the stomach after meals since their operation, and if they had suffered from vomiting which was more than mild and occasional. Initially it was attempted to divide the vomiting into biliary and food types, but later this was felt to be too inaccurate and was discontinued.

Operations considered here are for symptoms other than those of recurrent ulcer; for example, afferent-loop symptoms after Polya gastrectomies or gastro-jejunostomies, and late obstruction after pyloroplasty. The results are shown in *Table VI.* (In *Table VI* and in *Tables VII* and *VIII*, which consider nutritional factors and bowel habits, the results for all peptic ulcers are given together. Separate analysis showed virtually no difference in these factors between duodenal and gastric ulcers.)

Table VIII.—PERCENTAGE INCIDENCE OF ALTERATION IN BOWEL HABIT

BOWEL HABIT	GASTRECTOMY	VAGOTOMY AND DRAINAGE	TRUNCAL VAGOTOMY	SELECTIVE VAGOTOMY
Total No. of cases	378	305	280	25
Bowels improved	5·5	15·7	15·8	12·0
Moderate diarrhoea	1·6	3·6	3·9	—
Severe diarrhoea	0·3	1·3	1·4	—

Nutritional Problems.—The nutritional aspects examined were loss of appetite, where this was sufficient for the patient to complain about it; loss of weight, where this was more than 6·4 kg. compared with the preoperative weight; and anaemia, where the haemoglobin was 75 per cent or below. Only anaemia developing or persisting for more than 1 year after operation has been included. The results are shown in *Table VII.*

In addition there was 1 case of folic-acid-deficiency anaemia which occurred as part of a generalized malabsorption syndrome following a Billroth-I gastrectomy.

Diarrhoea.—Patients were asked whether their bowel habit had altered since their operation, and if so whether it had improved or whether they had suffered from diarrhoea. If they had suffered from diarrhoea they were asked whether they considered this to be mild, moderate, or severe. The results are shown in *Table VIII.* Results were obtained for the different types of gastrectomy, and different types of drainage, but they were similar to those for the whole group.

General Assessment.—At the end of reviewing each patient a general assessment was made on a modification of Visick's classification (Visick, 1948), into the following categories:—

Excellent: Perfect result; absolutely no symptoms.

Very good: No symptoms complained of, but on questioning specifically there were mild symptoms which did not bother the patient.

Good: Mild symptoms complained of, but which did not interfere with work or enjoyment of life and were easily kept under control.

Unsatisfactory: Moderate or severe symptoms, or complications which interfered considerably with work or enjoyment of life; all recurrent ulcers and second operations, further bleeding, etc., even if subsequently perfect.

The results are shown in *Table IX.*

Other Factors affecting the Results of Operation.—

1. *The Indication for and the Urgency of the Operation.*—The mortality for emergency operations was approximately twenty times that for elective operations, as would be expected. For duodenal ulcer the figures were 9·5 and 0·4 per cent and for gastric ulcer 11·4 and 0·6 per cent respectively. The mortality was highest for emergency gastrectomies for bleeding, being 15·5 per cent (9 out of 58 cases; 5 with duodenal ulcer and 4 with gastric ulcer). The lowest mortality occurred after operation for failed medical treatment, being approximately 0·5 per cent for both duodenal and gastric ulcers. There was 1 death after operation for each of the following indications: perforation (total, 81 patients), pyloric stenosis (total, 84 patients), and suspected malignancy (total, 34 patients). Of the 81 patients with perforation, 10 had gastric ulcer and 71 had duodenal ulcer, and the patient who died had a gastric ulcer.

Table IX.—PERCENTAGE DISTRIBUTION OF THE DIFFERENT CATEGORIES USED TO ASSESS THE RESULTS OF OPERATION

CATEGORY	DUODENAL ULCER		GASTRIC ULCER	
	Partial Gastrectomy	Vagotomy and Drainage	Partial Gastrectomy	Vagotomy and Drainage
Total No. of cases	228	275	129	18
Excellent	33·8	38·9	30·2	38·9
Very good	32·5	31·7	31·1	44·4
Good	23·6	18·9	27·1	11·1
Unsatisfactory	10·1	10·5	11·6	5·6

The operative morbidity was the same for elective and emergency operations and for the various indications.

The rate of recurrent ulceration was about the same for elective and emergency operations, and for each of the indications (i.e., between 2 and 3 per cent).

The incidence of patients requiring further operation for symptoms other than recurrent ulceration was similar for all the groups of patients, with one exception: 4 out of 13 patients who had had vagotomy and pyloroplasty for duodenal ulcer with pyloric stenosis subsequently developed a late stenosis of the pyloroplasty, requiring further surgery.

Out of the 81 patients who had a perforation, 51 had a simple suture followed by a definitive operation a few weeks or months later, and 21 had definitive procedures at the initial operation.

2. *Age.*—The patients were divided into three age-groups: under 30 years, 30–60 years, and over 60 years old. Gastric and duodenal ulcer cases were considered separately.

As would be expected, mortality increased with age. The mortality-rate for the over-60 age-group was 5·5 per cent for duodenal ulcer and 8·5 per cent for gastric ulcer as opposed to 0·5 per cent and none respectively for the under-60 age-groups. Postoperative morbidity was markedly lower in the under-30 group, being 10 per cent compared with about 20 per cent in the two older groups.

The recurrent ulcer rate was highest in patients under 30 with duodenal ulcer, being 7·7 per cent, whereas in the older age-groups it varied from 2 to 2·8 per cent for both duodenal and gastric ulcers.

The incidence of unsatisfactory results fell with age, being 15 per cent in the under-30 age-group, about 10 per cent in the 30–60 age-group, and about 7 per cent in the patients over 60.

The other factor worth noting is the incidence of emergency operations, which rose steadily with age, being 5 per cent in the under-30 group and 25–30 per cent in the over-60 group.

Table X.—PERCENTAGE DISTRIBUTION OF DIFFERENT RESULTS OF OPERATION COMPARED WITH THE SEX OF THE PATIENTS

RESULT	DUODENAL ULCER		GASTRIC ULCER	
	Males	Females	Males	Females
Total No. of cases	454	73	107	45
Recurrent ulcer on barium-meal examination	3·5	1·4	1·9	4·4
Further operation for recurrent ulcer	3·5	2·7	0·9	2·2
Unsatisfactory result	9·9	16·4	9·3	15·6

Table XI.—PERCENTAGE DISTRIBUTION OF DIFFERENT RESULTS OF OPERATION COMPARED WITH THE BLOOD GROUP IN PATIENTS WITH DUODENAL ULCER

RESULT	BLOOD GROUP				RHESUS FACTOR		AVERAGE FOR SERIES
	A	B	AB	O	+ve	−ve	
Incidence of this blood group in the general population	42·4	8·3	1·4	47·9	85	15	—
Total No. of patients with duodenal ulcers	36·6 (177)	7·9 (38)	4·6 (22)	50·9 (246)	83 (401)	17 (82)	483
Recurrence of ulcer on barium-meal examination	2·8	2·6	4·5 (1)	3·6	3·7	1·2	3·3
Further operation for recurrent ulcer	3·9	—	4·5 (1)	3·3	3·2	3·7	3·3
Unsatisfactory results	10·1	13·1 (5)	18·1 (4)	10·6	11·7	7·3	11·0

Table XII.—PERCENTAGE DISTRIBUTION OF DIFFERENT RESULTS OF OPERATION COMPARED WITH THE BLOOD GROUP IN PATIENTS WITH GASTRIC ULCER

RESULT	BLOOD GROUP				RHESUS FACTOR		AVERAGE FOR SERIES
	A	B	AB	O	+ve	−ve	
Incidence of this blood group in the general population	42·4	8·3	1·4	47·9	85·0	15·0	—
Total No. of patients with gastric ulcers	39·9 (57)	8·4 (12)	2·1 (3)	49·6 (71)	76·9 (110)	23·1 (33)	143
Recurrence of ulcer on barium-meal examination	—	—	—	4·2	1·8	3	2·1
Further operation for recurrent ulcer	1·8	—	—	—	0·9	—	0·7
Unsatisfactory result	12·3	—	—	14	12·7	9·0	11·9

3. *Length of Follow-up.*—The variation in the type of operation performed over the period of the study has already been shown (*Table II*).

The recurrent ulcer rate increased with the passage of time, being 1·8 per cent in the patients whose operation had been less than 5 years earlier, 2·7 per cent in patients operated on 5–10 years earlier, and 3·2 per cent in cases in whom the operation had been more than 10 years previously.

4. *Sex.*—The results of surgery for male and female patients are shown in *Table X*. The higher percentage of unsatisfactory results in females was due to an increased incidence of weight-loss, anaemia, vomiting, and diarrhoea.

5. *The Presence of Combined Gastric and Duodenal Ulcers.*—There were 34 patients with both duodenal and gastric ulcers, of whom 20 had gastrectomy, 12 had vagotomy and drainage, and 2 had gastrojejunostomy alone.

There were no deaths and no specific postoperative complications. Six patients had general complications (17·6 per cent), which is in keeping with the rest of the series. There were no episodes of bleeding, no symptoms of recurrent ulcer, and no reoperations. The result of operation in 1 patient was assessed as unsatisfactory owing to severe regurgitation after a Billroth-I gastrectomy.

6. *Blood Group.*—The blood groups of the patients are shown in *Tables XI* and *XII*. In some cases the blood group was not known, which accounts for the numbers shown being less than the total number of patients.

DISCUSSION

In 1968 the results of the Leeds/York trial (Goligher, Pulvertaft, de Dombal, and others, 1968) were published which showed that patients with duodenal ulcer who had a gastrectomy did marginally better than those having vagotomy and drainage. We were surprised by this and therefore decided to review our own results.

This is a retrospective study and we included both elective and emergency operations for both duodenal and gastric ulcers. We acknowledge the problems and discrepancies that can arise from retrospective surveys and in particular the large number of patients who cannot be traced. However, despite this, we feel some useful conclusions can be drawn as there still remains a large number of patients in the present review.

An ideal operation for peptic ulcer is one which is safe, simple, effective in curing the ulcer, and has a minimum of unwanted effects. The choice varies with the type of ulcer and to some extent with the degree of urgency.

Elective Operations for Duodenal Ulcers.—Billroth-I gastrectomy had a 29 per cent incidence of recurrent ulceration in our series. Other series have shown recurrence rates of 10 per cent (Mathieson, 1962) and 12·1 per cent (Newton and Judd, 1963), and it is widely accepted that this operation has a very high recurrent ulcer rate for duodenal ulcer. Simple gastrojejunostomy without vagotomy had a 16 per cent recurrent ulcer rate. Other series have shown recurrent ulcer rates of 34 per cent (Lewisohn, 1925) and 50 per cent (Swynnerton, 1955). We have therefore stopped performing gastrojejunostomy as a routine operation.

Polya gastrectomy was the most effective method of curing the ulcer, but had a mortality of 3·7 per cent. However, for elective operations the mortality was 1·1 per cent, and there were no deaths in the last 5 years of the survey.

The morbidity, both general and specific, was twice as high after gastrectomy as after vagotomy. The recurrent ulcer rate and incidence of diarrhoea were lower, but the other long-term complications were more frequent.

There were no deaths following vagotomy in this series. The recurrent ulcer rate was only slightly higher than that after gastrectomy, but the incidence of recurrent ulceration increases with time, and all the vagotomies were performed more recently than the gastrectomies. It is therefore likely that the incidence will increase slightly. The incidence of diarrhoea was slightly higher after vagotomy than that after gastrectomy, but severe diarrhoea only occurred in 1·4 per cent of cases. It should be remembered that the assessment used was the purely subjective view of the patient, but this is surely what matters.

The main criticism of vagotomy is knowing whether complete denervation has been obtained, whereas with gastrectomy it is easy to tell that an adequate amount of stomach has been resected. A postoperative insulin test is useful to the surgeon in training, but it does not help the individual patient. Burge's electrical stimulation test (Burge and Vane, 1958) is more immediately useful and we feel that it should be used more, particularly by surgeons learning the technique of vagotomy.

Selective vagotomy looks promising from the point of view of diarrhoea, and the extra dissection may well be a better guarantee of complete vagotomy (Burge and Frohn, 1969). It certainly warrants further investigations with larger series.

Pyloroplasty generally gave better results than gastrojejunostomy. However, we feel that it is wiser to do a gastrojejunostomy where pyloric stenosis is an indication for surgery because of the risk of recurrent stenosis of the pylorus. It is worth noting that late stenosis of the pylorus may be due to recurrent ulceration, and an insulin test should be done in these patients.

On general assessment the number of unsatisfactory results was the same for vagotomy and drainage as for gastrectomy, but the number of excellent results was better after vagotomy. Taking everything into consideration we feel that vagotomy and drainage is preferable for routine treatment of duodenal ulcer.

Elective Operations for Gastric Ulcer.—Comparing the types of gastrectomy, the recurrent ulcer rate was slightly higher after Billroth-I gastrectomy. Morbidity, postcibal symptoms, and nutritional problems were greater after Polya operations.

Vagotomy and drainage gave very good results for gastric ulcer in the present series, but there were only 30 patients. Other series have also shown favourable results (Hendry and Al Bahrani, 1965; Burge, 1966) and have rationalized this operation (Burge, 1966). Another series (Duthie and Smith, 1968) showed similar results for Billroth-I gastrectomy and vagotomy and pyloroplasty, but pointed out the danger of missing a carcinomatous ulcer. They recommended excising all the ulcer edge for biopsy. We feel that it is wiser to do a gastrectomy for all antral and greater curve ulcers, even if they appear benign, and to biopsy all lesser-curve ulcers, preferably by frozen section.

Other Factors.—The highest rate of recurrence occurred where the indication was suspected malignancy. We were unable to account for this.

As far as emergencies are concerned, it is important to differentiate between a definitive ulcer-curing operation and a life-saving operation which does nothing to stop the ulcer tendency. This applies to operations for bleeding or perforation, where the important thing is to tide the patient over the immediate emergency. However, if the patient is fit enough, and particularly if there have been previous symptoms, then a definitive operation can be done in the first instance.

Until fairly recently gastrectomy was the commonest operation for bleeding peptic ulcer. However, the mortality-rate is high, being 15·5 per cent of 58 patients in our series, whereas there were no deaths among the 21 patients who had emergency vagotomy and drainage for bleeding. A series from Oxford (Schiller, Truelove, and Gwyn Williams, 1970) showed a mortality-rate in operations for bleeding of 21 1 per cent for Polya gastrectomy, 13·2 per cent for Billroth-I gastrectomy, and 8 per cent for vagotomy and drainage.

Perforation has a lower mortality than bleeding, although it may be particularly dangerous in the elderly. The safest operation is simple suture, but there is a growing tendency towards definitive operation at the time of perforation.

In our series most of the patients had a definitive procedure subsequently as a matter of routine policy. In a series of 57 patients treated by simple suture (Hofkin, 1966) 52 per cent subsequently needed definitive surgery. We believe that patients with a perforation and previous ulcer history should have a vagotomy and drainage if they are fit enough and those with no previous symptoms whatever should have simple suture. However, the latter should be followed up for many years, and at the slightest suggestion of further ulceration, definitive surgery should be advised.

We are unable to account for the increased proportion of unsatisfactory results in females.

CONCLUSIONS

The mortality, morbidity, and the long-term complications, with the exception of diarrhoea, are greater after gastrectomy than after vagotomy and drainage. The recurrent ulceration rate is higher after vagotomy, but taking everything into account this is now preferred for duodenal ulcers.

Vagotomy does appear to give good results for gastric ulcers, but where there is a suspicion of malignancy gastrectomy is preferred, and in all cases the ulcer should be adequately biopsied.

Emergency operation for bleeding carries by far the highest mortality. The long-term results are similar for all the various indications for operation.

A pyloroplasty should be avoided where pyloric stenosis is an indication for operation.

The older age-group had a higher proportion of emergency operations, a higher mortality, but a better long-term result if they survived. Patients under 30 years had a higher incidence of recurrent ulceration.

Peptic ulcers are much less common in females but their outcome after surgery appears to be less favourable.

The occurrence of gastric and duodenal ulcers in the same patient does not affect the outcome adversely.

We found no correlation between blood group and the incidence or recurrence of ulcers.

Acknowledgements.—We would like to thank the following people for their kind help and co-operation: Mr. A. D. Messent and Mr. E. C. B. Butler for allowing us to study patients who were under their care; Mrs. Alison Spira who worked so hard as secretary for the project while the results were being obtained; the Brentwood Punch Card Bureau for analysing the data; Professor N. L. Browse and many other colleagues who gave advice and criticism.

ACID SECRETION IN RELATION TO RECURRENCE OF DUODENAL ULCER AFTER VAGOTOMY AND DRAINAGE

By D. J. COWLEY,* J. SPENCER,† and J. H. BARON
DEPARTMENT OF SURGERY, ROYAL POSTGRADUATE MEDICAL SCHOOL, LONDON

SUMMARY

The acid secretory responses of patients with recurrent ulcer after vagotomy and drainage have been compared retrospectively with those of patients with a positive insulin test but no recurrent ulcer and with those of patients with a negative insulin test. Patients with recurrent ulcer were on average 10 years younger than patients with an incomplete vagotomy but no recurrence, although their pre- and postoperative acid secretory responses were similar.

Insulin tests were unreliable when performed less than 3 months after vagotomy. The only possible criterion by which recurrent ulceration could be predicted was a postoperative reduction in the peak acid output after pentagastrin of less than 60 per cent. Equal numbers of patients with 'early' and 'late' positive responses to insulin developed a recurrent ulcer.

Routine postoperative insulin tests may be helpful in assessing the efficiency of the vagotomist but are of limited prognostic value.

The chief value of postoperative insulin tests appears to be in the diagnostic evaluation of post-vagotomy dyspepsia.

It is still not clear whether tests of acid secretion are of any value to clinicians in predicting which patients are liable to develop recurrent duodenal ulcer after vagotomy and drainage procedures. Although recurrent ulcers are almost always associated with incomplete vagotomy, the incidence of incomplete vagotomy evaluated by the insulin test is very much higher than the incidence of recurrent ulcer. Different authors, using the criteria of Hollander (1948) or multiple criteria, have found an incidence of incomplete vagotomy ranging from 15 per cent (Johnston and Goligher, 1971) to 50 per cent (Jordan and Condon, 1970). On the other hand, the reported incidence of recurrent ulcer ranged from 1·5 per cent (Burge, Stedeford, and Hollanders, 1970) to 27 per cent (Stempien, Dagradi, Lee, and Simonton, 1971) but has usually been less than 10 per cent.

It is thus apparent that many patients with an incomplete vagotomy will not develop recurrent ulcer and attempts have been made by various investigators to find criteria based upon acid-secretion tests which would predict which patients are prone to recurrent ulceration (Ross and Kay, 1964; Kronborg, 1972). No clear-cut discriminant functions have been found and the present study is a further attempt to seek such functions.

Three groups of similar size have been studied. Two groups had incomplete vagotomy by Hollander's criteria; all the patients in one of these groups had recurrent ulcer whereas those in the other group had remained symptom-free for at least 3 years after operation. The third group had undergone a complete vagotomy by the same criteria.

PATIENTS AND METHODS

The patients had all been treated by vagotomy and drainage for chronic duodenal ulcer during the decade 1960–9. Each patient had a postoperative insulin test. Some patients had undergone tests of maximum acid output before operation. The following three groups of patients were studied:—

1. **Recurrent Ulcer.**—Twenty-four patients had developed a recurrent duodenal ulcer (excluding one with Zollinger-Ellison syndrome). Sixteen of the patients (13 males and 3 females) had a definite recurrent ulcer which was confirmed by inspection at a second operation, and 8 (6 males and 2 females) had a probable recurrent ulcer which was diagnosed on the basis of recurrent symptoms with radiological demonstration of an ulcer.

2. **No Recurrence.**—Twenty-five patients (23 males, 2 females) had an incomplete vagotomy by the criteria of Hollander (1948) and were followed up for at least 3 years without developing symptoms of recurrent ulcer. These were a consecutive series, excluding the patients who had been lost to follow-up.

3. **Complete Vagotomy.**—Twenty-five patients (23 males, 2 females) had undergone complete vagotomy as judged by Hollander's criteria. These were a consecutive series of such patients chosen at random from our records.

Gastric Secretion Tests.—These were performed after an overnight fast. A size 14 French gauge nasogastric tube was passed into the stomach, the position was checked fluoroscopically, and the resting contents were aspirated and discarded. Fifteen-minute collections of gastric juice were then made by continuous pump and intermittent hand suction. After a basal hour insulin, 0·2 U. per kg., was injected rapidly intravenously and a further eight 15-minute collections were made. In some patients this was followed by the intramuscular injection of pentagastrin, 6 μg. per kg., and a further four 15-minute collections. Preoperative tests were performed in some patients with either histamine acid phosphate, 0·04 μg. per kg. subcutaneously (Kay, 1953), or pentagastrin, 6 μg. per kg. intramuscularly.

Analyses.—The volume of each specimen was recorded and the titratable acidity was determined by titrating to *p*H 7 with *N*/50 NaOH using a glass electrode and autoburette.

---

† All communications should be sent to Mr. John Spencer, Department of Surgery, Royal Postgraduate Medical School, Hammersmith Hospital, London, W.12.

Peak acid output (mEq./hr.) in response to insulin, histamine, or pentagastrin was calculated by adding the two highest consecutive 15-minute outputs and multiplying by two. Blood-glucose was determined by the Autoanalyzer method of Wincey and Marks, (1961).

Statistical Methods.—Student's *t*-test for paired and unpaired data was used where appropriate. Data for males and females have been pooled because there were so few females, even though our previous study (Spencer, Burns, Cheng, Cox, and Welbourn, 1969) had shown significant differences between the sexes in their response to insulin.

RESULTS

1. Timing of the Postoperative Test.—Before November, 1969, all postoperative insulin tests were performed before the patient was discharged from hospital. Since November, 1969, insulin tests have been performed 3 months after the operation. *Table I* shows the mean intervals after operation at which postoperative insulin tests were performed in patients in each of the three groups. Twelve (50 per cent) of the patients with recurrent ulcer were Hollander negative at their first test, but when they were re-tested on a second occasion because of recurrent symptoms all had become Hollander positive. The other 12 patients were Hollander positive at the first test and were no re-tested. Nine of the 12 patients with false-negativ results to their first test had this test less than 4 week after operation.

Table I.—INTERVAL AFTER OPERATION AT WHICH THE INSULIN TESTS WERE PERFORMED IN PATIENTS IN THE THREE GROUPS

INTERVAL AFTER OPERATION	HOLLANDER RESPONSE			
	Positive with Recurrence		*Positive without Recurrence*	*Negative 'Complete'*
	Positive First Test	Positive Second Test		
1–4 wk.	9	–	19	10
1–3 mth	1	2	4	14
3 mth.+	2	10	2	1

Table II.—MEAN DURATION OF FOLLOW-UP AFTER THE INITIAL OPERATION OF PATIENTS IN THE THREE GROUPS

GROUP	TIME (yr.)	
	Mean ± S.E.M.	Range
1 Recurrence		
Reoperated*	2·6 ± 0·42	0·2–6·5
Probable	3·0 ± 0·66	1 –6
2. No recurrence	4·1 ± 0·33	3 –10
3. Complete vagotomy	2·2 ± 0·10	1·4–2·6

* Interval between operations

Table III.—PREOPERATIVE BASAL AND PEAK ACID OUTPUTS (TO HISTAMINE OR PENTAGASTRIN) OF PATIENTS WHO SUBSEQUENTLY HAD AN INCOMPLETE VAGOTOMY

TEST	ACID OUTPUT (mEq./hr.)		*P*
	Recurrence ($n = 20$)	No recurrence ($n = 22$)	
Basal	5·2 ± 1·8	4·5 ± 0·8	0·6
Peak acid output	39·8 ± 4·7	38·9 ± 3·6	0·8

Patients who were Hollander positive at the firs test but have not developed symptoms of a recurren ulcer have not been tested again. Twenty-three o the 25 patients were tested less than 3 months postoperatively. Twenty-four of the 25 patients in th complete vagotomy group were tested either at months or at a shorter interval after the operation None of these patients has been tested again.

2. Duration of Follow-up after Initial Operation.—It can be seen from *Table II* that the mea interval between operations in patients who wer reoperated on for recurrent ulcer was 2·6 years whilst patients with probable recurrence had bee followed up for a mean of 3·0 years. On the othe hand, patients with an incomplete vagotomy but n recurrence have so far been followed up for a mean o 4·1 years with a minimum follow-up period of 3 years

3. Age at Time of First Operation.—The ag distribution of patients with a positive insulin tes who developed a recurrent ulcer and of those wh have remained symptom-free is shown in *Fig.* 1. Th mean age of the recurrent ulcer group was 9·7 year lower than that of the no-recurrence group; this is highly significant difference ($P < 0·01$). There wa no difference in age between patients with confirme recurrence and those with probable recurrence.

4. Gastric Acid Secretion.—

a. Preoperative Acid Secretion.—There was n significant difference between the mean basal aci output or the peak acid output of the patients wit recurrent ulcer and those with no recurrence (*Tabl III*).

Table IV.—POSTOPERATIVE BASAL ACID SECRETION O PATIENTS IN THE THREE GROUPS

GROUP	PEAK ACIDITY (mEq./l.)	*P*	ACID OUTPUT (mEq./hr.)	*P*
1 Recurrence	40·8 ± 4·9	0·003	2·99 ± 0·6	0·02
2 No recurrence	21·3 ± 4·1	0·2	1·36 ± 0·3	0·7
3. Complete vagotomy	29·0 ± 4·2		1·50 ± 0·3	

Table V.—POSTOPERATIVE ACID RESPONSE TO INSULI (0·2 U. per kg.) OF PATIENTS IN THE THREE GROUP

GROUP	PEAK ACIDITY (mEq./l.)	*P*	P.A.O. (I) (mEq./hr.)	*P*
1. Recurrence	100 ± 5·0	0·03	11·25 ± 1·43	0·4
2 No recurrence	83·2 ± 6·4	<0·001	9·42 ± 1·26	<0·001
3. Complete vagotomy	26·5 ± 4·4		1·64 ± 0·35	

P.A.O. (I), Peak acid output to insulin.

b. Postoperative Acid Secretion.—

i. *Basal secretion* (*Table IV*, *Figs.* 2, 3): The mea peak basal acidity and the mean basal acid outpu were significantly higher in patients with recurren ulcer than in patients with incomplete vagotomy bu no recurrence. The corresponding results fo patients with complete vagotomy were intermediat between these two groups. There was almost complete overlap between the three groups.

ii. *Insulin-stimulated secretion*: Mean changes in titratable acidity from basal levels after intravenous insulin are shown in *Fig.* 4. In general, patients with recurrent ulcer attained a significantly higher level of acidity than patients with incomplete vagotomy but no recurrence. However, the increase of acidity above the basal levels was almost identical in each group as the patients with recurrent ulcer started from a higher basal level of acidity. Peak acidity and acid output after insulin are shown in *Table V*. There was no significant difference in peak acid output after insulin between patients with and without recurrence.

The blood-glucose values of the different groups were examined and no differences were found between the groups with regard to fasting, or lowest or maximum fall in blood-glucose.

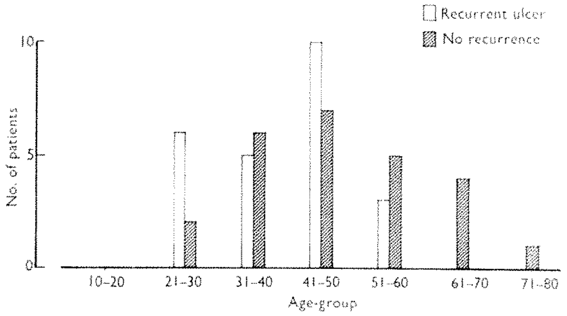

FIG. 1.—Age at the time of the initial vagotomy operation in the patients with an incomplete vagotomy.

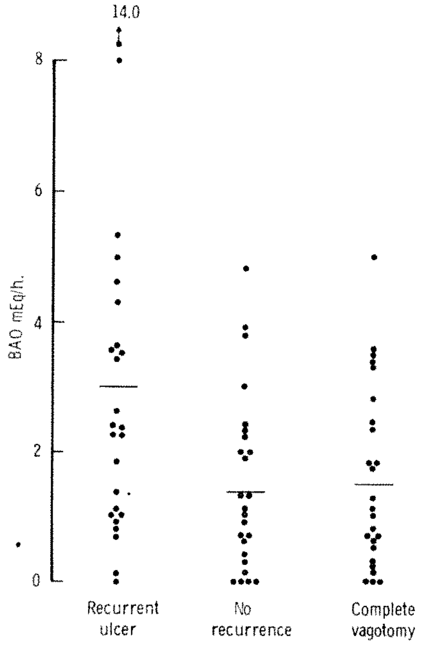

FIG. 3.—Basal acid output (mEq./hr.) during the postoperative secretion test of individuals in the three groups.

iii. *Timing of the Hollander response to insulin* (*Table VI*): The patients with a positive Hollander response have been divided into those whose response was achieved during the first hour (early responders) and those who responded in the second hour (late responders). The numbers of early and late responders were about equal in each group, suggesting that the distribution was completely random. This finding also applied when the patients with recurrent ulcer whose insulin test was positive at either the first or the second test were studied separately. On the other hand, there were quantitative differences; the peak acid output after insulin in both groups was greater in early responders than in late responders, a difference which is significant only when both groups were combined. It can be seen from *Fig.* 5 that the titratable acidity was also greater in the early

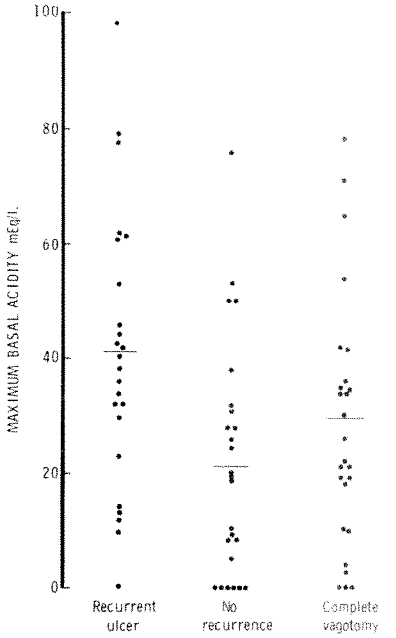

FIG. 2.—Maximum basal acidity (mEq./l.) during the postoperative secretion test of individuals in the three groups.

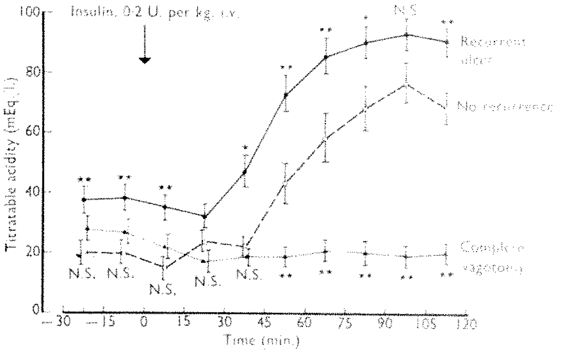

FIG. 4.—Mean titratable acidity (mEq./l.) at the end of each 15-minute period in patients with a positive Hollander response before and after insulin, 0·2 U. per kg. N.S., Not significant. *, $P < 0·05$. **, $P < 0·01$.

responders in both groups. No difference was found in the peak acid output to pentagastrin between early and late responders.

c. Pentagastrin or Histamine-stimulated Secretion.—The peak acid outputs in the three groups are plotted in *Fig.* 6. The scattergram shows considerable overlapping of the groups, and the differences between the mean values of the three groups were of borderline significance. No level of peak acid output could be set which would separate most of the patients with recurrent ulcer from those with no recurrence. The percentage reduction of peak acid output in the smaller number of patients in each group who were tested both before and after operation is shown in *Table VII*. The difference between the mean reduction in patients with recurrent ulcer and in those with no recurrence was not significant at the 5 per cent level, but there was a significant difference between patients with recurrence and those with complete vagotomy ($P < 0{\cdot}05$). Individual results are plotted in *Fig.* 7. Maximum discrimination was achieved between the groups by drawing an arbitrary line at a reduction of 60 per cent. Thirteen out of 17 patients with complete vagotomy and 7 out of 11 patients with no recurrence had a reduction of at least 60 per cent, whereas only 2 of the 19 patients with recurrent ulcer achieved this percentage reduction of peak acid output.

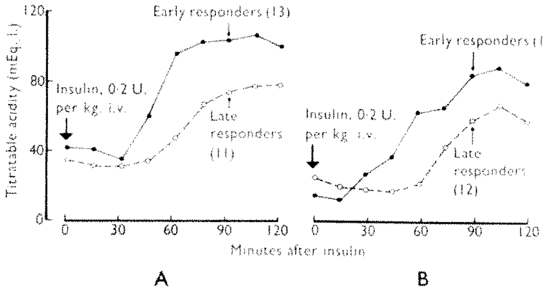

FIG. 5.—Mean titratable acidity at the end of each 15-minute period after insulin, 0·2 U. per kg., in (A) patients with a positive Hollander response who developed a recurrent ulcer, and (B) patients with a positive Hollander response with no recurrent ulcer.

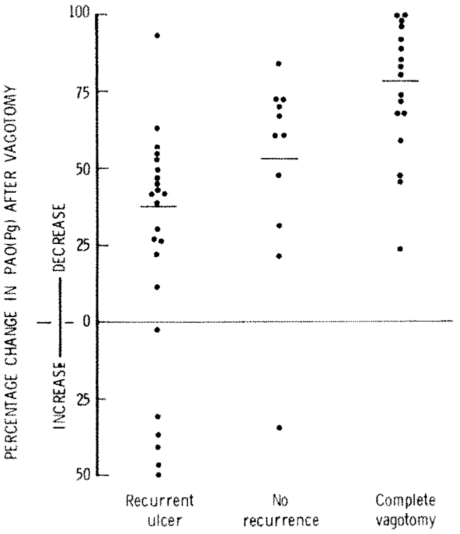

FIG. 7.—Percentage change in peak acid output to pentagastrin after vagotomy in individuals in the three groups pre- and postoperatively.

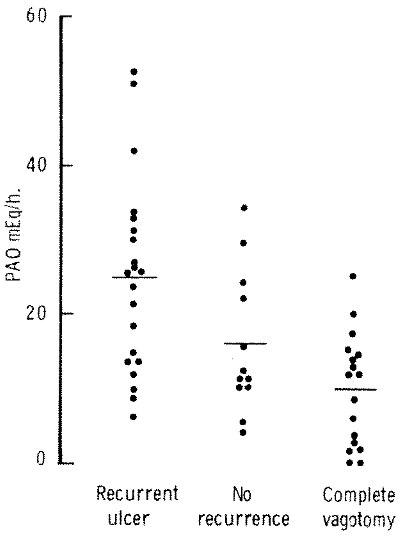

FIG. 6.—Postoperative peak acid output of individuals in the three groups. The difference between the means in the recurrent ulcer and the complete vagotomy groups was significant ($P < 0{\cdot}01$).

Table VI.—TIMING OF THE HOLLANDER RESPONSE IN PATIENTS WITH AND WITHOUT RECURRENT ULCER

GROUP	EARLY RESPONDERS		LATE RESPONDERS		P
	No. of Patients	P.A.O. (I) (mEq./hr.)	No. of Patients	P.A.O. (I) (mEq./hr.)	
1. Recurrence					
Confirmed	9		7		
Probable	4		4		
All	13	13·60	11	8·47	0·07
2. No recurrence	13	11·03	12	7·67	0·2

Mean P.A.O. (I) was significantly higher in patients with an early response ($P < 0{\cdot}05$), although there was no significant difference in P.A.O. (Pg) (pentagastrin) between the two groups.

DISCUSSION

The patients in this series who developed a recurrent ulcer were on average 10 years younger at the time of the first operation than those who have not so far developed a recurrence, although their pre- and postoperative acid secretory responses were very similar at all ages. Thus, vagotomy and drainage appears in this regard to be an acceptable procedure in older patients, but its use in young patients seems to require a more considered evaluation in the future. If vagotomy is used, no effort should be spared in seeking to achieve a complete nerve section.

Our findings are in agreement with those of Watkin and Duthie (1971), who found that the results of insulin tests performed less than 1 month postoperatively were unreliable but that the results of tests at 6 months seemed to represent the final pattern of secretion. Half of the present patients who developed recurrent ulceration had a negative response to an early test and were reported as having had a complete vagotomy. However, once recurrent symptoms had developed all these patients had become Hollander positive, suggesting incomplete vagotomy, when re-tested. We therefore agree with the proposition that postoperative insulin tests should be delayed for several months.

Table VII.—Percentage Reduction of Peak Acid Output to Pentagastrin or Histamine (P.A.O. (Pg or H)) after Vagotomy in Patients in the Three Groups Pre- and Postoperatively

Group	No. of Patients	P.A.O. (Pg or H) (mEq./hr.)		Reduction (per cent)	*P*
		Pre-operatively	Post-operatively		
1. Recurrence	19	40·3	23·4	37*	0·09
2. No recurrence	11	35·2	16·5	53	0·02
3. Complete vagotomy	17	43·5	9·8	78*	

* For groups 1 and 3, $P < 0{\cdot}05$.

One patient with recurrent ulcer after vagotomy and pyloroplasty was excluded from the study because he was found to have a gastrinoma. Two insulin tests carried out at least 6 months after the first operation showed no increase in titratable acidity above the basal levels and it may be assumed that he had had a complete vagotomy. The arbitrary criteria of Hollander (1948) appeared to be useful in that they demonstrated an 'incomplete vagotomy' in patients with recurrent ulcer. On the other hand, the finding of a positive Hollander response is of little value in helping to predict the patients who are liable to develop a recurrent ulcer. In the present study the patients in the no-recurrence group who were followed up for 1½ years longer than the interval between operations in the recurrent ulcer group had a positive Hollander response less than 1 month after the operation. We agree with Kronborg (1971) that insulin tests, however analysed, provide no quantitative data which allow discrimination between groups of patients.

Many investigators have sought criteria which would allow acid-secretion tests to help in predicting which patients are at risk of developing a recurrent ulcer. Kronborg (1972) studied large numbers of patients and found that the following criteria provided the best discrimination: patients were more liable to develop a recurrent ulcer if they had (1) a preoperative maximum acid output (M.A.O.) to histamine or pentagastrin greater than 46 mEq./hr.; (2) a postoperative M.A.O. of more than 20 mEq./hr.; (3) a postoperative reduction of less than 70 per cent in the M.A.O.

The peak acid outputs of our three groups of patients were very similar (*Tables VI, VII*), and Kronborg's first two criteria would have been of little discriminatory value. On the other hand, the percentage decreases in peak acid output did differ between the groups (*Fig.* 7). Patients with a complete vagotomy had the greatest reduction and patients with recurrence the smallest one. A reduction of less than 70 per cent gave some discrimination, but the best discrimination (far from complete) was achieved by a reduction of less than 60 per cent.

In this study of the effects of vagotomy the peak acid output before and after vagotomy has been studied as conventionally described. We appreciate, however, that there is evidence that the dose of pentagastrin required to achieve peak acid output may increase after vagotomy (Konturek, Wysock, and Olesky, 1968; Aubrey and Forrest, 1970; Rosato, Rosato, and MacFadyen, 1971), and in this sense our postoperative dose of pentagastrin may have been 'submaximal'.

Ross and Kay (1964) believed that there were two types of positive response to insulin after vagotomy: an 'early' response, which occurred within the first 45 minutes after insulin, and a 'late' response, which occurred during the 45–120-minute period. Subsequent workers have taken 60 minutes as the dividing time between early and late responders (Johnston, Thomas, Checketts, and Duthie, 1967). The latter group of workers found that the incidence of recurrent ulcer was higher in patients with an early positive Hollander response (36 per cent) compared with 7 per cent in the late positive group. We have failed to confirm this finding in the present study and have found that equal numbers of patients with an early and late response developed a recurrent ulcer. Furthermore, patients who have not developed a recurrent ulcer despite a positive Hollander response were also distributed equally between the two groups of responders. This finding is in accordance with that of Burns, Cheng, Cox, Payne, Spencer, and Welbourn (1969), who studied 100 patients with unoperated duodenal ulcer, found 37 per cent with a 'late positive' response, and concluded that the division into 'early' and 'late' responders was artificial. It must be emphasized, however, that the peak acid output to pentagastrin of early responders in the present study was greater than that of late responders, a finding which is in agreement with that of Giles, Mason, and Clark (1968).

We therefore believe that although the insulin test, when carried out several months after operation and with Hollander's criteria applied, may be helpful in assessing the completeness of vagotomy, basal secretion, preoperative peak acid output, and the insulin test, as judged by any criteria, are not of any value in predicting which patients are liable to develop a recurrent ulcer. The sole criterion we have found of possible value in the prediction of recurrent ulcer is a postoperative reduction of peak acid output after pentagastrin of less than 60 per cent.

We therefore consider that the chief role of gastric acid tests after vagotomy operations (apart from the diagnosis of the Zollinger-Ellison syndrome) is the evaluation of residual vagal innervation in patients with recurrent dyspepsia. We doubt if there is at present a place for routine insulin tests after vagotomy except as part of the systematic assessment of the vagotomist (Kay, 1969; Johnston and Goligher, 1971).

Acknowledgements.—We wish to thank Staff Nurses Shearman, Pope, and King for assistance in carrying out the tests. The support of the Wellcome and Peel Trusts to J. H. B. is gratefully acknowledged.

TEN YEARS' EXPERIENCE IN THE SURGICAL TREATMENT OF BASAL-CELL CARCINOMA

A STUDY OF FACTORS ASSOCIATED WITH RECURRENCE*

BY G. ALLAN TAYLOR†

SAMUEL MCLAUGHLIN FOUNDATION TRAVELLING FELLOW

AND DINO BARISONI‡

REGISTRAR IN PLASTIC SURGERY, ODSTOCK HOSPITAL, WILTSHIRE

SUMMARY

A retrospective review of 817 basal-cell carcinomas which were treated surgically and confirmed by histological examination is presented.

Slightly more than half of the 590 patients were men. Eighty per cent of the lesions occurred in patients over the age of 50 years.

Ninety-four per cent of the lesions occurred in the head and neck with the highest density in the nasal and periorbital regions.

One lesion in 4 had been unsuccessfully irradiated prior to referral.

Less than one-half of the pathology reports gave any indication of completeness of removal. Nineteen per cent of these reported tumour in the margin of resection, indicating incomplete removal.

Over half of the lesions were kept under observation for more than 2 years.

The overall recurrence rate for the series was 9·8 per cent, but for the 535 lesions treated primarily by us the recurrence rate was 5·2 per cent.

Factors producing an increased risk of recurrence probably operate in combination making it difficult to evaluate them individually. Such factors are: (*a*) the anatomical site, the nasal and periorbital regions carrying the highest risk; (*b*) previous treatment before referral, including irradiation; (*c*) free skin-grafting as a method of repairing the defect; (*d*) the presence of tumour histologically in the margin of resection.

Fifty-nine lesions did not recur in spite of pathology reports which indicated incomplete removal. This was not related to either a shorter length of follow-up or the type of repair used in these cases.

THE basal-cell carcinoma which is the commonest of the malignant skin tumours is currently treated in several different ways. The method chosen usually depends on the clinical orientation or discipline of the physician or surgeon involved. Accordingly, surgeons excise these lesions and repair the defects surgically, dermatologists curette or electrofulgurate them, and radiotherapists irradiate them. Each applies his own method more or less unselectively to most of the lesions that he sees, referring certain ones to a colleague when his own form of treatment seems unsuitable. The surgeon is in a unique position in this respect, since his method alone has no limitation to its application. Surgical removal and repair are rarely or never contra-indicated by the size, location, or number of the lesions, or by their clinical subtype (Lever, 1967). Furthermore, the surgeon, unlike his colleagues in dermatology and radiotherapy, is rarely obliged to abandon recurrent lesions. Indeed, he is often consulted in cases of multiple recurrence when the anatomical extent of the lesion or the total dose of ionizing radiation required makes these other forms of treatment unsuitable. Since few, if any, of these tumours are rejected as unsuitable for surgical removal, case selection cannot be expected to play a significant part in improving the results of surgery in any large series. On the contrary, the results might be adversely affected by the inclusion of a large proportion of recurrences, i.e., failures of one of the other methods of treatment.

MATERIAL AND METHODS

Odstock Hospital is the regional Plastic Surgery Centre for southern England, serving a population of approximately 2·5 million people. Skin tumours of all types, including basal-cell carcinomas, are referred to the centre from general practitioners and consultant specialists in the region. The centre has been operating for 20 years and most patients are referred directly by their own family doctor. A significant but lesser number are sent by dermatologists and radiotherapists. These patients have either new lesions which are considered to be unsuitable for non-surgical treatment or recurrent lesions.

The authors felt that such a large and broadly based clinical experience would offer a unique opportunity to study the results of surgery in an unselected series. With this aim in mind a 10-year retrospective study was undertaken based on all the pathology reports of basal-cell carcinoma submitted during the years 1956 to 1965 inclusive. The study was divided into two parts. In the first part the composition and various statistical features of the series will be described. In the second part our interest will focus on the lesions which recurred following surgical treatment. Knowing that a significant number of the lesions that were referred were failures of other forms of treatment, we were particularly interested in determining whether they carried a higher risk of further recurrence after surgical treatment.

COMPOSITION AND STATISTICAL FEATURES OF THE SERIES

1. Age and Sex.—Five hundred and ninety patients made up the series and this included 341 males and 249 females. They presented with a total of 817 lesions. The age distribution is shown in *Fig.* 1. It should be noted that 80 per cent of the patients were over 50 years of age, but also that these lesions may infrequently be encountered in the second and third decades of life.

2. Multiple Lesions.—Eighty per cent of the patients were treated for solitary lesions. In the remaining 20 per cent multiple lesions were present up to a maximum of seventeen in 1 patient. Patients with more than three lesions comprised less than 4 per cent of the series.

Table I.—ANATOMICAL DISTRIBUTION OF 817 LESIONS

Anatomical Site	*No. of Lesions*	*Per cent*	
Scalp, frontotemporal	158	20	Head and neck 94 per cent
Periorbital	158	20	
Nose	212	26	
Cheek	92	11	
Ear	70	9	
Lower face	48	6	
Neck	16	2	
Trunk	41		Body and limbs 6 per cent
Upper limb	16		
Lower limb	6		

3. Anatomical Site.—*Table I* shows the distribution of the 817 lesions by anatomical site. Ninety-four per cent were removed from the head and neck region. Two-thirds of the lesions were located in the upper face and scalp, with by far the highest density being found in the nasal and periorbital regions.

4. Previously Treated Lesions.—More than one-third of the 817 lesions had been unsuccessfully treated elsewhere prior to referral. *Table II* shows the types of treatment used in this group before we received them. Such methods were designated as either 'surgery', 'radiotherapy', or 'other', the latter including electrical and chemical cautery, curettage, etc. Two hundred and eighty-two of the 817 lesions had received one or more of these forms of treatment unsuccessfully before we saw them. Radiotherapy, with or without other methods, had been used in just over three-quarters of the previously treated group (218 lesions).

Table II.—TYPES OF PREVIOUS TREATMENT IN 282 CASES

Nature of Previous Treatment	*No. of Cases*
Irradiation	184
Surgery	36
Other (chemical and electrocautery, curettage, CO_2 snow)	26
Irradiation plus surgery	25
Irradiation plus other	9
Surgery plus other	2

Table III.—TYPES OF REPAIR AFTER REMOVAL OF 817 LESIONS

Method of Repair	*No. of Cases*	*Per cent*
Direct closure	438	54
Free skin-graft	207	25
Local flap	162	20
Distant flap	10	1

5. Lesion Size.—Knowing the importance of lesion size in determining recurrence rate, we were very disappointed to find that clinical records were not detailed enough to enable us to record it in any significant number of the total. We felt that some indirect indication of size is given by the method of repair used in each case.

6. Method of Surgical Repair.—*Table III* shows the various methods used to repair the defects. More than one-half of them required simple approximation of wound edges. Free skin-grafts or flaps were required for the remainder in roughly equal proportion.

7. Histology of Margin of Resection.—In 429 or just over one-half of the pathology reports no indication was given of the completeness of removal. Eighty per cent of the reports which did give this information stated that the margins of resection were histologically free of tumour.

8. Duration of Follow-up.—Various factors contributed to the wide variation in the duration of follow-up observation of the patients in the series. Age and general health, together with certain geographical limitations, were the commonest factors. Many patients were sent back to the referring physician for follow-up soon after suture removal. These patients were obviously followed up for a longer time than our records could show. Despite these limitations, 55 per cent of the patients were followed up for more than 2 years postoperatively, and only 17 per cent for less than 6 months.

RECURRENT LESIONS

What is a recurrence? Many factors influenced our decision in each instance, but often there was great difficulty in deciding whether a lesion which reappeared in the same site was a true recurrence or a new lesion. First, lesions appearing many months or years after removal can hardly be called 'recurrent', but it is difficult to establish an arbitrary time after which recurrence is unlikely. Secondly, only by examining serial sections cut in three planes can the pathologist accurately comment on completeness of removal. Very few of the specimens in this series were so examined. We feel that this approach is justified in a busy pathology department dealing with a tumour of such low-grade malignancy. Thirdly, reports which do indicate incomplete removal should localize the residual tumour to either a deep or peripheral margin of resection so that the location of a future recurrence with respect to the scar of removal can be correlated with this information. Such an approach is neither possible nor practical in the majority of centres. Our records were certainly not detailed enough to enable us to take all these factors into account; therefore, we designated lesions as 'recurrent' when suspicion of recurrence was queried by the surgeon on the clinical notes or pathology requisition. Thus, the referring physician, the patient, or the surgeon himself noted the presence of some abnormality in or immediately adjacent to the scar of previous removal or repair.

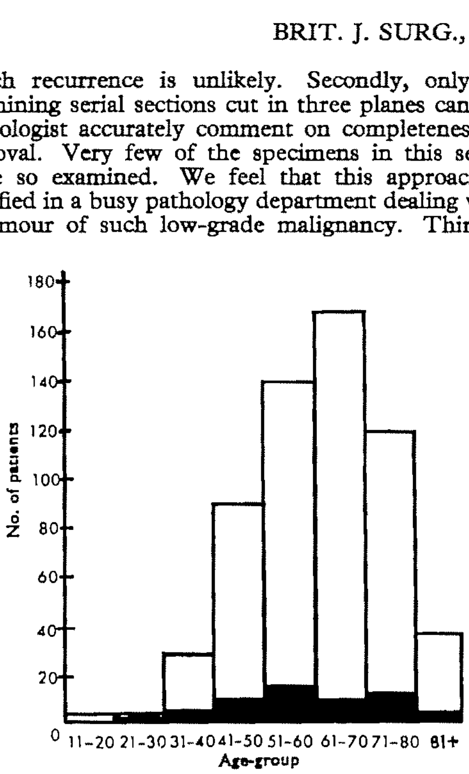

FIG. 1.—Age distribution of 590 patients with basal-cell carcinoma. ■, Recurrences.

There were 59 recurrent lesions found in 52 patients. Several of the 59 lesions recurred more than once, so that the total number of tumours in this group was 82. This represents an overall recurrence rate for the series of 9·8 per cent. We were interested to note that in many instances where recurrence was suspected clinically and a biopsy was carried out, there was no evidence of tumour histologically. It is regretted that exact numbers were not recorded to support this observation.

1. Age and Sex.—The age distribution of recurrent lesions, as shown in *Fig.* 1, is similar to that for the whole series. There were a few more males than females in the recurrent group.

2. Anatomical Site.—*Table IV* shows the distribution of the recurrences by anatomical site. The recurrence rate in the nasal and periorbital regions was significantly higher then in the rest of the head and neck. The higher risk in these areas may be more apparent than real because of the very high incidence of lesions in these relatively small areas. The greater technical difficulties encountered in removing lesions and repairing the defects around the eyelids and nose may also account for the greater incidence to some extent.

3. Previous Treatment.—There were 31 recurrences amongst the 282 lesions which had been treated previously elsewhere (a rate of 11 per cent). The recurrence rate for the 558 lesions treated primarily by us was 5·2 per cent, which seems to be significant. Lesions which had previously been treated surgically had a recurrence rate of 8·7 per cent compared with 17 per cent for those treated by 'other' methods prior to referral.

4. Recurrence Interval.—*Table V* shows the length of time between the removal of the lesion and the detection of a recurrence. Recurrences continue to appear at a fairly constant rate over 3 years in our experience. Only one-third appeared within a year of excision, while one-fifth had still not become apparent by the end of the third year.

Table IV.—ANATOMICAL DISTRIBUTION OF 82 RECURRENCES

Anatomical Site	*No. of Recurrences*	*Recurrence Rate* (per cent)
Scalp, frontotemporal	11	6·9
Periorbital	25	15·8
Nose	28	13·2
Cheek	8	8·7
Ear	3	4·3
Lower face	3	6·3
Neck	0	—
Trunk	4	9·7

Table V.—RECURRENCE INTERVAL OF 82 RECURRENT LESIONS

Time from Removal until Recurrence	*No. of Cases*	
0–6 mth.	11	36 per cent in first year
7–12 mth.	19	
13–24 mth.	18	22 per cent in second year
25–36 mth.	17	21 per cent in third year
36 mth	17	21 per cent after 3 years

Table VI.—TYPES OF REPAIR USED IN 82 RECURRENT LESIONS

Method of Repair	*No. of Cases*	*Recurrence Rate* (per cent)
Direct closure	27	6
Free skin-graft	37	17
Local flap	16	10
Distant flap	2	20

5. Method of Repair.—The relationship between recurrence and the type of repair used is shown in *Table VI.* Not unexpectedly, the use of either a free graft or flap carried a higher risk of recurrence. As stated previously, this is an indirect measurement of the size of the lesion. Of greater interest to us was the fact that the use of a free graft seemed to carry a higher risk of recurrence than a local flap. In order to exclude the possibility that free grafts enable a potential recurrence to be detected sooner owing to the thin coverage, we compared the recurrence interval in grafted defects with that in ones closed with bulkier tissue. No significant difference was found. It has also been suggested that thick coverage over residual tumour may inhibit or even prevent its growth. To test this theory we examined the method of repair used in 59 lesions which did *not* recur clinically in spite of pathology reports indicating the presence of tumour in the margins of resection. A flap type of repair was not found to have been used more frequently in these lesions.

The higher recurrence rate which appears to be associated with the use of a free graft repair is probably related to several other factors which are selectively introduced when this method is chosen by the surgeon. The anatomical site of the lesion is an obvious factor. Periorbital and nasal lesions, with their intrinsically higher recurrence rate, are also places where free skin-grafts are used more frequently because of local technical considerations. Also, free grafts are frequently used when removal is known to be incomplete and in extremely large lesions.

Table VII.—Margins of Resection in 840 Lesions and 82 Recurrences

Pathologist's Report	No. of Cases	No. of Recurrences	Recurrence Rate (per cent)
Margin of resection clear of tumour	333	19	5·7
Tumour present in margin of resection	78	19	24·4
No indication given	429	44	9·7

6. Histology of Margins of Resection.—The correlation between clinical recurrence and the pathologist's report as to the completeness of removal is shown in *Table VII*. Lesions reported as being incompletely removed were more than four times as likely to recur as those said to be completely removed. Of particular interest also is the fact that only 1 in 4 lesions removed incompletely according to the pathologist actually gave rise to a clinical recurrence. This was not due to a shorter length of follow-up since over one-half of this group of patients was followed for more than 2 years.

CONCLUSIONS

Because of an anticipated increase in the risk of recurrence, basal-cell carcinomas in the following categories probably require observation over a period of approximately 3 years: (*a*) lesions in the nasal and periorbital regions; (*b*) lesions which have already recurred following any form of treatment; (*c*) lesions in which residual tumour is reported in the margin of resection.

As noted earlier, cold-knife surgical removal and repair are rarely contra-indicated. The recurrence rate of 5·2 per cent for an unselected group of 535 lesions treated primarily in this series is significantly better than that reported in two similar series (Shanoff, Spira, and Hardy, 1967; Monballiu, 1968) where other forms of treatment were selectively applied. Although lower recurrence rates have been reported in series treated by electro-desiccation and curettage, such series rejected lesions over a certain size or in certain locations, or those which had previously recurred. We feel that our findings strongly support surgical excision and repair as the ideal method for primary treatment of basal-cell carcinomas.

Acknowledgements.—The authors wish to thank Mr. John Barron and Mr. J. E. Laing for access to the clinical records of their patients at Odstock Hospital. We are also grateful to Dr. J. R. H. Pinkerton for his co-operation in obtaining the pathology reports upon which all the clinical material in this paper is based.

OBSTRUCTIVE UROPATHY IN GRANULOMATOUS BOWEL DISEASE

By R. A. H. MOONEY and G. R. SANT

DEPARTMENTS OF SURGERY, TRINITY COLLEGE AND MEATH HOSPITAL, DUBLIN

SUMMARY

Ureteral obstruction is a seldom recognized complication of Crohn's disease and its incidence and natural history are unknown. The intravenous pyelogram findings in 5 cases of Crohn's disease are discussed and it is suggested that ureteral involvement signifies severe disease necessitating operation. The operative treatment of 1 of the cases by ureterolysis plus bowel excision is presented and discussed. Routine intravenous urography is recommended as part of the assessment of cases of Crohn's disease.

Among the urological complications of granulomatous bowel (Crohn's) disease, ureteral obstruction is an uncommon but increasingly frequently diagnosed complication (Present, Rabinowitz, Banks, and Janowitz, 1969). Up to 1970, 28 cases of ureteral obstruction developing as a consequence of Crohn's disease were reported in the American literature (Enker and Block, 1970). No similar reports have appeared in the British literature. This paper reports a case of Crohn's disease presenting as obstructive hydronephrosis and discusses the intravenous pyelogram findings in this patient and 4 other cases of Crohn's disease.

CASE REPORT

Case 1.—N. O'M., a 22-year-old male, was referred to the Meath Hospital Urological Department in August, 1971, for investigation of a right-sided hydronephrosis. He presented with an 8-month history of weight-loss (19 kg.), abdominal pain (especially in the right flank and right thigh), loss of energy, and constipation. He had a past history of appendicitis complicated by peritonitis in 1968, for which he had had an operation in another hospital. Examination revealed a thin, sick-looking young man. His weight was 47·2 kg.; haemoglobin, 12·4 g. per cent; leucocytes, 13,900 per c. mm.; erythrocyte sedimentation rate, 116 mm. per hour; urea, 38 mg. per cent; serum protein, 7·5, with albumin 2·8. A vague mass was palpable in the hypogastrium and there was a small, fluctuant swelling in the left gluteal region.

Intravenous urography on 10 Aug., 1971, revealed a grade III dilated right pelvis, and a grade II–III dilated right ureter (*Fig.* 1). Radiographs of the chest and hips were negative. Rectal examination revealed a large stenosing rectal mass of 10 cm. Biopsy showed non-specific inflammation with focal mucosal ulceration. The gluteal abscess was aspirated and the aspirate grew *Streptococcus faecalis* and *Escherichia coli*. Tubercle bacillus culture was negative. Repeated urine cultures were sterile, as were blood cultures.

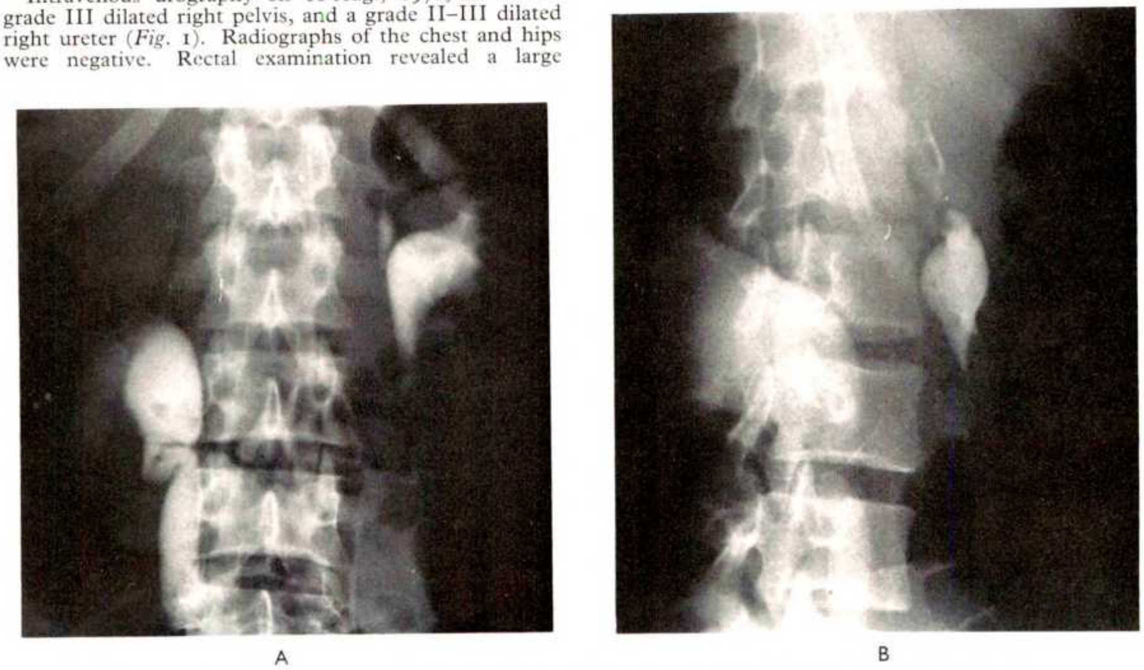

FIG. 1.—*Case* 1. A, Intravenous urogram, showing the dilated right ureter (grade II–III) and pelvis (grade III). B, Oblique view of A showing the grossly dilated right pelvis.

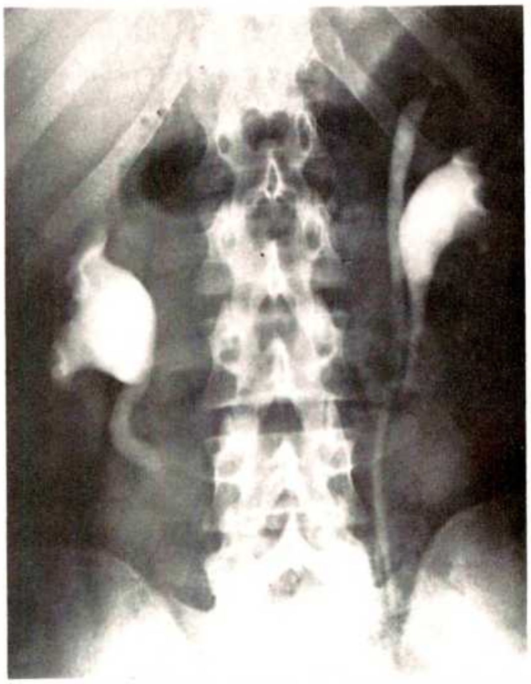

FIG. 2.—*Case* 1. Intravenous urogram 2 weeks postoperatively showing marked reduction in the ureteral and pelvic dilatation.

At laparotomy on 23 Aug. the terminal ileum and caecum were found to be thickened and adherent to the large bowel and a large rectal mass was adherent to the sacrum. The right ureter was dilated by approximately 2 cm. down to the pelvic brim, where it was involved by the inflammatory mass. The ureter was dissected free from the mass and an anterior resection of the rectum was performed together with a transverse colostomy.

The pathology report was as follows: the excised rectum was diffusely thickened and the overlying mucosa showed a cobble-stone appearance. There were foci of mucosal ulceration, subserosal fibrosis, and granulomas, with occasional giant cells.

Repeat urograms 2 weeks postoperatively prior to discharge showed a reduction in the ureteral and pelvic dilatation (*Fig.* 2). A barium-enema examination revealed an irregular mucosal pattern in the caecum and terminal ileum consistent with Crohn's disease.

The colostomy was closed on 24 Feb., 1972, following a course of cortenemas through the proximal loop. Intravenous urograms on 18 Feb. revealed grade I–II ureteral dilatation and grade I pelvic dilatation. The patient's weight was 66·2 kg.; haemoglobin, 16 g. per cent; erythrocyte-sedimentation rate, 4 mm. per hour. At a follow-up examination on 28 March the patient weighed 71·7 kg. and had returned to work after an absence of 14 months.

UROGRAPHY FINDINGS IN 4 CASES OF CROHN'S DISEASE

Case 2.—E. F., a 21-year-old female, was investigated for pyrexia of unknown origin and found to have severe Crohn's disease of the large bowel with enteric fistulation.

The erythrocyte-sedimentation rate was 120 mm. per hour and an intravenous pyelogram showed a grade I–II dilatation of the right pelvis and ureter.

Case 3.—E. O'D., a 22-year-old female, developed reactivation of Crohn's disease after an ileotransverse anastomosis 5 months previously. A barium-enema examination showed an abnormal mucosal pattern in the caecum and fistula formation. The erythrocyte-sedimentation rate was 70 mm. per hour and an intravenous pyelogram revealed grade I dilatation of the right pelvis.

Case 4.—T. M., a 55-year-old male, had been followed up for 2 years after a right hemicolectomy for Crohn's disease of the terminal ileum and caecum. A barium-enema examination showed normal mucosa in the terminal ileum. The erythrocyte-sedimentation rate was 5 mm. per hour and an intravenous pyelogram showed normal appearances.

Case 5.—M. H., a 50-year-old female, had been asymptomatic after an ileotransverse anastomosis for Crohn's ileitis 18 months previously. The erythrocyte-sedimentation rate was 10 mm. per hour and an intravenous pyelogram showed no ureteral or pelvic dilatation.

DISCUSSION

Hyams, Weinberg, and Alley (1943) were the first to report ureteral obstruction as a complication of Crohn's disease. Since then it has been increasingly recognized and reported.

The true incidence of ureteral involvement in Crohn's disease is not known. Schofield, Staff, and Moore (1968), using radioactive renography, demonstrated ureteral stasis in 50 per cent of patients with regional enteritis. The intravenous urographic findings in the 5 cases reported here would seem to indicate that ureteral involvement occurs in cases of severe, active Crohn's disease (i.e., with fistulation, elevated erythrocyte-sedimentation rates, perianal complications, etc.). Present and others (1969), in a report from New York, found obstructive hydronephrosis in 7 per cent of patients affected by Crohn's disease. They attributed this high incidence to the fact that most of their patients were referred from other centres because of severe complicated disease.

The reasons for ureteral involvement in Crohn's disease are not clear. Redish (1952) regards it as a reflex disturbance of ureteral tone resulting from the adjacent intestinal inflammation. However, Schofield and others (1968) favour the view that it results from the direct involvement of the peri-ureteral tissue by intestinal microperforation and resulting inflammation.

Prior to the report of Enker and Block (1970) the treatment of this complication of Crohn's disease was centred exclusively on the involved intestine, and surgical intervention to liberate the involved ureter was considered unwarranted by Present and others (1969). However, results of this approach to treatment have been unsatisfactory. Of the 21 cases in the literature which were not treated by ureterolysis, 50 per cent achieved ureteral decompression at a cost of at least two operative procedures (including two nephrectomies).

CONCLUSION

1. A case of Crohn's disease presenting as a right-sided ureteral obstruction is presented. The best treatment is probably directed simultaneously at both the intestinal and urological disorders.

2. From our small experience obstructive uropathy must be considered a sign of advanced inflammatory bowel disease and, as such, constitutes an indication for operative intervention.

3. The literature on the subject of ureteral involvement in Crohn's disease is briefly reviewed. Routine intravenous urography is recommended as part of the investigations of all cases of Crohn's disease in order (*a*) to ascertain the true incidence of obstructive uropathy and (*b*) to assess the activity of the disease and the need for operation.

LOBULAR CARCINOMA IN SITU OF THE BREAST

BY R. A. A. MACAULAY* AND M. J. MITCHINSON†
DEPARTMENT OF PATHOLOGY, UNIVERSITY OF CAMBRIDGE

SUMMARY

Ten patients with lobular carcinoma in situ of the breast have been seen in 2½ years in Cambridge. Within that period of time 8 of these patients also had infiltrating carcinoma. Four out of 5 cases had bilateral lobular carcinoma in situ and 2 patients had bilateral infiltrating carcinomas. The pre-malignant nature of lobular carcinoma in situ is not proven but is likely. It is suggested that the evidence supports previously expressed views that a histological diagnosis of lobular carcinoma in situ merits mastectomy and a large contralateral biopsy in the first instance.

IT is only in recent years that most pathologists have become fully aware of lobular carcinoma in situ of the breast and its apparent dangers, although it

† Address for reprints: Dr. M. J. Mitchinson, Department of Pathology, Tennis Court Road, Cambridge CB2 1QP.

was first described 32 years ago (Foote and Stewart, 1941; Muir, 1941). Increased interest in the subject has been stimulated by studies in the U.S.A. which suggest that the disease may be multifocal, bilateral, and premalignant in a high proportion of cases (McDivitt, Hutter, Foote, and Stewart, 1967; Hutter and Foote, 1969; Urban, 1969; Farrow, 1970). The lack of published accounts in this country prompts us to record our experience with this condition.

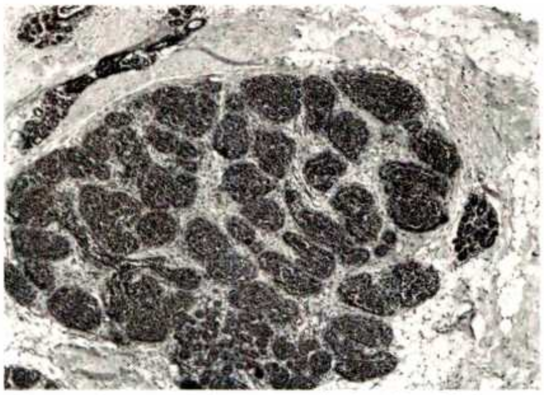

FIG. 1.—*Case* 4.—Lobular carcinoma in situ. H. and E. (× 33.)

The histological diagnosis of lobular carcinoma in situ has been made in 10 patients in the Department of Pathology, University of Cambridge, over a period of 2½ years. During this time approximately 850 breast biopsy and mastectomy specimens have been examined. In each of the 10 cases of lobular carcinoma in situ the diagnosis was made independently by at least two observers. All the mastectomies described were simple.

CASE REPORTS

Case 1.—In late 1971 a biopsy of a right breast lump in a 51-year-old woman showed lobular carcinoma in situ. A right mastectomy was performed and a blind biopsy of the left breast was taken. Both specimens showed only dysplasia. The patient then developed a lump in the left breast. A larger biopsy was taken which showed lobular carcinoma in situ. A left mastectomy was performed, and examination of the specimen revealed multifocal lobular carcinoma in situ with no evidence of an infiltrating carcinoma.

Case 2.—In early 1971 a right breast lump in a 32-year-old woman proved on biopsy to be an infiltrating lobular carcinoma. The right mastectomy specimen showed residual infiltrating carcinoma. One year later a biopsy of a lump in the left breast also showed an infiltrating carcinoma, and, in addition, lobular carcinoma in situ. Re-examination of sections of the right mastectomy specimen revealed lobular carcinoma in situ which had not been reported originally.

Case 3.—In late 1971 a large biopsy of a right breast lump in a 49-year-old woman showed extensive lobular carcinoma in situ with a tiny focus of infiltration in one area. A right mastectomy revealed neither residual infiltrating carcinoma nor lobular carcinoma in situ. The left breast has not yet been biopsied.

Case 4.—A 51-year-old woman complained in mid-1971 of a lump in the left breast; an unnoticed ill-defined nodular area was also found in the right breast. The left biopsy showed only dysplasia but that of the right breast demonstrated lobular carcinoma in situ. A right mastectomy revealed extensive lobular carcinoma in situ (*Fig.* 1) with a tiny focus of infiltration (*Fig.* 2). A larger biopsy of the left breast then revealed lobular carcinoma in situ; the left mastectomy specimen showed multifocal lobular carcinoma in situ but no infiltrating carcinoma.

Case 5.—In 1968 a 48-year-old woman complained of a discharge from the right nipple. No mass was palpable but a biopsy of the mammary ducts was reported as showing dysplasia. In 1969 a recurrent lump in the same region proved on biopsy to be an infiltrating carcinoma. The right mastectomy specimen showed residual infiltrating carcinoma. In 1971 a lump was found in the left breast and proved to be an infiltrating carcinoma. The left mastectomy specimen showed no residual infiltrating carcinoma but extensive lobular carcinoma in situ. The sections of the biopsy of the right mammary ducts taken 3 years previously were then reviewed and showed unequivocal lobular carcinoma in situ. This patient is now (mid-1972) dying from carcinomatosis.

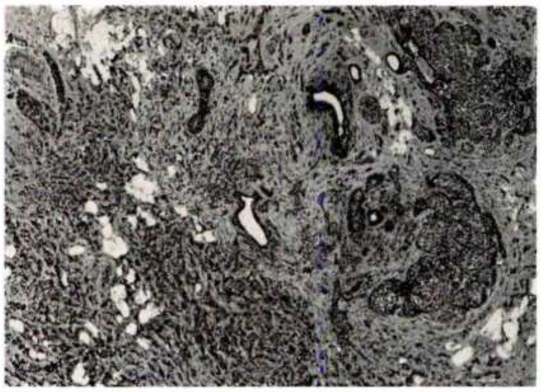

FIG. 2.—*Case* 4. Early infiltrating carcinoma in the area of lobular carcinoma in situ. H. and E. (× 33.)

Case 6.—In mid-1971 an infiltrating carcinoma was found in the biopsy of a right breast lump in a 27-year-old woman. The mastectomy specimen showed residual infiltrating carcinoma and multifocal lobular carcinoma in situ. Biopsy of the other breast has not been performed.

Case 7.—In early 1971 a biopsy of a left breast lump in a 72-year-old woman showed an infiltrating carcinoma. The mastectomy specimen showed no residual carcinoma but a few foci of lobular carcinoma in situ. Biopsy of the other breast has not been performed.

Case 8.—In late 1970 a biopsy of a right breast lump in a 72-year-old woman showed an infiltrating carcinoma and lobular carcinoma in situ. Sections of the mastectomy specimen showed only dysplasia. No contralateral biopsy has been performed.

Case 9.—In 1970 a biopsy of a left breast lump in a 47-year-old woman showed an infiltrating carcinoma. The mastectomy specimen revealed some residual infiltrating carcinoma and lobular carcinoma in situ. The other breast has not been biopsied.

Case 10.—In mid-1970 a biopsy of the right mammary ducts was performed in a 51-year-old woman complaining of a persistent discharge. This showed infiltrating carcinoma as well as lobular carcinoma in situ. A right mastectomy showed another area of lobular carcinoma in situ. Two subsequent blind biopsies of the left breast have shown only dysplasia.

DISCUSSION

In all except 1 of the 10 patients diagnosed as having lobular carcinoma in situ there was an infiltrating carcinoma on one or both sides. It would, however, be grossly incorrect to conclude that lobular carcinoma in situ gives rise to infiltrating carcinoma in 9 out of 10 cases, because in 6 of the current series the lobular carcinoma in situ only came to light when an infiltrating carcinoma was palpated. The majority of cases of lobular carcinoma in situ are probably clinically silent. However, 2 of the 9 infiltrating carcinomas were small and found in the centre of large expanses of lobular carcinoma in situ. The appearances suggested that at least in these 2 patients lobular carcinoma in situ may have developed into an infiltrating carcinoma. Of the 5 cases in which both breasts have been examined histologically, 4 have so far shown evidence of bilateral lobular carcinoma in situ with 2 bilateral infiltrating carcinomas. There is also abundant evidence from the present 10 patients that lobular carcinoma in situ is a multifocal disease.

Clearly such small numbers add nothing to the overall statistical study of the disease and the evidence presented here is purely anecdotal. Nevertheless, some of these case reports present striking sequences of events. For instance, it is likely that the impalpable tiny infiltrating carcinoma in the mastectomy specimen in *Case* 4 would have remained undetected if lobular carcinoma in situ had not been seen on the biopsy and mastectomy advised. It is also possible that the unfavourable outcome in *Case* 5 might have been prevented by the recognition and treatment of lobular carcinoma in situ at the time of the first breast biopsy.

In view of these observations we have attempted to find examples of lobular carcinoma in situ in sections seen in this department in the years 1946–61 in the hope of providing a retrospective study of patients followed for 10 years or more. This has proved somewhat frustrating because of the small numbers and inadequate follow-up. Two hundred and eighteen specimens were re-examined because they had been indexed as showing dysplasia with epithelial proliferation. Only 4 examples of lobular carcinoma in situ which had been treated by biopsy only were found. Three of these 4 patients have been followed for 10 or more years, with no clinical recurrence of breast disease. Eight examples of lobular carcinoma in situ were found in sections of breasts removed because of infiltrating carcinoma (6 cases) or persistent nipple discharge. Clinical follow-up data are available for these 8 patients at 0, 3, 4, 6, 9, 9, 14, and 18 years after mastectomy respectively. None has had clinical contralateral disease. Clearly this retrospective study, admittedly of very limited value, would not lead one to suppose that lobular carcinoma in situ is a dangerous disease, in contrast to the findings in our more recent patients.

The histological diagnosis of lobular carcinoma in situ is not difficult. In several of the present cases it was made on cryostat sections. The appearances have been reviewed elsewhere (McDivitt, Stewart, and Berg, 1968). The pathological differential diagnosis includes benign epithelial proliferation as well as direct lobular invasion by a ductal carcinoma (Feckner, 1971).

Lobular carcinoma in situ appears to be clinically silent in most cases. Out of 14 breasts with the disease in this series of 10 patients, 4 were palpable lumps, 1 was found after a nipple discharge, and the others were apparently silent until a carcinoma was palpated or a blind biopsy was performed.

The management of a patient with lobular carcinoma in situ is often a problem. To judge from the American retrospective studies quoted above if lobular carcinoma in situ alone is found on biopsy the risk of another focus of carcinoma in situ in the same breast giving rise to infiltrating carcinoma is high (up to 35 per cent in 20 years) and merits immediate mastectomy. From the same studies it appears that the incidence of bilateral lobular carcinoma in situ is also high (up to 54 per cent) and held to justify a large contralateral biopsy even if the other breast is clinically normal. Clearly if this biopsy also shows carcinoma in situ then another mastectomy would be indicated.

Comment on this advice seems unjustified after our small experience of the condition, but at least we have seen nothing in our study to contradict this suggested management. The only exceptions might be the elderly or those in whom the operative risk is high. Lobular carcinoma in situ has received insufficient attention in this country; further retrospective and prospective studies are justified in centres where large numbers of patients with breast disease are seen.

We do not feel qualified to judge the merits of introducing expensive screening procedures such as mammography in the hope of detecting the 'silent' cases of lobular carcinoma in situ. It does, however, seem that the evidence that lobular carcinoma in situ is a premalignant condition is not dissimilar from that suggesting that carcinoma in situ of the cervix leads to invasive carcinoma. In both these relationships the pathological and statistical evidence is suggestive but not conclusive. It is safer to regard lobular carcinoma in situ seriously than to ignore it.

TRAUMATIC ANEURYSMS OF THE SUPERFICIAL TEMPORAL ARTERY

BY I. C. BAILEY AND J. W. M. KIRYABWIRE

DEPARTMENT OF SURGERY, MAKERERE UNIVERSITY MEDICAL SCHOOL, KAMPALA, UGANDA

SUMMARY

Six patients with aneurysm of the superficial temporal artery are reported from Africa. The presenting symptom was a pulsating swelling in the temporal region, and blunt trauma to the side of the head was the aetiological agent in every case. Treatment by surgical excision is advocated. It is suggested that aneurysms of the superficial temporal artery occur more frequently than reports in the literature suggest.

THE earliest reported case of superficial temporal aneurysm appears to have been that of Bartholin in 1740 which is included in a group of 37 cases in De Santis's book of 1884 (Brown and Mehnert, 1942). Up to 1970 a total of 131 cases had been reported in the literature (Schecter and Gutstein, 1970). It would seem, therefore, that these aneurysms are infrequently encountered and are for the most part overlooked by the authors of standard textbooks on head injury. It is our belief that the paucity of the case reports belies the real incidence of this complication of head trauma. The 6 patients presented here are the first cases reported from Africa and are used to emphasize the fact that post-traumatic aneurysms of the superficial temporal artery occur more commonly than is generally supposed.

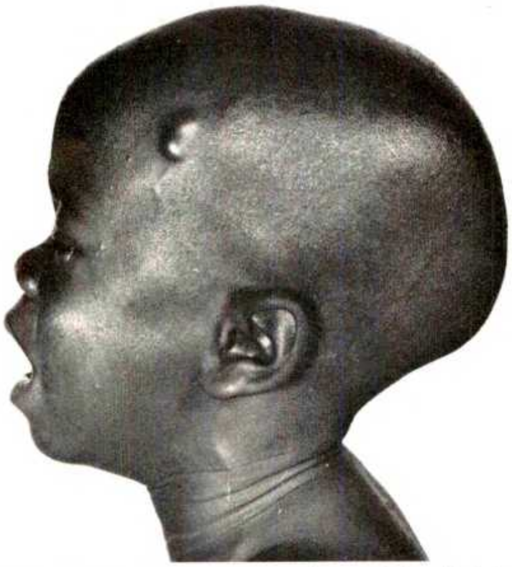

FIG. 1.—*Case* 1. Bilocular aneurysm on the anterior branch of the superficial temporal artery.

CASE REPORTS

Case 1.—A 3-year-old boy knocked his head against a chair after which a large haematoma developed in the left temporal area. When this resolved there remained a small swelling which gradually became larger.

On examination there was a bilocular swelling in the left anterior temporal region on the line of the anterior branch of the superficial temporal artery (*Fig.* 1). The lower part of the swelling was pulsatile and the upper part solid. No bruit was audible over the mass. Compression of the superficial temporal artery below the swelling abolished the pulsation and a diagnosis of an aneurysm was made.

At operation the superficial temporal artery was ligated above and below the aneurysm and the mass was excised *in toto*. Microscopic examination confirmed that the aneurysm contained some organized blood-clot in its lumen (*Fig.* 2).

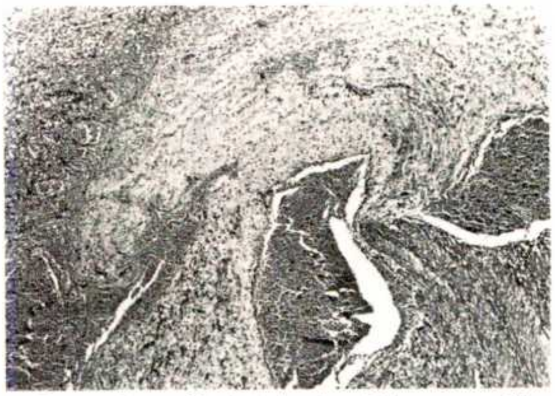

FIG. 2.—*Case* 1. Histological section of the aneurysm. The lumen (upper left) contains some solid blood-clot. There is some intramural haemorrhage in the aneurysm wall. H. and E. (× 28.)

Case 2.—A 36-year-old man presented with a swelling in the left temple which had progressively increased in size since it had first been noticed a month previously. It had appeared 4 days after he had been assaulted about the head.

On examination there was a pulsatile swelling 2·0 cm. in diameter situated just above the zygomatic arch (*Fig.* 3). A thrill was palpable but there was no audible bruit over the mass. The swelling was completely excised together with a small length of the adjacent superficial temporal artery. Histological examination showed that this was a false aneurysm.

Case 3.—A 28-year-old man tripped and fell, striking his head against the floor. He immediately developed a painful swelling of the right forehead. After this had subsided there remained two small pulsatile swellings in the right temporal area which were reducible by direct pressure.

At operation these swellings were found to be two small aneurysms on the anterior branch of the superficial temporal artery.

Case 4.—A 42-year-old man sustained a laceration on the right side of his forehead as the result of a motor accident. One week later he noticed two small 'tumours' in the right temporal region.

On examination there were two small pulsatile dilatations on the anterior branch of the superficial temporal artery but these were not directly related to the adjacent forehead wound (*Fig*. 4). The swellings were compressible and non-tender, and were diagnosed as aneurysms. They were excised after proximal and distal ligation of the parent artery.

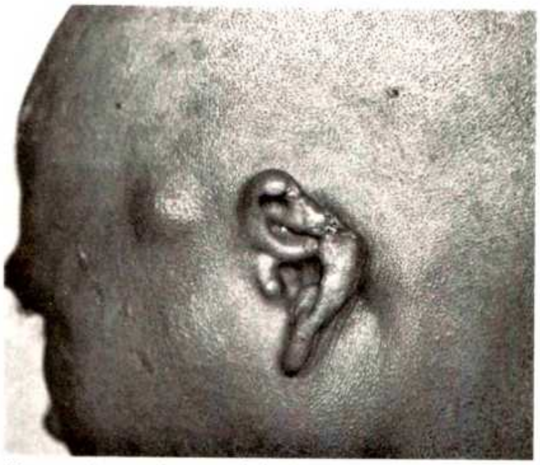

FIG. 3.—*Case* 2. Aneurysm lying just above the left zygomatic arch.

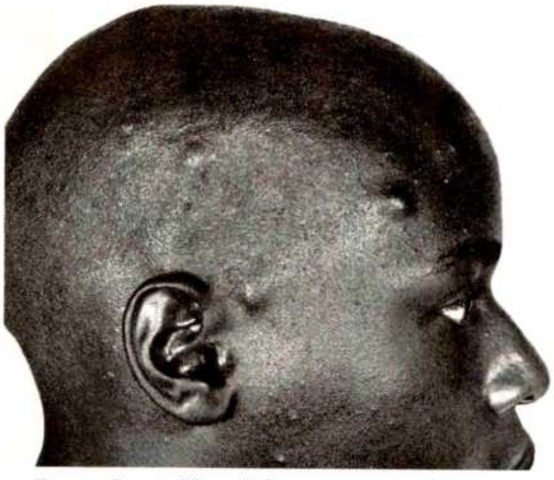

FIG. 5.—*Case* 6. Three distinct aneurysms on the superficial temporal artery; one over the zygomatic arch, one on the anterior branch, and the third on the posterior branch.

Case 5.—A 25-year-old man was involved in a fight and sustained multiple small lacerations and bruises about the head. Four weeks later he presented complaining of a pulsating mass in the left temple. This was an aneurysm on the anterior branch of the superficial temporal artery. Operation was not carried out as the patient failed to appear for admission and efforts to trace him were unsuccessful.

Case 6.—A 26-year-old man presented with three distinct swellings in the right temple, all of which had developed a few weeks after a closed head injury (*Fig*. 5). One was located over the zygomatic arch, another on the anterior branch of the superficial temporal artery, and the third was on the posterior branch. They were soft, pulsatile, and compressible. A palpable thrill over each swelling was abolished by proximal compression of the superficial temporal artery as it crossed the zygomatic arch.

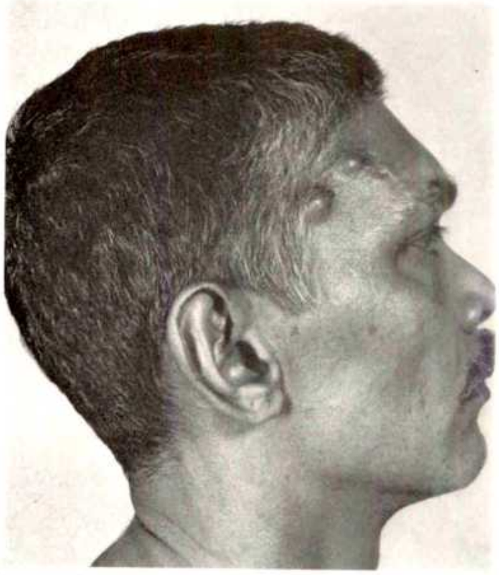

FIG. 4.—*Case* 4.—Two distinct aneurysms on the forehead adjacent to a previous scar.

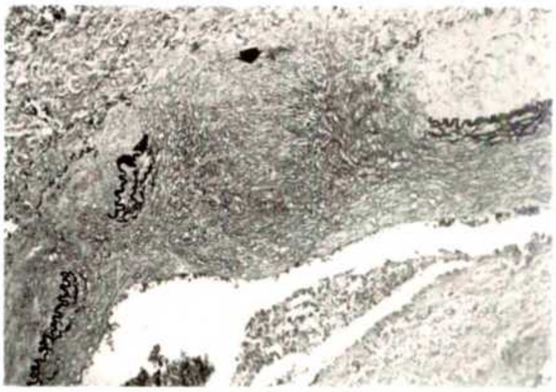

FIG. 6.—*Case* 6. Photomicrograph illustrating the disruption of the tunica elastica at the site of origin of the aneurysm (arrow). Weigert. (× 70.)

Having demonstrated by angiography that each swelling was a small aneurysm, they were excised after ligation of the parent artery above and below each swelling. Histological examination showed that they were all false aneurysms with disruption of the tunica elastica (*Fig*. 6).

DISCUSSION

All 6 patients in this series were males whose ages ranged from 3½ to 42 years (average age 26 years). Five were Ugandan Africans and 1 was an Asian. The aneurysms were equally distributed on each side of the head. In 2 instances (*Cases* 2, 5) there was a single aneurysm, 1 was bilocular (*Case* 1), while in the remaining 3 cases there were multiple distinct aneurysms.

Fig. 7 is a composite drawing showing the sites of the aneurysms in this series. It can be seen that they most commonly occurred either where the superficial temporal artery crossed the zygomatic arch or at the attachment of the temporalis fascia to the superior temporal line. More aneurysms were found on the anterior branch of the artery than on the posterior one.

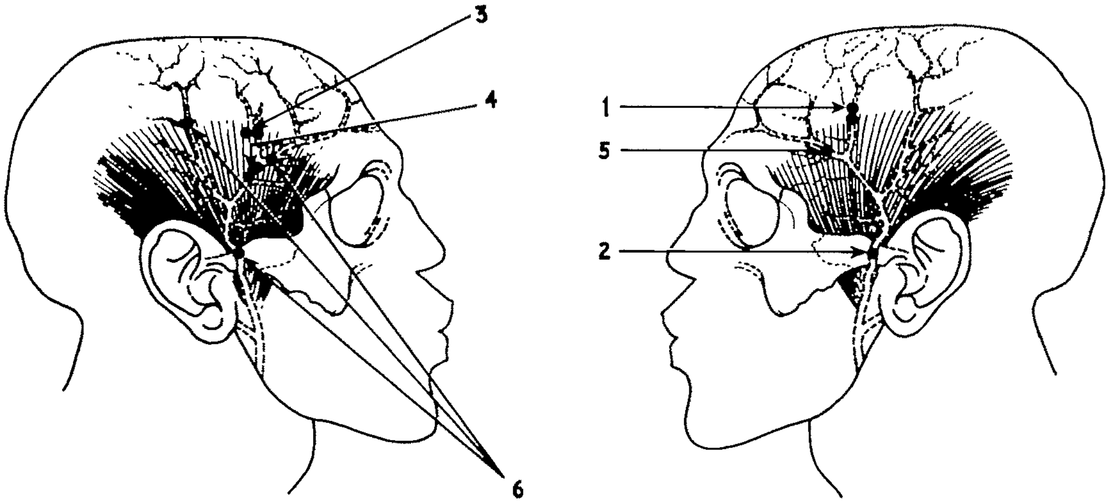

FIG. 7.—Composite diagram indicating the sites of the aneurysms in the present series

Blunt trauma to the side of the head is the commonest cause of this aneurysm nowadays and was the aetiological agent in all the cases in this series. The superior temporal line is often salient anteriorly but fades away posteriorly (*Gray's Anatomy*, 1969). It is postulated that the anterior branch of the artery, which is unprotected by overlying muscles, may be crushed against this prominent ridge by a blow to the side of the head.

Aneurysms of the superficial temporal artery have also been reported following open wounds, especially in the nineteenth century when sword duelling was common practice and temporal arteriotomy was in vogue for the treatment of epilepsy and apoplexy (Davies, 1961). Spontaneous development of this type of aneurysm is rare and only 11 cases have been reported (Schecter and Gutstein, 1970). These were either congenital or arteriosclerotic in origin. No luetic or mycotic aneurysms have been reported.

The usual presenting symptom is a pulsating swelling in the temporal region or a throbbing headache. The presence of a bruit or a palpable thrill over the aneurysm is dependent on the amount of thrombus in the swelling. A continuous bruit implies that an arteriovenous fistula has developed between the artery and its accompanying vein.

These aneurysms can usually be obliterated by direct pressure, while proximal arterial compression will maintain the collapsed state. Angiography can be used to confirm that the pulsation is caused by an aneurysm but this is not usually necessary to make the diagnosis.

Histologically, these are false aneurysms, part of the wall being formed by intimal lined fibrous tissue. It is assumed that the blow causes local necrosis of the arterial wall with subsequent saccular dilatation. Spontaneous complete thrombosis of the aneurysm may theoretically occur although this has never been documented.

Surgical excision is the usual mode of treatment because these aneurysms progressively enlarge and there is a risk of profuse haemorrhage from a subsequent head injury. Surgery is also indicated to relieve the throbbing headache and for cosmetic reasons.

Acknowledgements.—We are grateful to Dr. T. Poltera for the histological reports and to Professor Sir Ian McAdam and other members of the Department of Surgery, Makerere University Medical School, who referred some of these cases to us. Our thanks are also extended to the Chief Medical Officer, Ministry of Health, Uganda, for permission to publish this paper.

THE EFFECT OF VAGOTOMY ON THE INHIBITION OF GASTRIC SECRETION BY INTRADUODENAL FAT*

By A. S. WARD†

QUEEN ELIZABETH HOSPITAL, BIRMINGHAM, AND THE MIDDLESEX HOSPITAL, LONDON

SUMMARY

It has been suggested that the inhibition of gastric secretion by intraduodenal fat is a vagal phenomenon in man. Selective and highly selective vagotomy, by preserving this reflex, could offer advantages over truncal vagal section. This paper reports the effect of intraduodenal fat on pentagastrin-stimulated gastric secretion in duodenal ulcer patients before and after truncal vagotomy.

Marked inhibition of gastric secretion occurred in all the patients. In the postoperative group gastric secretion was almost totally abolished following fat infusion despite the absence of an abdominal vagal supply. The results suggest that inhibition of gastric secretion by intraduodenal fat is mediated by a non-vagal mechanism in man; from this point of view, therefore, there is little advantage in attempting to preserve the nerve-supply to the duodenum at vagotomy.

THE presence of fat in the duodenum is known to inhibit gastric secretion in animals (Lim, Ivy, and McCarthy, 1925; Sircus, 1958; Konturek and Grossman, 1965) and in man (Ewald and Boas, 1886; Shay, Gershon-Cohen, and Fels, 1939; Windsor, Cockel, and Lee, 1969). This response appears to be humoral (Feng, Hou, and Lim, 1929; Lim, 1933; Halvorsen, Middleton, Bibler, Harkins, and Nyhus, 1966; Debas, Bedi, Gillespie, and Gillespie, 1969), though Johnston and Duthie (1969) have suggested involvement of a vagal reflex in man. Selective or highly selective vagotomy, by preserving this reflex, could offer advantages over total vagal division (Griffith, 1969; Johnston and Wilkinson, 1970). In view of the lack of agreement on this point the present study was undertaken to reassess the effect of intraduodenal fat on gastric secretion in man before and after total vagotomy.

MATERIAL AND METHODS

Six patients with duodenal ulcer were investigated before operation and a further 6 patients after truncal vagotomy and pyloroplasty. One additional patient was successfully tested both before and after operation. It has not so far been possible to test other patients in this way because of the technical difficulties of the test, the natural reluctance of patients to attend for both pre- and postoperative investigation, and the difficulty in always securing a complete vagotomy in patients with a satisfactory preoperative test. Eleven men and 2 women were investigated; the mean age of the preoperative group was 48 years and of the postoperative patients 54 years. In the latter group completeness of vagal section was confirmed by a Hollander test as a preliminary to the main part of the study. All post-vagotomy tests were carried out after a minimum interval of 6 months.

The method of assessing duodenal inhibition was similar to that of previous reports (Ward, Wilkins, Cockel, and Windsor, 1969; Windsor and others, 1969). After an overnight fast a fine polyvinyl tube was introduced via the nose into the stomach and subsequently manipulated into the distal duodenum under fluoroscopic control. A Salem sump tube was then placed in the gastric antrum. Sampling was by continuous suction and 10-minute collections were made throughout. Basal secretion was collected for approximately half an hour and then an intravenous infusion of pentagastrin (6 μg. per kg. per hour) was commenced and continued until the end of the test. After a plateau response, i.e., three successive collections of similar volume had been obtained, 20 ml. of Prosparol (a commercial emulsion of ground-nut oil) at 37° C. were infused into the distal duodenum over a 5-minute period. Gastric collection was continued for a further hour. The Prosparol was labelled with 1 per cent polyethylene glycol (M.W. 4000) in all cases so that any reflux from the duodenum to the stomach could be measured. Reflux was less than 5 per cent in all the patients studied. Failure to provoke significant reflux may be attributed to the relatively slow infusion rate and to the distal siting of the perfusion zone. Nausea may also invalidate such investigations (Grossman, Woolley, Dutton, and Ivy, 1945) and careful observations were made to exclude this possibility.

Table I.—THE EFFECT OF INTRADUODENAL FAT ON GASTRIC ACID OUTPUT IN DUODENAL ULCER PATIENTS BEFORE VAGOTOMY

* Based on a communication to the Surgical Research Society in January 1972.

† Present address: University Department of Surgery, The Royal Infirmary, Sheffield.

Control studies were carried out in 5 duodenal ulcer patients. In 3 cases a pentagastrin infusion alone was continued for 3 hours to detect possible diminution of the gastric secretory response with time. None was noted. In 2 patients 20 ml. of physiological (0·9 per cent) saline were instilled into the duodenum, again without effect on the plateau response.

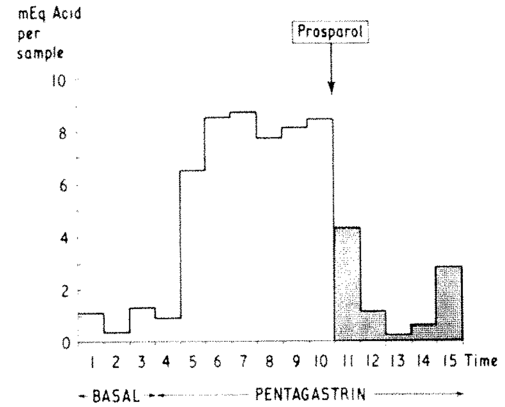

FIG. 1.—The effect of intraduodenal fat on gastric acid output in a duodenal ulcer patient before vagotomy. The open columns denote acid output prior to duodenal infusion and the shaded columns the post-instillation samples. The stimulus was pentagastrin infused at a rate of 6 μg. per kg. per hour.

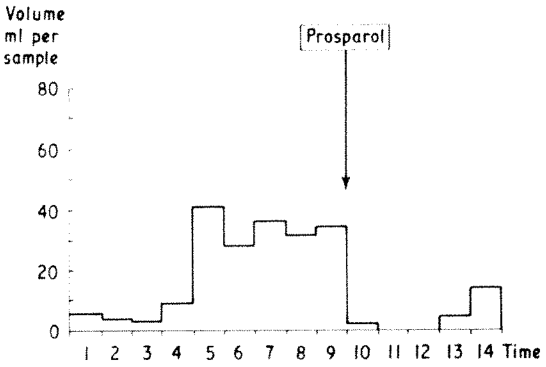

FIG. 3.—The effect of intraduodenal fat on the volume of gastric secretion in a vagotomized patient.

The following estimates were made on the gastric aspirate: (1) the volume of each sample per 10-minute collection period; (2) the *p*H and hydrogen ion concentration by titration to *p*H 7 with 0·1 *N* NaOH; (3) the polyethylene glycol concentration in the post-instillation samples by a turbidimetric method (Malawer and Powell, 1967).

RESULTS

The results are shown in *Tables I* and *II*. Acid output prior to duodenal infusion has been represented by the mean of the three 10-minute collections constituting the plateau. Acid output during inhibition is shown by the mean of the three lowest consecutive collections after the fat infusion. Mean acid output in the preoperative group (*Table I*) decreased from 9·8 ± 1·1 mEq. per 10 minutes during the plateau to 2·1 ± 0·5 mEq. per 10 minutes after the fat infusion, a highly significant response ($t = 6{\cdot}2$, $P < 0{\cdot}001$). Inhibition occurred within minutes of commencing the infusion in all the patients and lasted for approximately 40 minutes. A typical response is shown in *Fig.* 1.

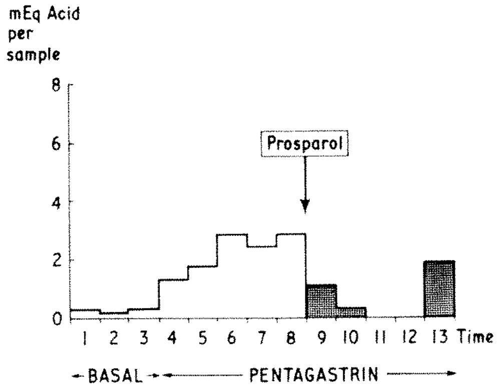

FIG. 2.—The effect of intraduodenal fat on gastric acid output in a duodenal ulcer patient after vagotomy.

Table II.—THE EFFECT OF INTRADUODENAL FAT ON GASTRIC ACID OUTPUT IN DUODENAL ULCER PATIENTS AFTER VAGOTOMY

PATIENT No.	ACID OUTPUT DURING PLATEAU (mEq. per 10 min.)	ACID OUTPUT DURING INHIBITION (mEq. per 10 min.)	INHIBITION (mEq. per 10 min.)
7	1·9	0·0	1·9
8	2·5	0·7	1·8
9	2·2	0·0	2·2
10	2·6	0·0	2·6

W.A.*	2·3	0·0	2·3
Mean	2·2	0·2	2·0
Standard error	0·1	0·1	0·1

* *See Fig.* 4.

In the vagotomized patients (*Table II*) marked inhibition was again apparent, the mean acid output falling from 2·2 ± 0·1 mEq. per 10 minutes during the plateau to 0·2 ± 0·1 mEq. per 10 minutes after intraduodenal fat. This reduction in acid output was highly significant ($t < 13{\cdot}3$, $P < 0{\cdot}001$). The latent period was slightly longer than before vagotomy in 2 patients, but in the remainder the onset of inhibition was immediate and the duration of the response again approximately 40 minutes. *Fig.* 2 shows a typical sequence of events in one of the vagotomized patients. Changes in acid output in this group are small in absolute terms and reduction in the volume of the gastric aspirate provides a clearer indication of the extent of the response (*Fig.* 3).

One patient was investigated both before and after vagotomy (*Fig.* 4). Intraduodenal fat produced marked inhibition of gastric secretion before operation; 6 months later after a complete truncal vagotomy a similar effect was again observed.

The acid concentration remained constant in both pre- and postoperative patients following fat infusion (*Fig.* 5). Inhibition of acid output was therefore due solely to reduction in volume of the gastric juice.

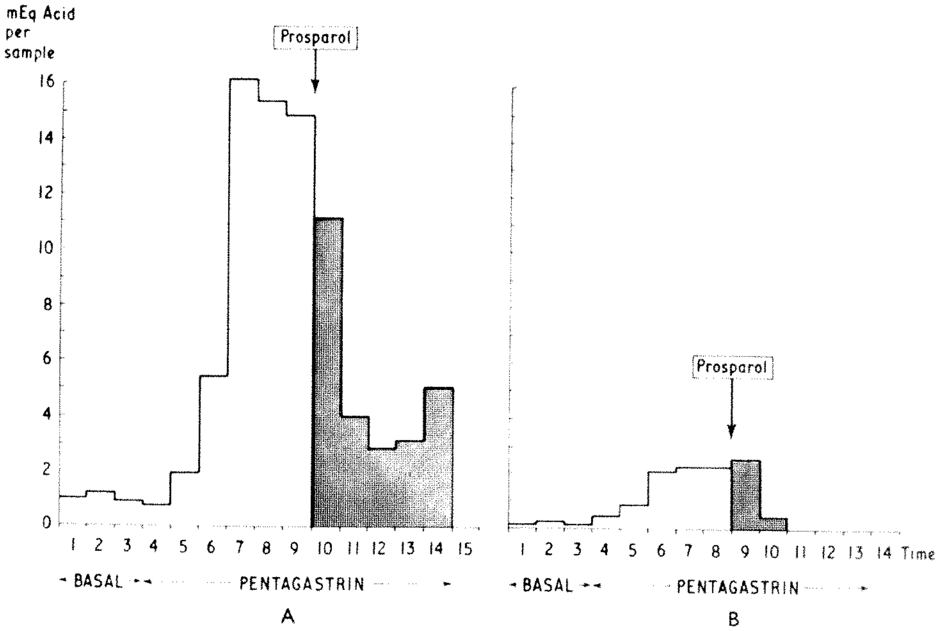

FIG. 4.—The effect of intraduodenal fat on gastric acid output in a duodenal ulcer patient before and after vagotomy. A, The preoperative response. B, The response 6 months after total abdominal vagotomy.

DISCUSSION

The results of this study show that fat in the duodenum inhibits gastric secretion in man both before and after vagotomy. Direct comparison of the magnitude of inhibition in the two circumstances is inappropriate but a highly significant response is apparent in both groups ($P<0\cdot001$). The latent period and duration of inhibition are also similar, suggesting that the underlying mechanism is the same. The almost total abolition of gastric secretion observed in vagotomized patients would appear to leave little room for involvement of a vagal component in this mechanism. Such a component cannot, however, be entirely excluded in patients with intact vagi because the absolute changes in acid output after fat infusion are so much greater in this group than in vagotomized subjects.

Inhibition of gastric secretion was due solely to a volume effect, the acid concentration remaining unchanged after duodenal fat infusion. A similar situation has been noted previously during inhibition by osmotic agents (Ward and others, 1969).

The claim that the inhibitory response to fat is independent of a vagal nerve-supply rests on satisfactory proof of the completeness of the vagal section. The early response to insulin is unreliable (Mason and Giles, 1969; Gillespie, Elder, Gillespie, Kay, and Campbell, 1970) and gastric investigations were therefore deferred until at least 6 months after vagotomy. Insulin tests were then judged positive or negative according to Hollander's original criteria (Hollander, 1948); in fact all the tests in this study were negative according to the additional criteria suggested by subsequent authors (Waddell, 1957; Bachrach, 1962; Stempien, 1962; Ross and Kay, 1964; Bank, Marks, and Louw, 1967). Furthermore, maximal acid output in the vagotomized patients did not exceed 15 mEq per hour, which is within the range of secretory activity expected after complete vagotomy (Bank and others, 1967; Mason and Giles, 1968). The 85 per cent reduction in maximal acid output noted in 1 patient after vagotomy (*Fig.* 4) is similarly in accord with a complete vagal section (Bank and others, 1967; Multicentre Study, 1967).

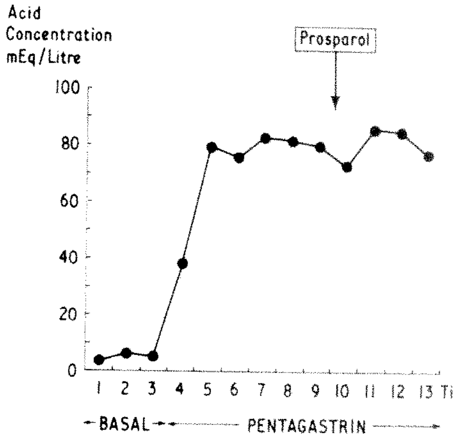

FIG. 5.—The effect of intraduodenal fat on the acid concentration of gastric juice in a vagotomized patient.

Inhibition of gastric secretion by intestinal fat has been shown to occur in the absence of a vagal nerve-supply in many animal studies (Feng and others, 1929; Sircus, 1958; Halvorsen and others, 1966; Debas and others, 1969). Isaza, Sugawara, Curt, and Woodward (1971), however, noted a reduction in the inhibitory response to fat after mesenteric denervation. This reduction was evident in dogs with an intact gastric nerve-supply but not in those with Heidenhain pouches so that it is difficult to draw definite conclusions from this report.

In a recent study in man Johnston and Duthie (1969) noted an increase in gastric secretion after intraduodenal fat in vagotomized patients. Their results were obtained in the immediate postoperative period when a degree of gastro-intestinal stasis and distension exists and the capacity to deal with an intraluminal fluid load is diminished. Relatively large volumes of fat were circulated through the duodenum and these volumes together with the resultant flow of bile and pancreatic juice may have produced appreciable distension of the duodenum and proximal small bowel with subsequent release of gastrin (Sircus, 1953; Nagano, Johnson, Cobo, Oberhelman, and Dragstedt, 1960). The use of submaximal gastric stimulation in their study may then have permitted an increase in gastric secretion due to endogenous gastrin released from such a source.

The magnitude of the response observed in the preoperative patients was similar to that of earlier reports (Sircus, 1958; Windsor and others, 1969) though others have failed to demonstrate such a marked effect (Konturek and Grossman, 1965; Johnston and Duthie, 1969). The explanation for this difference is uncertain. The degree of saturation of the constituent fatty acids is said to influence the extent of the response in man (Roberts, 1931), but since the iodine value of Prosparol is similar to that of the fats used in other studies this factor is unlikely to be of much importance. Variation in the chain length of the constituent fatty acids may be of greater significance.

Although the response to intraduodenal fat does not appear to depend upon an extrinsic vagal supply a local enteric reflex could still be involved. Animal studies, however, have shown that inhibition persists when the stomach and duodenum are completely disconnected (Lonnqvist, 1906; Lim and others, 1925; Konturek and Grossman, 1965), so that this explanation is unlikely to be correct.

There is considerable experimental evidence in favour of a humoral basis for inhibition by fat (Kosaka and Lim, 1930; Lim, 1933; Sircus, 1958; Konturek and Grossman, 1965). The precise nature of the humoral agent (or agents) remains, however, unknown; neither secretin nor cholecystokinin-pancreozymin appear to be implicated in the response in man and the existence of a specific chalone ('enterogastrone') seems likely. The subject is comprehensively reviewed by Johnson and Grossman (1971).

Although the precise details of the inhibitory mechanism remain uncertain the present results indicate that the response to fat persists after total abdominal vagotomy in man. One of the advantages which selective and highly selective vagotomy are said to offer compared with truncal division is that the nerve-supply to the duodenum is preserved and gastric inhibitory reflexes are thereby allowed to continue undisturbed (Griffith, 1969; Johnston and Wilkinson, 1970). The results of this study, however, suggest that inhibition of gastric secretion by intraduodenal fat is not a vagally dependent phenomenon in man and from this point of view, therefore, there is little advantage in preserving the nerve-supply to the duodenum at vagotomy. Whether the response to other inhibitory agents such as intraduodenal acid and osmotic solutions also persists after vagal denervation remains for further study.

Acknowledgements.—The technical assistance of Miss Sheila Nutter is gratefully acknowledged. Professor Le Quesne, Mr. Michael Hobsley, and Dr. Roy Cockel kindly advised in the preparation of the manuscript. This study was initiated through the financial support of the Endowment Research Committee of the United Birmingham Hospitals.

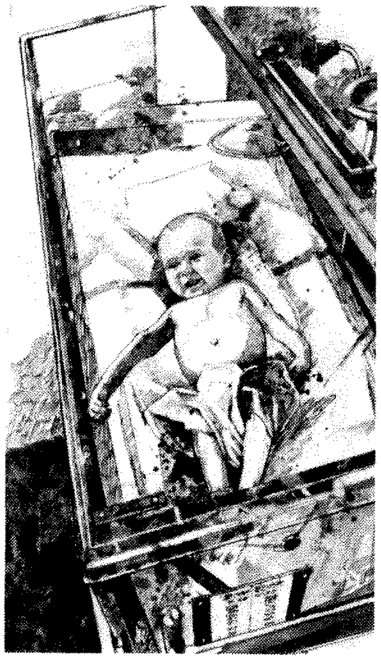
First and for all.



In severe neo-natal infections

In septicaemias

In serious post-operative situations

G-DAY-those first vital 24 hours in serious bacterial infections:

● when effective therapy must be initiated to prevent rapid deterioration in the patient's condition

● when the causative organism is unknown or uncertain

● when there is no time for trial and error

When these situations occur in acute or acute on chronic infections, Genticin Injectable, the antibiotic with the broadest bactericidal spectrum of all, has proved eminently successful as first-line therapy in a wide range of conditions.

"It therefore follows that on sensitivity testing alone, gentamicin (Genticin) would be the best single antibiotic for blind chemotherapy."[1]

[1] Reference: J Irish med Ass, 65, No 20, 514, 1972.

Genticin Injectable is available in 2 ml multidose vials and snap-off ampoules. Each 2 ml contains 80 mg gentamicin base as gentamicin sulphate.

Further details are available on request from:
Genticin Technical Service, Slough 23971
Nicholas Laboratories Limited PO Box 17, Slough SL1 4AU

ANORECTAL SUPPURATION: THE RESULTS OF TREATMENT AND THE FACTORS INFLUENCING THE RECURRENCE RATE

By R. BUCHAN* and R. H. GRACE†

DEPARTMENT OF SURGERY, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

SUMMARY

One hundred and eighty-three patients admitted to hospitals in the Cardiff teaching group (1961–5) with a diagnosis of anorectal abscess were studied; 147 of these patients were traced in 1969. It is shown that when the diagnosis was that of an ischiorectal abscess and that when a 'deroofing' procedure was used, the in-patient stay and the time lost from work were increased.

It is also shown that recurrence was related to a previous history of multiple abscesses, but not to the duration of the presenting history or the type of the presenting abscess or the initial drainage procedure employed. However, the detection and laying open of a 'fistula' at a second examination under anaesthesia within 2 weeks reduced the incidence of recurrence.

It is suggested that incision and drainage, followed by a second examination under anaesthesia within 2 weeks, should be the treatment of choice, and that there is now no place for saucerization or 'deroofing' procedures.

In England and Wales between 5000 and 6000 patients are admitted to hospital annually because of anorectal suppuration (Hospital In-patient Enquiry, 1964, 1965). We have reviewed the clinical features and treatment of patients with anorectal abscesses treated in Cardiff between 1961 and 1965 in an attempt to identify the factors influencing the outcome.

MATERIALS AND METHODS

The records of all the patients admitted between 1961 and 1965 to hospitals in the Cardiff teaching group with a diagnosis of anorectal suppuration (I.C.D. codes 574 and 575) were studied; these patients were treated in two hospitals by surgeons of varying experience. A few patients with very minor anorectal suppuration may have been treated in casualty departments, but the records of these patients were not available.

There were 183 patients admitted with a diagnosis of anorectal abscess, and information was obtained from their notes. In 1969 all the patients were sent a simple questionnaire regarding recurrent symptoms; 126 patients replied, and sufficient information was given by general practitioners for a further 21 patients, making a total of 147 patients for whom follow-up information was available. Thirty-six patients were lost to follow-up: 2 had died, 28 had left the area and could not be traced, and 6 did not reply and their family doctors were unable to give any information about them.

TERMINOLOGY

Recurrence.—Recurrence was defined as the appearance of a further abscess or of a fistula after the presenting abscess had healed.

'Fistula'.—A 'fistula' was defined as the finding of a connexion between the presenting abscess and the anal canal by the surgeon at the original drainage procedure.

Fistula.—The standard fistula-in-ano of anorectal surgery was described as a fistula (without inverted commas).

RESULTS

1. Original Group of 183 Patients.—

a. Incidence.—The incidence during this 5-year period was fairly steady at 33 cases per annum, with a slightly higher incidence in 1964. The incidence was highest in the third and fourth decades (*Table I*) and was low in children. In this series anorectal sepsis was about three times more common in males (*Table I*).

Table I.—AGE AND SEX INCIDENCE OF PATIENTS WITH ANORECTAL SUPPURATION

AGE (yr.)	TOTAL NO. OF PATIENTS	MALE	FEMALE
0–19	20	15	5
20–39	78	59	19
40–59	59	44	15
60 +	26	24	2

b. Associated Disease.—There was a low incidence of associated bowel disease: 2 patients had Crohn's disease, 3 had ulcerative colitis, and 2 had rectal cancer. Two patients had active tuberculosis. There were 3 diabetics. Two children had spina bifida, reflecting the high incidence of this defect in South Wales.

c. Previous History.—Thirty patients had a history of a single previous anorectal abscess, while 21 had had multiple previous abscesses (*Table II*); a previous history of a single fistula-in-ano was present in 7 patients and of multiple fistulae in 2 patients (*Table II*).

d. Duration of Symptoms.—Almost 50 per cent of the patients had symptoms for longer than 5 days, while only 21 patients (11·5 per cent) had a history of less than 48 hours (*Table III*). Patients with ischiorectal abscesses did not have a significantly longer history than those with perianal abscesses ($P > 0{\cdot}2$).

* Present address: Lecturer in the Department of Clinical Surgery, Edinburgh Royal Infirmary, Edinburgh.

† Present address: Senior Registrar, St. Thomas's Hospital, London, S.E.1.

e. Type of Abscess.—Perianal abscesses (102 patients) and ischiorectal abscesses (77 patients) accounted for 98 per cent of all the cases (*Table IV*).

f. Treatment.—

i. *Operation*: As shown in *Table IV*, saucerization was performed five times more often than incision and drainage; only 5 patients were treated by incision and primary suture. Four patients did not require operation because the abscess discharged spontaneously, and in 1 patient there was no record of the type of operation performed.

Table II.—Relationship of Previous History of Anorectal Suppuration to Recurrence

	Total No. of Patients	Recurrent Abscess	Recurrent Fistula	Recurrent Abscess and Fistula
Previous history of anorectal abscess				
None	132	15	17	7
Single abscess	30	6	1	1
Multiple abscesses	21	6	4	4
Previous history of fistula in ano				
None	174	27	21	7
Single fistula	7	0	1	0
Multiple fistulae	2	0	0	0

Table III.—Duration of Symptoms of Anorectal Suppuration

Duration of History (d.)	Perianal Abscess	Ischiorectal Abscess	Total
2	14	7	21
3–5	38	26	64
5 +	46	44	90
No information	4	—	4
Total	102	77	179

Table IV.—Type of Presenting Abscess and the Primary Treatment

Type of Abscess	Total No. of Patients	Incision and Drainage	Saucerization	Incision and Primary Suture	No Treatment
Perianal	102	20	75	3	4
Ischiorectal	77	8	68	1	
Submucous	1	1			
Pelvirectal	0				
Not known	3		1	1	
	183	29	144	5	4

ii. *Examination for 'fistula'*: Surgeons identified a connexion with the anal canal in 39 of 115 patients at the first operation, and in a further 13 of 18 patients who were examined again under anaesthesia within 2 weeks (*Table V*). No attempt was made to look for a 'fistula' in 46 patients.

iii. *Antibiotics*: A number of patients had been given antibiotics prior to admission, and 34 were given antibiotics in hospital.

g. Bacteriology.—Bacteriological swabs were sent for culture in only 120 of the total of 183 patients (*Table VI*). Coliform organisms (25·6 per cent) were most commonly cultured, followed by coagulase-positive staphylococci (16·9 per cent); in 14 patients more than one organism was grown. No growth was obtained in 22 cases.

Table V.—Incidence of Fistula-in-Ano at Presentation and its Effect on Recurrence

Fistula	Total No. of Patients	Recurrent Abscess	Recurrent Fistula
Fistula found at drainage operation	39	9	5
Fistula found within 10 days	13	0	1
No fistula found	81	13	9
No examination for fistula	46	5	7
Total	179	27	22

h. Duration of In-patient Treatment.—Seventy-one patients were in hospital for less than 1 week, while a further 59 patients were in-patients for less than 2 weeks; however, 16 patients were still in hospital 4 weeks after admission. Prolonged admission was related to the presenting abscess being ischiorectal ($P < 0{\cdot}001$), treatment by saucerization ($P < 0{\cdot}05$), and a 'fistula' being found at operation. While a 'fistula' was found in only 10 per cent of the patients who stayed in hospital for less than a week, 55 per cent of those who were in-patients for more than 3 weeks had a 'fistula' laid open.

2. Four-to-nine-year Follow-up Group of the 147 Patients who were traced.—Adequate information regarding the 4–9-year results was available in 80 per cent of the entire treatment group. There was no difference between the original 183 patients and the 147 who were successfully traced when they were compared for age of the patients ($P > 0{\cdot}5$), duration of symptoms ($P > 0{\cdot}3$), type of abscess ($P > 0{\cdot}3$), and type of operation ($P > 0{\cdot}3$), including examination for possible fistulae.

a. Recurrence.—Recurrence was defined as the appearance of a further abscess or a fistula after the presenting abscess had healed.

i. *Overall incidence* (*Table VII*): Thirty-seven patients (25·2 per cent) required further in-patient treatment. Fifteen patients had a recurrent abscess while 10 developed a fistula. Twelve patients had both a recurrent abscess and a fistula.

Table VI.—BACTERIOLOGY OF THE PRESENTING ABSCESS

Bacteriological Result	*No. of Patients*	*Percentage*
Staphylococcus aureus (coagulase positive)	30	16·9
Escherichia coli	47	25·6
Others	35	29·1
Sterile	22	12·0
Not cultured	63	34·4

Table VII.—OVERALL INCIDENCE OF RECURRENT ANORECTAL SUPPURATION IN 147 PATIENTS

Recurrence	*No. of Patients*	*Percentage*
Abscess	15	10·2
Fistula	10	6·8
Abscess and fistula	12	8·1

Table VIII.—TIME OF DETECTION OF RECURRENT ABSCESS OR FISTULA

TIME OF RECURRENCE (mth.)	ABSCESS	FISTULA
2	5	5
2–6	4	6
6–12	3	2
12–24	5	5
24 +	10	5

ii. *Onset* (*Table VIII*): Ten patients (5 with abscesses, 5 with fistulae) developed further symptoms within 2 months: one-third of the abscesses and half of the fistulae had recurred within 6 months of the primary treatment. However, about one-third of the patients developed their first recurrence longer than 2 years after the original operation.

iii. *Previous history*: There was a significant increase of recurrent abscess in patients with a previous history of multiple abscesses ($P < 0{\cdot}05$), but not following a single abscess ($P > 0{\cdot}2$) or fistula ($P > 0{\cdot}2$).

iv. *Relation to original abscess*: Although there was an apparently higher incidence of recurrent abscess when the original abscess had been ischiorectal this did not reach significant levels ($P > 0{\cdot}2$), and there was no difference in the occurrence of subsequent fistulae (*Table IX*). Of 27 recurrent abscesses, 24 were at the site of the original abscess, while most of the 22 fistulae also appeared at the site of the original abscess. Recurrence was not related to the duration of symptoms of the presenting abscess.

v. *Relation to operation*: Different drainage procedures did not influence the recurrence rate ($P > 0{\cdot}2$) (*Table X*).

The findings of a 'fistula' at the primary treatment did not reduce the subsequent recurrence rate when this was compared with no 'fistula' being found ($P > 0{\cdot}2$) (*Table V*). When a 'fistula' was identified at a further examination within 2 weeks of the original operation the recurrence rate was reduced ($P < 0{\cdot}02$), but the number of patients in this group was small.

b. Time off Work.—Although 66 patients (mainly housewives and retired persons) did not complete this part of the questionnaire, there were 81 patients who gave details. Forty-three patients were off work for longer than 4 weeks, 36 of these being for longer than 6 weeks.

Table IX.—TYPE OF ABSCESS AND INFLUENCE ON RECURRENCE

TYPE OF ABSCESS	TOTAL NO. OF PATIENTS	RECURRENCE			
		Abscess		*Fistula*	
		No.	Per cent	No.	Per cent
Perianal	80	12	15	12	15
Ischiorectal	64	14	21·9	9	14·1
Other	3	1		1	

Table X.—INFLUENCE OF THE TYPE OF OPERATION ON THE RECURRENCE RATES

OPERATION	TOTAL NO. OF PATIENTS	RECURRENCE			
		Abscess		*Fistula*	
		No.	Per cent	No.	Per cent
Incision and drainage	25	4	16	4	16
Saucerization	113	21	18·6	16	15·1
Other	5	1		1	

c. Group with Anal Discharge.—Thirteen patients replied stating that they had suffered anal discharge since their primary operation. Two patients refused further examination and 2 lived too far away to be seen; of the remaining 9 patients, 3 had definite fistulae and 6 had pruritus without clinical evidence of a fistula.

DISCUSSION

These results have confirmed the findings of other authors (Goligher, 1961; Wilson, 1964) that anorectal suppuration occurs commonly in males in the third and fourth decades, that perianal abscess is the commonest type, and that pelvirectal and submucous abscesses are very rare. There is also confirmation that when a large number of anorectal abscesses are followed there is a relatively low incidence of associated bowel disease (Rawls, Martin, Spencer, and Hoffman, 1963; Edwards and Truelove, 1965; de Dombal, Watts, Watkinson, and Goligher, 1966), but it is still of value to obtain biopsy material of the abscess cavity as suppuration may be an early manifestation of inflammatory bowel disease (Morson and Lockhart-Mummery, 1959).

In this country anorectal abscesses are usually treated by a 'deroofing' or saucerization procedure, which may be combined with a search for an internal opening: the wounds created are large and healing may take some weeks. An alternative method has been used by Ellis (1960), who described incision, exploration, and curettage of the abscess cavity followed by suture, under antibiotic cover. Patients usually returned to work with the wound healed in about a week (Wilson, 1964).

In North America treatment is influenced by the cryptoglandular hypothesis of the aetiology of anorectal suppuration. This has been supported in this country by Parks (1961). It is believed that infection tracks along the lumen of one anal gland to its termination between the internal and external sphincters. It is suggested that an intersphincteric abscess develops first and that this may extend downwards to present as a perianal abscess, or laterally to present as an ischiorectal abscess (Nesselrod, 1949; Eisenhammer, 1956a, b, 1961). The intersphincteric abscess and the associated anal gland are therefore believed to be the important area for surgical attack, which may explain why a 'fistula' is nearly always found in American reports. However, the rationale of this approach has been placed under considerable doubt following the report by Goligher, Ellis, and Pissidis (1967) that an intersphincteric abscess could be identified in only 8 of 28 cases of anorectal abscess. They concluded that anal continence would be risked unnecessarily if this intra-anal approach was used routinely. This is of particular importance when it is remembered that most anorectal abscesses are initially treated by relatively junior surgeons.

When any treatment of anorectal abscess is considered the incidence of recurrent abscess or fistula is very important. In the present series there was a high recurrence rate (25 per cent), but this is comparable to that of Wilson (1964), who quoted a 22 per cent recurrence rate. Most other reported series have had an inadequate follow-up (Naunton Morgan, 1929; Granet, 1948; Mcelwain, Alexander, and Maclean, 1966; Hill, 1967).

Several factors which might influence recurrence rates have been examined. We have no evidence that the duration of symptoms of the presenting abscess is related to recurrence, or that recurrence is influenced by the original drainage procedure.

Wilson (1964) reported a 33 per cent recurrence rate after ischiorectal abscess, which was more than twice that after perianal abscess; although our figures show a similar trend the difference is less striking (30 per cent after ischiorectal abscess, 23·9 per cent after perianal abscess) and it is not significant ($P > 0{\cdot}2$). We had expected that the demonstration of a connexion with the anal canal ('fistula') at the original operation would have reduced the recurrence rate, but this was not so ($P > 0{\cdot}2$). In the acute phase tissues are friable and oedematous, and it is easy to create false tracks; it is possible that some of the fistulae found in our cases (and perhaps in other reports) were iatrogenic. It may be more relevant that the recurrence rate was reduced when a 'fistula' was found after the acute phase had settled ($P < 0{\cdot}02$).

The time of the recurrence is of interest. Recurrent disease appearing within 2 months of treatment must arise because the initial therapy was inadequate, but while most abscesses and fistulae recurred within 2 years about 30 per cent of patients developed a recurrence more than 2 years after the primary treatment, and 3 fistulae were detected by examination after replying to our questionnaire 4 or more years later.

If the standard treatment of anorectal abscess produces no better results in terms of recurrence than the primary suture technique, then healing time becomes an important factor. Describing the results of the primary suture technique, Wilson (1964) stated: 'If it can be established that the long-term results from treatment by primary suture are no worse than those which follow "unroofing" then it is not irrelevant to include economic factors.' In our series about 50 per cent of the patients replying to our questionnaire were off work for longer than 4 weeks, an interval similar to the healing time quoted by Goligher and others (1967) for saucerization operations; in comparison, most patients treated by incision, curettage, and suture had returned to work within a week (Wilson, 1964). If Wilson's results were to be repeated elsewhere incision and primary suture might produce valuable medical and economic advantages for the patient (and for the National Health Service).

It is suggested that there is now no place for the traditional 'deroofing' or saucerization procedures in the treatment of anorectal abscess. Until the value of primary suture has been further explored it is thought that incision and drainage (possibly with immediate exploration for a fistula if the surgeon is experienced in anorectal disease) followed by a second examination under anaesthesia within 2 weeks produces the best results in terms of economy while not prejudicing the recurrence rate.

Acknowledgements.—We are grateful to the surgeons at the Cardiff Royal Infirmary and the Llandough Hospital for allowing us to study their patients, and to Professor A. P. M. Forrest and Mr. H. E. Lockhart-Mummery for their criticism of the manuscript.

ACUTE MESENTERIC VASCULAR OCCLUSION OCCURRING ON TOP OF CHRONIC LOCALIZED OCCLUSION

BY A. H. PETTY AND A. W. GOODE

DEPARTMENT OF SURGERY, NEWCASTLE GENERAL HOSPITAL

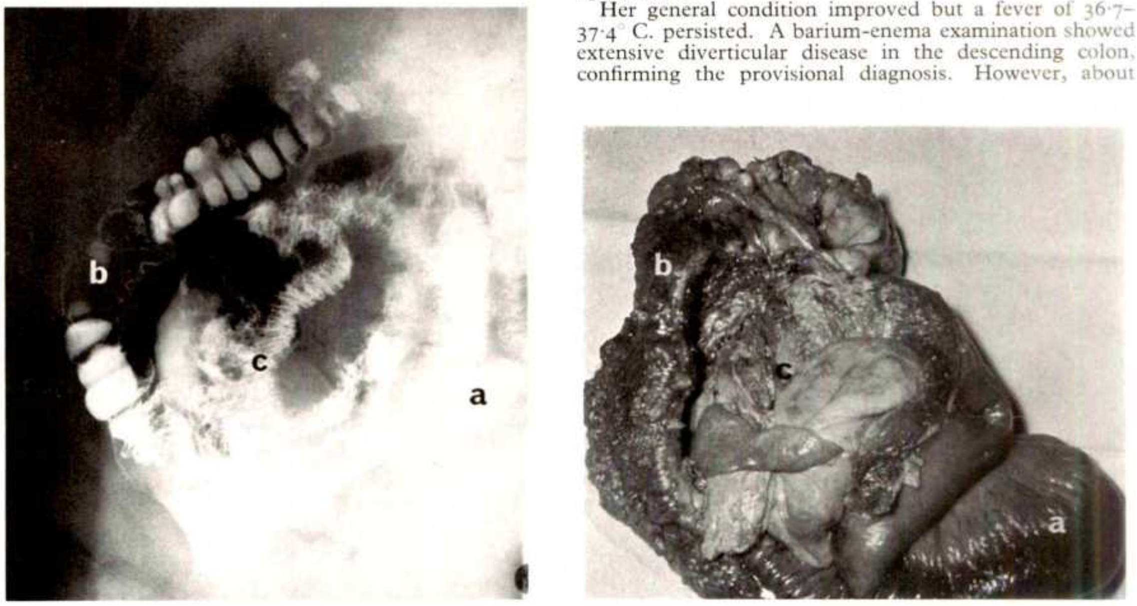
SUMMARY

Acute mesenteric arterial occlusion occurring on top of chronic occlusion and causing necrosis of a short length of bowel is rare.

Three such cases are described. All were operated upon but only 1 has survived.

The literature on the subject is discussed.

ACUTE ischaemia of the bowel is a well-recognized clinical entity, even though early diagnosis is usually difficult. Chronic ischaemia, though well documented in the literature, is difficult to diagnose and a much less clear-cut condition. Acute ischaemia occurring in chronic ischaemia of a localized area of bowel is a less well-documented entity. The purpose of this paper is to describe and discuss 3 such cases, in 2 of which acute vascular occlusion occurred and caused necrosis.



A B

FIG. 1.—*Case* 1. A, Barium-meal and follow-through film showing: a, terminal ileum; b, ascending colon; c, barium filling a large cyst cavity. B, Operation specimen: a, terminal ileum; b, ascending colon; c, cystic mass.

CASE REPORTS

Case 1.—Mrs. E. Y., aged 61 years, had no previous history suggestive of cardiovascular disease, but over the past 10 years she had had four or five short attacks of colicky abdominal pain and vomiting, each one being worse than the last. Apart from these she had been well.

She was admitted as an emergency with a 16-hour history of central abdominal pain, vomiting, and abdominal distension similar to but much more severe than the five previous attacks.

Examination showed an obese woman with a temperature of 36·7° C. and central abdominal tenderness. Her blood-pressure was 150/90 and she was not shocked. A provisional diagnosis of diverticular disease was made. Twenty-four hours after admission her symptoms had spontaneously disappeared.

Investigations showed the following: haemoglobin, 8 g. per 100 ml.; white-blood count, 9400; urea and electrolytes, normal; occult blood was negative on four occasions; an electrocardiogram was normal; plasma proteins: albumin, 2·5 mg. per cent, globulin, 3·8 mg. per cent; erythrocyte-sedimentation rate, 24 mm. in 1 hour. Sigmoidoscopy was carried out and showed no abnormality up to 20 cm.

Her general condition improved but a fever of 36·7–37·4° C. persisted. A barium-enema examination showed extensive diverticular disease in the descending colon, confirming the provisional diagnosis. However, about 10 days after admission severe abdominal pain and vomiting returned and a mass was felt in the right iliac fossa. Barium follow-through studies showed a grossly dilated segment of terminal ileum, which was thought most probably to be an ischaemic lesion (*Fig.* 1 A).

At laparotomy a huge cystic mass was found occupying almost the whole of the right side of the abdominal cavity. The cyst, its wall formed from bowel mesentery and omentum, contained several loops of pale necrotic bowel, free faeces, and barium (*Fig.* 1 B). The cyst was excised and bowel continuity was restored by end-to-end anastomosis of the ileum to the transverse colon.

Postoperative recovery was complicated by a short period of respiratory difficulty and a wound infection, but the patient was discharged home a month later, when she was very well.

She was readmitted about 6 weeks later with shortness of breath and left chest pain, and a radiograph of the chest showed an opacity in the right upper zone. The day after admission she collapsed and a diagnosis of pulmonary embolism was made. In spite of anticoagulants and antibiotics, her condition steadily deteriorated and she died 10 days after admission. Post-mortem examination was refused.

The operation specimen consisted of 62 cm. of terminal ileum, together with caecum and 20 cm. of ascending colon. In addition to an area of necrotic bowel with a perforation, the proximal ileum showed loss of villi and Paneth's cells, an increase in goblet cells (*Fig.* 2), and more proximally marked thickening, induration, and congestion. There were areas of fat necrosis and fibrosis and plasma-cell infiltration in the mesentery (*Fig.* 3). The artery

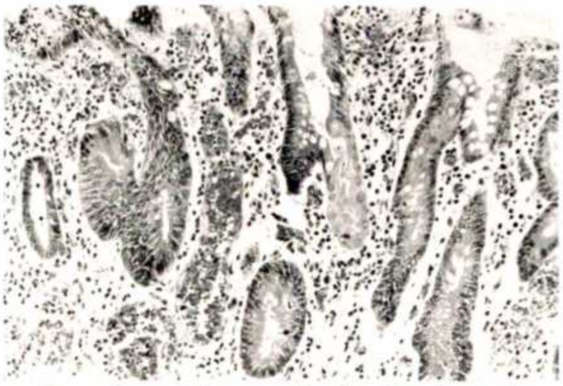


FIG. 2.—*Case* 1. Ileal mucosa of the affected bowel showing loss of villi and Paneth's cells and a marked increase in goblet cells. H. and E. (× 80.)

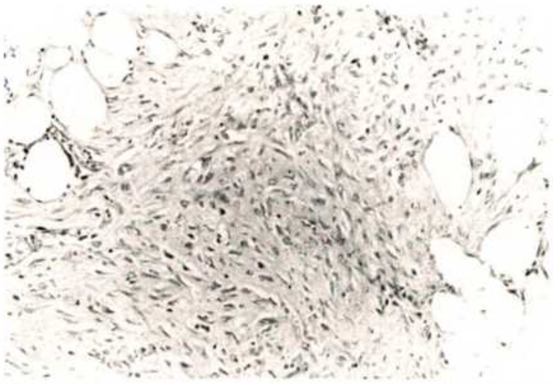

FIG. 3.—*Case* 1. Mesentery showing an area of fibrosis and plasma-cell infiltraton. H. and E. (× 80).

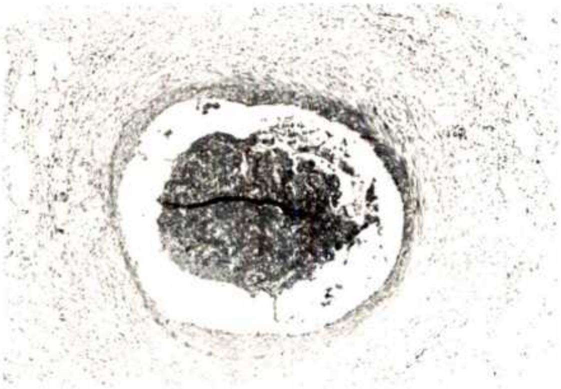

FIG. 4.—*Case* 1. Artery supplying the segment of affected bowel showing a fresh thrombus proximal to the original thrombus. H. and E. (× 80.)

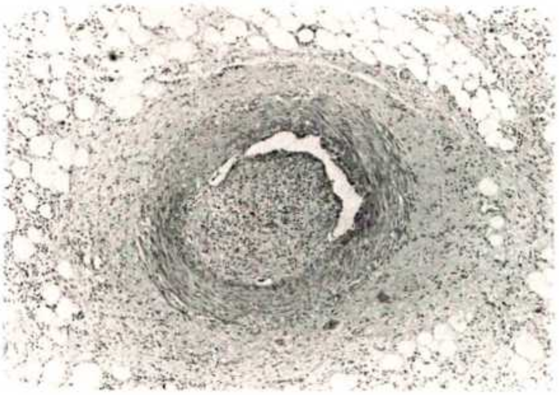

FIG. 5.—*Case* 1. Artery supplying the segment of affected bowel showing an organized partially recanalized thrombus. H. and E. (× 80.)

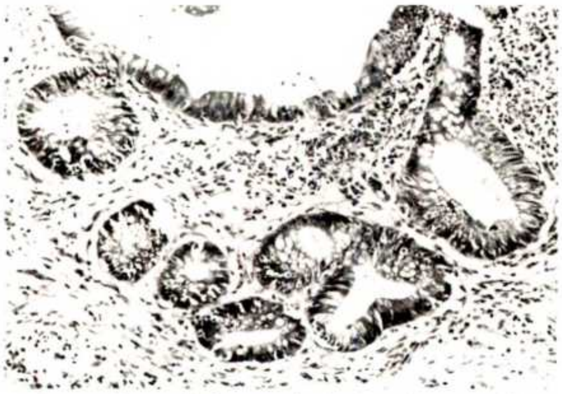

FIG. 6.—*Case* 2. Ileal mucosa showing loss of mucosal villi, a decrease in Paneth's cells, mucosal ulceration, and an infiltrate of chronic inflammatory cells. H. and E. (× 80.)

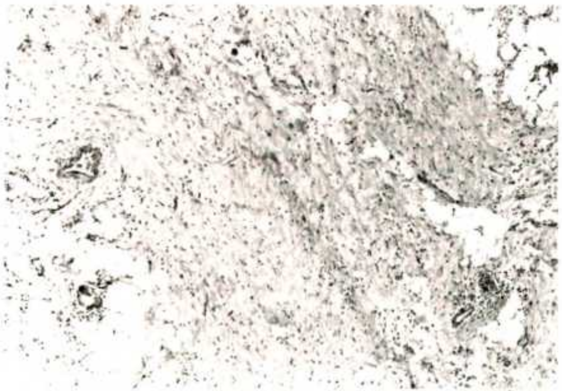

FIG. 7.—*Case* 2. Mesentery showing fat necrosis and marked fibrosis. H. and E. (× 32.)

supplying the bowel showed a fresh occlusive thrombus and also, nearer the bowel, an organized and recanalized thrombus (*Figs.* 4, 5). The appearance was thought to be the result of partial ischaemia of some duration, complicated by a sudden fresh occlusion.

Case 2.—Mr. H. D., aged 65 years, was admitted as an emergency with a 5-day history of colicky abdominal pain, diarrhoea, and vomiting. There was also some weight-loss. Previously he had had a slight stroke and was on hypotensive drugs. There was no past history of abdominal pain.

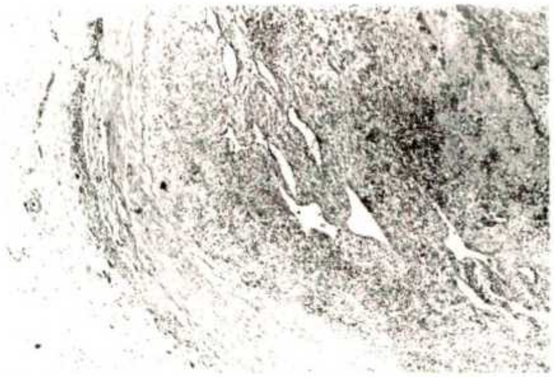

FIG. 8.—*Case* 2. Artery supplying the affected bowel showing a recanalizing thrombus. H. and E. (× 32.)

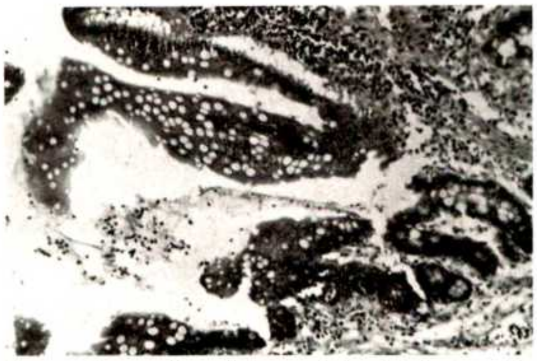

FIG. 10.—*Case* 3. Mucosal ulcers and chronic infarction with acute inflammatory-cell infiltration. H. and E. (× 80.)

The patient was obese and dehydrated, and had a temperature of 38·6° C. He had marked lower abdominal tenderness but no muscle rigidity.

A provisional diagnosis of diverticular disease was made and he was treated with intravenous fluids and antibiotics.

Shortly after admission he became stuporose and jaundiced, but recovered slowly and a barium-enema examination showed no abnormality. A barium follow-through study shortly afterwards demonstrated an abnormal loop of terminal ileum which was dilated and had loss of mucosal pattern. A possible diagnosis of lymphosarcoma was suggested.

The patient's condition again deteriorated and he became uraemic.

At laparotomy about 4 weeks after admission, several loops of ileum were found matted together and adherent to the anterior abdominal wall and liver. The mass of bowel was resected and continuity was restored by end-to-side anastomosis of the ileum to the transverse colon.

The patient's condition deteriorated and he died 11 days after operation.

The operation specimen of 70 cm. of bowel showed atrophy of the bowel with extensive mucosal ulceration, and fat necrosis and fibrosis in the mesentery (*Figs.* 6, 7). There was an organized and recanalized thrombus in the artery supplying the bowel (*Fig.* 8) and a recent thrombus.

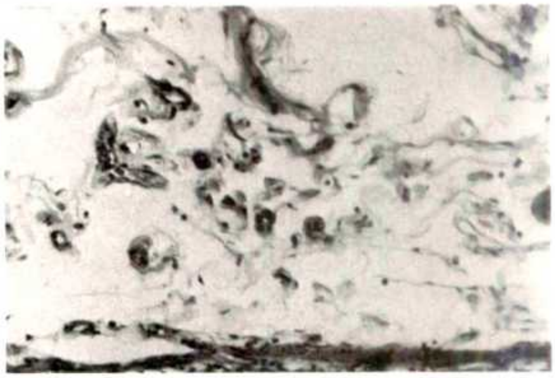

FIG. 9.—*Case* 3. Oedema of the mesentery of the bowel with a few inflammatory cells and arterioles showing a narrowed lumen. H. and E. (× 80.)

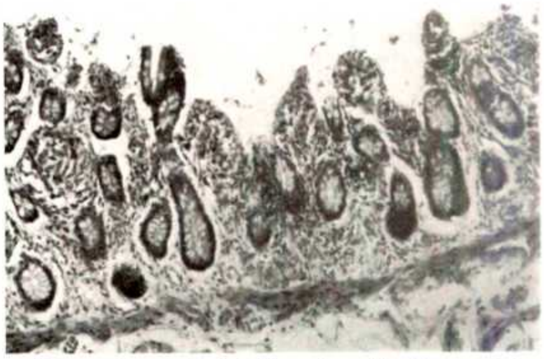

FIG. 11.—*Case* 3. Acute inflammatory-cell infiltration of the mucosa and submucosa with an area of mucosal ulceration. H. and E. (× 80.)

Post-mortem examination showed a recent right pulmonary embolus, severe atherosclerotic changes in the aorta, an infarct of the left kidney, and thrombosis of the left femoral vein. In the superior mesenteric artery a fresh thrombus was found and the entire small and large bowel showed areas of intense congestion.

Case 3.—Mrs. I. D., aged 72 years, was a long-term in-patient at a geriatric hospital, with a diagnosis of senile dementia. There was a very vague history of intermittent abdominal pain.

In July, 1970, after a short history of abdominal pain and vomiting, a strangulated femoral hernia was diagnosed. No bowel resection was necessary and the hernia was repaired. The rest of the bowel was not examined.

She made an uneventful recovery but about a month later she again developed abdominal pain and vomiting. Examination revealed marked upper abdominal tenderness but no mass. A straight abdominal radiograph showed no abnormality. The blood-count, electrolytes, and the serum amylase were all within normal limits. A diagnosis of acute intestinal obstruction was made and laparotomy was carried out at once. A length of terminal ileum which had obviously been involved in the femoral hernia was found to be thickened and deformed, and was resected. In addition, a 7-cm. length of proximal ileum was found to be thickened, red, oedematous, and densely adherent to the sigmoid colon. At one point the bowel was almost perforated. There was fibrosis and oedema of the mesentery (*Fig.* 9). This length of bowel was also resected.

Examination of this specimen showed areas of bowel in which there were atrophic changes in the mucosa and acute inflammatory infiltrate involving all the coats and extending into the peritoneum (*Figs.* 10, 11). The infiltrate in the submucous and serous coats included a number of haemosiderin-containing histiocytes. A number of diverticula were seen and there were areas of fat necrosis in the mesentery. Some arteries in the bowel wall showed thickening of the wall, irregularity and fragmentation of elastic tissue, and evidence of recanalized thrombi. The histology suggested that the lesion was due to chronic partial ischaemia.

The patient made a slow recovery and remains well.

DISCUSSION

Acute ischaemia of short lengths of bowel is seen in volvulus, strangulated hernia, and intussusception. Resection may be required or a fibrous stricture may develop later (Marston, 1964; Cunningham and Regan, 1965). It is, however, difficult to understand how localized ischaemia of bowel can otherwise occur because of the rich blood-supply and extensive anastomoses (Mavor, Lyall, Chrystal, and Proctor, 1962a; Mavor, Lyall, Chrystal, and Tsapogas, 1962b; Reiner, Platt, Rodriguez, and Jimenez, 1960; Reiner, Rodriguez, Jiminez, and Platt, 1962; Marston, 1972). Mavor and others (1962b) stated that a peripheral vascular occlusion will cause a limited or no infarction of the bowel, and Vargas (1967) concluded that such peripheral occlusions are always asymptomatic. Dunphy and Whitfield (1940) pointed out that a gradual occlusion of the superior mesenteric artery may also be asymptomatic. There are a few reports of localized bowel infarction (McClenahan and Fisher, 1948; Arosemena and Edwards, 1967) but none of acute infarction occurring in chronic localized disease.

The cases described here are unusual. In each a limited area of bowel was involved and chronic ischaemia and perforation was survived for years in the first patient. In each case the typical history in chronic bowel ischaemia of postprandial pain was absent—perhaps owing to the limited length of bowel involved—yet all the patients presented as an acute abdominal emergency with abdominal pain and vomiting. The first patient improved, then deteriorated, and developed an abdominal mass. Barium follow-through studies showed an abnormal terminal ileum, suggesting the diagnosis of chronic bowel ischaemia. The initial episode of abdominal pain probably followed the fresh occlusion—necrosis and perforation of the bowel occurring before laparotomy 12 days later.

At laparotomy extensive fibrosis and disorganization of the bowel, with a long-standing occlusion in the main artery and a fresh thrombus, were the findings in the first 2 patients. In the third patient no fresh thrombus was found but the resected bowel was red and swollen. A striking feature in each case was marked areas of fibrosis in the mesentery, of varying size and severity, which may have been the result of leakage of intestinal contents. The fibrosis was obvious at laparotomy and may be of diagnostic value.

Mucosal atrophy and infiltration of the mucosa and submucosa by iron-rich histiocytes were constant pathological findings. Boley, Schwartz, and Williams (1971) have described a characteristic pattern of mucosal destruction and fibrosis, but not the mesenteric changes found in the present cases. The vascular thrombosis may be secondary to Fredrickson type 3 hyperlipoprotinaemia, though Marston (1972) pointed out that biochemical investigation is usually normal even in well-established lesions.

Chronic ischaemia of a localized length of bowel complicated or not by a fresh thrombus is rare. It is of interest that 1 patient has survived resection and is alive and well 2 years later. It is accepted that ancillary investigation is of little value in supporting the clinical diagnosis of ischaemia, but barium follow-through examination showed abnormal small bowel in the first 2 patients and a confident preoperative diagnosis of chronic ischaemia was made in the first case.

Acknowledgements.—The authors wish to thank Mr. R. A. Piachaud, F.R.C.S., under whose care *Case* 2 was admitted, for permission to report his case.

The authors are grateful to Dr. B. J. Smith and Dr. Subbuswamy who carried out the pathological examination and helped in the preparation of this paper, Dr. Sheila Hale who carried out the radiological examinations, and Miss J. E. Tomlison for her help in organizing and typing the manuscript.

EVALUATION OF ORAL THYMOXAMINE IN PATIENTS WITH PERIPHERAL VASCULAR OCCLUSION OF THE LOWER LIMBS

By MARGARET THOMAS, H. CAMPBELL, AND G. E. HEARD

DEPARTMENTS OF SURGERY AND MEDICAL STATISTICS, UNIVERSITY HOSPITAL OF WALES, AND WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

SUMMARY

To determine the effectiveness of oral thymoxamine (Opilon) as a cutaneous vasodilator in patients with peripheral vascular occlusion of the lower limb, double-blind trials of a placebo, of tolazoline in a dose of 50 mg., and of thymoxamine in single doses of 20, 40, 60, 80, and 100 mg. have been undertaken using skin temperature and skin blood-flow as measures of response. Thymoxamine produced no significant increases in skin temperature and blood-flow at any dose level, whereas in the same patients tolazoline produced highly significant increases.

THERE is doubt regarding the value of vasodilator drugs in patients with atherosclerotic arterial occlusion affecting the lower limbs. It has been shown that alcohol (Gillespie, 1967) and tolazoline (Priscol) (Thomas, Campbell, and Heard, 1968) have no effect on the skin blood-flow in the feet of patients with ischaemia severe enough to cause continuous rest pain. Thomas and others (1968) have shown that there is a good response to tolazoline if the nutrition of the feet is normal, whereas in patients with intermediate grades of nutritional disturbance (i.e., persistent colour change at rest, ulceration, or intermittent pain but no continuous rest pain) there is a smaller but significant response to tolazoline. It is in the latter group of patients that vasodilator drugs may (or may not) be of value.

Furthermore, most of the available vasodilator drugs have certain side-effects, some of which are attributable to the non-specific action of the drug; e.g., tolazoline has in addition to an α-adrenergic blocking action a direct effect on smooth muscle and also a histamine-like vasodilator effect.

Recently, the drug thymoxamine (Opilon) has attracted interest. Its pharmacology has been investigated by Birmingham and Szolcsanyi (1965). It has an α-adrenergic blocking effect but no β-adrenergic blocking action, and it may prove to be the most specific α-adrenergic blocking agent (Brownlee, 1966). It has theoretical advantages as a vasodilator of skin vessels. It has been shown to increase blood-flow in the foot distal to an arterial occlusion when given intravenously (Myers, Hobbs, and Irvine, 1968; Kane, 1970).

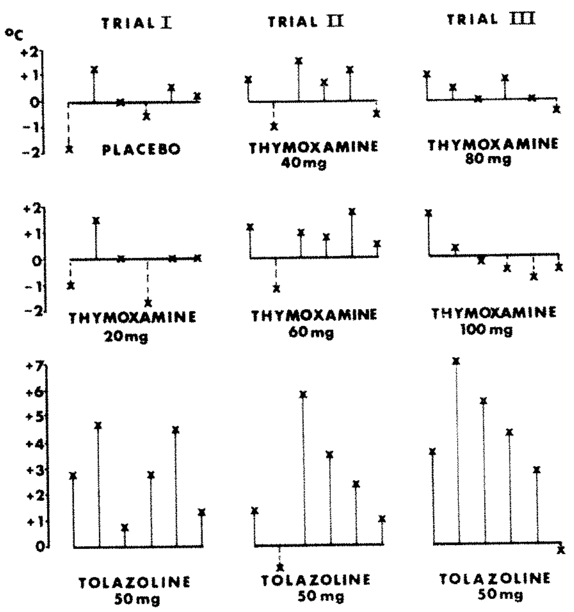

FIG. 1.—Skin temperature changes in response to different dosages of thymoxamine and tolazoline or a placebo in individual patients.

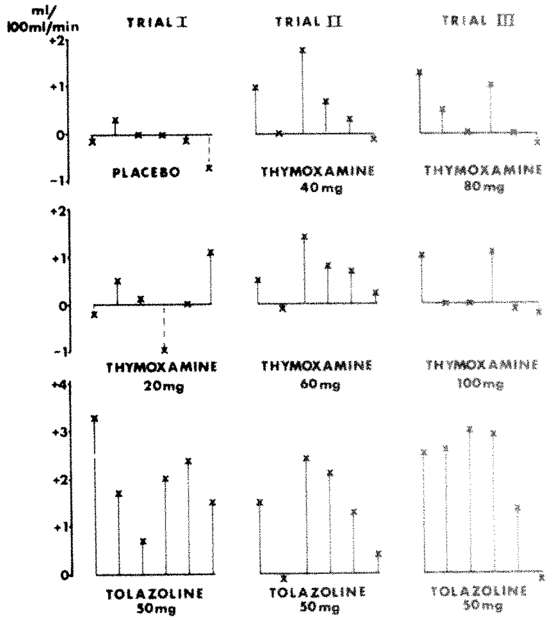

FIG. 2.—Blood-flow changes in response to different dosages of thymoxamine and tolazoline or a placebo in individual patients.

The present investigation has been undertaken to determine the effectiveness of thymoxamine as a cutaneous vasodilator when administered orally in patients with peripheral vascular occlusion of the lower limb. It has been designed to permit comparison of a range of single doses of thymoxamine with a placebo and with tolazoline.

MATERIAL AND METHODS

Eighteen patients who had chronic atherosclerotic arterial occlusion in a lower limb were studied. All the patients presented with claudication. Diabetic and sympathectomized patients were excluded from this series. Fifteen of the patients had normal foot nutrition at rest (grade I), while the remaining 3 patients had mild persistent colour changes at rest (grade II).

Table I.—MEAN RESTING TEMPERATURE AND BLOOD-FLOW BEFORE THE ADMINISTRATION OF A DRUG OR PLACEBO (MEAN OF 6 PATIENTS)

	TEMPERATURE (° C.)	BLOOD-FLOW (ml. per 100 ml. per min.)

Each patient was observed at three sessions during which he received orally one of the following: tolazoline, a placebo, or different doses of thymoxamine. The orders of the three treatments were randomized so as to form balanced blocks for each group of 6 patients. Any response was observed by measurement of the skin temperature and skin blood-flow. So that proprietary preparations of the active drugs could be employed, placebos resembling both tolazoline and thymoxamine were used at random.

Three trials, studying 6 patients in each, have been carried out.

In *trial I* the patients (all grade I) received the placebo; 20 mg. thymoxamine; 50 mg. tolazoline.

In *trial II* the patients (3 grade I and 3 grade II) received 40 mg. thymoxamine; 60 mg. thymoxamine; 50 mg. tolazoline.

In *trial III* the patients (all grade I) received 80 mg. thymoxamine; 100 mg. thymoxamine; 50 mg. tolazoline.

In each trial the drugs or placebo were administered so that each medication appeared in all possible orders, but the patients were allocated to the various regimens at random.

Skin temperature was measured by an electric thermometer using a thermocouple attached to the dorsum of the foot just proximal to the first web. Room temperature and rectal temperature were also observed.

Skin blood-flow was measured by venous occlusion plethysmography using the mercury-in-rubber strain gauge and the method of calibration of Whitney (1953). The gauge was applied around the forefoot, and since the flow through tendon and fascia in this area is small, this technique is considered to measure the blood-flow through the skin and subcutaneous tissues (Cooper, Edholm, and Mottram, 1955).

The collecting cuff producing venous occlusion was applied just above the ankle and was inflated automatically for 6 seconds and released for 6 seconds, giving five inflow slopes per minute. The collecting cuff pressure was determined individually using the lowest pressure giving the maximal resting flow.

PROCEDURE

The patient, having fasted for 2 hours and with an empty bladder, was brought to a quiet laboratory with an air temperature maintained at 22° C. (± 1° C.).

1. The standing blood-pressure and pulse were recorded.

2. The patient was placed in a supine position, with his head on a single pillow, the foot under study slightly elevated, and his trunk covered with a single blanket.

3. The thermocouple was arranged. The strain gauge was fitted, its position was marked, and it was calibrated.

4. The optimum collecting cuff pressure was determined.

5. The resting blood-flow and skin temperature were recorded until a steady skin temperature had been attained (usually 45–60 minutes).

6. A single dose of a drug or placebo was administered.

7. The resting skin blood-flow, skin temperature, pulse-rate, and blood-pressure were recorded at 15-minute intervals for a further 90 minutes.

8. Any subjective symptoms and other side-effects were noted.

RESULTS

Table I shows the mean initial skin temperature and blood-flow before the administration of a drug or placebo in each of the three trials. There were no differences of any statistical significance between any of these initial measurements.

Tables II, III, and *IV* show the skin temperature and blood-flow in each patient before the administration of a drug or placebo and 90 minutes afterwards. The individual responses to the different forms of treatment are illustrated in *Fig.* 1 (skin-temperature changes) and *Fig.* 2 (blood-flow changes). It can be seen that in each of the trials and in 16 out of 18 patients tolazoline produced increases while there was little change following the placebo or the various doses of thymoxamine.

The mean changes in temperature and blood-flow in response to the different drugs and dosages are given in *Table V*, where the statistical significance of the results is indicated. All the changes following tolazoline were statistically significant, while neither the placebo nor any dose of thymoxamine produced a significant change.

Table VI shows the accumulated observations of the three trials. The effect of tolazoline is clear-cut while thymoxamine produced no increase in skin temperature or blood-flow greater than might have been achieved by chance with the use of a placebo.

There was no alteration of blood-pressure or pulse-rate after the taking of the drugs.

DISCUSSION

The results show that as a cutaneous vasodilator in the foot in the presence of atherosclerotic arterial occlusion, oral thymoxamine (Opilon) in the single doses used did not produce a significant increase in the temperature of the foot or in the rate of blood-flow although in the same patients oral tolazoline (Priscol) 50 mg. did produce statistically significant effects.

Table V.—MEAN CHANGES IN SKIN TEMPERATURE AND BLOOD-FLOW IN RESPONSE TO DIFFERENT DRUGS AND DOSAGES

	TEMPERATURE (°C.)		BLOOD-FLOW (ml. per 100 ml per min.)	
	Mean	*t*	Mean	*t*

Table VI.—ACCUMULATED OBSERVATIONS OF THE THREE TRIALS

	NO. OF READINGS	CHANGES IN TEMPERATURE (°C.)			CHANGES IN BLOOD-FLOW (ml. per 100 ml. per min.)		
		Mean	S.E.	*t*	Mean	S.E.	*t*
Placebo	6	−0·07	0·60	−0·1	+0·17	0·31	0·5
Tolazoline	18	+2·93	0·35	8·4	+1·73	0·18	9·6
Thymoxamine	30	+0·25	0·27	0·9	+0·40	0·14	2·9

Furthermore, there is no evidence of a dose-response curve with increasing doses of thymoxamine. An inactive placebo was not used in trials II and III, but in every trial the contrast therapy used for all the patients was a 50-mg. dose of tolazoline. In trial I the advantage of tolazoline, 50 mg., over thymoxamine, 20 mg., was 3·0° C. in increased temperature and 1·8 ml. per 100 ml. per minute in blood-flow; in trial III the advantage of tolazoline, 50 mg., over thymoxamine, 100 mg., was 3·8° C. and 1·7 ml. per 100 ml. per minute. A fivefold increase in thymoxamine had not narrowed the comparison with tolazoline. In trial II half the patients were rather more severely affected by atherosclerotic disease than in the other two trials and the potency of tolazoline in producing a vasodilatation, although still statistically significant at a level of $P = 0·02$, was reduced so that the advantage of tolazoline, 50 mg., over thymoxamine, 60 mg., was only 1·7° C. and 0·7 ml. per 100 ml. per minute. This is in accord with our previous findings (Thomas and others, 1968) that there is a decrease in response to tolazoline with increasing severity of disease. As a consequence the contrast between the drugs was not so large in trial II as it was in trials I and III; it is also apparent that in trial II no effect was produced by increasing the dose of thymoxamine from 40 to 60 mg.

The oral dose of thymoxamine needed to obtain an optimum response is uncertain. Myers, Hobbs, and Irvine (1966) reported increased skin-flow in patients with peripheral vascular disease after intravenous thymoxamine using a dose of 0·1 mg. per kg. Subsequent studies of blood levels have suggested that an equivalent oral dose would be 40 mg. (Hobbs, 1967). This is the dose recommended by the manufacturers. We employed single oral doses of 20, 40, 60, 80, and 100 mg. without a significant effect.

Working with tolazoline, Thomas and others (1968) found a single oral dose to have different results from those observed by Gillespie (1966) using intravenous drugs. Thus, while Gillespie encountered a reduction of the peripheral blood-flow (the borrowing–lending phenomenon) in 60 per cent of the limbs with arterial occlusion, we found that oral vasodilators produced a reduction in only 1 of 24 limbs (4 per cent). It would appear unwise to assume from studies with intravenous drugs a similar action when the drug is given orally.

Doses of 20 and 40 mg. of thymoxamine produced no side-effects but with the larger doses (60 mg. and above) there were side-effects in 2 of the 12 patients; headache and nausea in 1 patient and profuse sweating in the other. This is a similar incidence to the side-effects that we have encountered with 50 mg. of tolazoline orally.

Dexon* is the suture that superseded catgut – but

don't take our word for it!

Although Dexon* sutures have been used extensively in British hospitals for the past three years and throughout the world, not every surgeon has yet used them and so demonstrated their advantages for himself.

- Dexon* is a synthetic absorbable suture that causes minimum tissue reaction and inflammation.
- Although it is totally absorbable it is consistently stronger than catgut for the critical first 7–10 days of healing.
- The braided construction means that every knot holds securely.
- Dexon* is synthetic, and therefore produced to exact, predictable specifications – and this includes predictable absorption.
- Cost savings can be made when Dexon* is used in place of a variety of other suture materials.

We will be happy to tell you more about Dexon sutures but*

Why not prove Dexon* for yourself ?

OESOPHAGEAL PERFORATION

A REPORT OF 13 CASES

By J. VAN WALLEGHEM and H. MULLER

DEPARTMENT OF SURGERY, UNIVERSITY HOSPITAL DIJKZIGT, ROTTERDAM, THE NETHERLANDS

SUMMARY

A series of 13 cases of oesophageal perforation seen between 1961 and 1972 is reported. The various causes of perforation are discussed, with emphasis on the need for rapid diagnosis.

Conservative treatment is considered to lead to a high mortality-rate. One of the 10 patients who were treated surgically in this series died. It is recommended that patients with a carcinoma be treated in a single operation, and in achalasia of the cardia the use of a rigid oesophagoscope should be avoided.

ALTHOUGH many diagnostic and therapeutic methods require the passage through the oesophagus of various instruments (bougie, gastric tube, oesophagoscope, gastroscope), perforation of the oesophagus is fortunately a rare complication. The literature contains only a few series of perforation of the oesophagus comprising 10 or more patients, including cases of spontaneous perforation and perforation due to swallowed objects (Seybold, Johnson, and Leary, 1950).

Between 1961 and 1972, 13 patients with an oesophageal perforation were treated in the University Hospital Dijkzigt at Rotterdam. In 9 cases the perforation was the result of a diagnostic or therapeutic procedure (iatrogenic trauma), in 3 cases it was caused by a foreign body, and 1 case was a spontaneous perforation (*Table I*).

Table I.—CAUSE OF OESOPHAGEAL PERFORATION IN 13 PATIENTS IN THE PRESENT SERIES

Cause	*No. of Cases*
Iatrogenic trauma	
Oesophagoscopy	5
Dilatation	2
Biopsy	2
Accidental	
Foreign body	3
Spontaneous	1

In the treatment of these cases the main emphasis was consistently put on early diagnosis on the basis of the history, clinical findings, and radiographic appearance of the thorax and oesophagus. Usually a thoracotomy was performed with closure of the perforation, high doses of antibiotics being administered preoperatively. This treatment represents a combination of the recommendations in the literature, i.e., on the one hand, surgical treatment with prompt performance of a thoracotomy and closure of the perforation and, on the other hand, conservative treatment with parenteral feeding and high doses of antibiotics. Many authors now support rapid surgical treatment (Weisel and Raine, 1952; McBurney, Kriklin, and Hood, 1953; Overstreet and Ochsner, 1955; Blalock, 1957; Nealon, Cuddy, and Gibbon, 1961; Lauschke, Han, and Perper, 1970; Bertelsen, 1971; Dubost, 1971; Mühe, Bünte, Bürger, and Kuhnlein, 1972), but a few continue to advise conservative treatment (e.g., Mengoli and Klaassen, 1965).

Oesophageal perforations can be divided into four groups according to cause: iatrogenic trauma, accidental, spontaneous, and microperforation (Terracol, 1951).

Iatrogenic oesophageal perforations can occur during oesophagoscopy (5 patients in the present series), instrumental dilatation of the oesophagus (2 patients), and the taking of a biopsy specimen (2 patients) (Bertelsen, 1971), but cases have also been reported resulting from instrumental manipulations during difficult intubations for intratracheal anaesthesia (Dubost, 1971).

Accidental perforations are caused by foreign bodies, such as pieces of wood, fish bones, chicken bones, etc. (3 patients).

Spontaneous perforations occur when the oesophagus ruptures, in most cases as the result of violent vomiting; this type of perforation is called the Boerhaave syndrome (1 patient).

*Micro*perforations which do not give rise to clinical signs or symptoms are caused by the swallowing of fine-pointed objects (e.g., safety pins swallowed by children), or occur during oesophagoscopy, biopsy, or electromyography of the oesophagus. Neither this type of perforation nor that caused by oesophageal abscesses or other complications following thoracic or abdominal surgery is included in the present series and therefore they are not discussed.

SYMPTOMS AND DIAGNOSIS

In the early stages the patient's complaints are not particularly characteristic in either proximal or distal perforation of the oesophagus (Wichern, 1970). The main complaints associated with distal perforations are epigastric discomfort, persistent retrosternal pain, pain between the shoulder-blades, difficulty in breathing, and elevated temperature. With a proximal perforation the patient immediately experiences severe pain on swallowing, movement of the head, and respiration, often accompanied by excessive salivation, and there is usually a rise in the temperature within 8 hours. Special attention must be given to the latter group of complaints after oesophagoscopy.

In cases of perforation due to a foreign body, stenotic complaints predominate. Foreign bodies are usually trapped above natural constrictions in the oesophagus, i.e., just under the pharynx, centrally at the level of the aortic arch, and above the hiatus (Seybold and others, 1950). Dysphagia and pain on swallowing accompanied by an elevation of the body temperature within 24 hours constitute useful diagnostic indications.

In spontaneous post-emetic oesophageal perforations (Boerhaave syndrome) the occurrence of sudden violent vomiting with the simultaneous development of severe retrosternal and epigastric pain is highly suggestive of oesophageal rupture. A predisposing disease is almost always present, for instance oesophagitis (Muller and Nauta, 1952), gastric or duodenal ulcer, or a carcinoma of the cardia. At operation the mucosal tear usually proves to be much longer than outward inspection of the oesophageal lesion suggests (Lauschke and others, 1970, Keighley, Girdwood, Tonescu, and Wooler, 1972).

Clinical examination almost always reveals a slight subcutaneous emphysema in the neck, regardless of the type of perforation involved, the reason being that unlike other hollow organs the oesophagus is not provided with a serous membrane. Because the oesophagus 'hangs' within the loose network of connective tissue of the mediastinum an inflammatory process arising from a perforation can spread unhindered to the hiatus, the neck, and interpleurally in a lateral direction.

If the diagnosis is not made promptly (within 24 hours) mediastinitis, pleural emphysema, or even a subdiaphragmatic abscess can develop rapidly. If this stage is reached a lethal course cannot be prevented in more than 80 per cent of the cases (Seybold and others, 1950; Derbes and Mitchell, 1956). For the differential diagnosis, gastric perforation, acute peptic ulcer, cardiac infarction, strangulated hernia of the oesophageal hiatus, pancreatitis, and other acute processes of the upper abdomen should be taken into consideration (Keighley and others, 1972).

The occurrence of a pneumomediastinum on a routine chest radiograph suggests an oesophageal perforation. Air escaping from the oesophagus spreads rather easily through the loose connective tissue of the mediastinum, which widens within a few hours as an early symptom of mediastinitis. In some cases an exudate in the pleural cavity shows on the side of the oesophagus where the perforation is located. In addition, subcutaneous emphysema is often seen in the region of the neck and at the base of the skull owing to the upward dispersion of the escaping air at each inspiration and expiration. In some cases there is also an appreciable accumulation of air in the pleural cavity a few hours after the perforation has occurred and this is seen on the chest radiograph as a distinct fluid level.

The final diagnosis and localization of the perforation are based on an investigation of the oesophagus with Gastrografin, the contrast medium accumulating outside the oesophagus and in the pleural cavity on the perforated side. This method sometimes fails to reveal small perforations (Callaghan, 1972), but when the diagnosis is probable on clinical grounds the Gastrografin may be detected in the urine a few hours after the radiological examination. This medium is not resorbed in the digestive tract but when there is extravasation it is immediately resorbed by the tissues surrounding the digestive tract and excreted by the kidneys (Mühe and others, 1972).

MATERIAL

The present series includes 6 men and 7 women, ranging in age from 38 to 72 years. Of the 13 patients, 3 suffered from a malignant neoplasm (squamous-cell carcinoma of the oesophagus, gastric adenocarcinoma, and adenocarcinoma of the cardia), 4 from achalasia, 2 from an oesophageal stricture due to ingestion of acid or lye, and in 4 cases the perforation was caused by a foreign body.

In the 3 patients with carcinoma the perforation occurred during oesophagoscopy in 1 case, during the taking of a biopsy specimen in the second case, and in the third patient during violent vomiting. In all 4 patients with achalasia the perforation was caused by endoscopy. In the 2 patients with a stricture the perforation resulted from dilatation with a mercury bougie. Of the 4 patients admitted with a foreign-body perforation, the perforation was caused directly by the foreign body in 3 cases, while in the fourth perforation occurred during the taking of a biopsy sample after careful removal of a hard lump of food (*Table II*). Thus, in this series the oesophagus was twice perforated by taking a biopsy, the other patient having a squamous-cell carcinoma of the distal part of the oesophagus.

Table II.—ORIGINAL DISEASE AND CAUSE OF PERFORATION

ORIGINAL DISEASE	NO. OF CASES		CAUSE OF PERFORATION	NO. OF CASES
Carcinoma		3	Spontaneous	1

Foreign body		4	Foreign body	3
			Biopsy	1
Oesophageal stenosis		2	Dilatation	2
Lye	1			
Acid	1			
Total		13		

Perforations resulting from the use of a rigid oesophagoscope mainly occur in two areas: in the cervical part of the oesophagus and just above the diaphragm. The cervical perforation occurs where the posterior wall is pressed against the cervical vertebrae by the oesophagoscope. The introduction of the oesophagoscope is particularly difficult in patients with spondylolisthesis or cervical arthrosis. Distal perforations are not rare in achalasia, occurring in the region where the oesophagus makes an S-shaped curve over the diaphragm.

The frequency of oesophageal perforation, as a complication of the use of a rigid oesophagoscope (with or without biopsy), is rather low, according to the literature being between 0·4 and 1 per cent (Quintana, Bartley, and Wheat, 1970). In the University Hospital Dijkzigt 1050 oesophagoscopies were performed with this instrument between 1 Jan., 1961, and 1 Jan., 1972, with 7 perforations, or 0·67 per cent (*Table III*). It is therefore evident that the use of this instrument is not entirely without risk. It does, however, have the advantage of easy removal of small foreign bodies. The flexible fibroscope is much less likely to cause a perforation and is therefore being increasingly used for diagnostic purposes.

Our series includes 2 cases of a perforation in the proximal oesophagus, 1 occurring during oesophagoscopy of a patient with achalasia and severe kyphosis and the other being caused by a foreign body.

The middle part of the oesophagus was perforated twice; once by a foreign body and once by bougienage performed by the patient herself.

Table III.—Frequency of Oesophageal Perforation in Oesophagoscopy at the University Hospital Dijkzigt between 1961 and 1970

Year	*No. of Oesophagoscopies*	*No of Perforations*
1961	5	
1962	30	
1963	68	1
1964	82	
1965	84	1
1966	111	
1967	109	1
1968	114	
1969	133	1
1970	150	2
1971	164	1
	1050	7 (0·67 per cent)

Dilatation	2	2	—	—	—
Foreign body	3	2	—	1	—
Spontaneous	1	—	1	—	—
	13	9	1	1	2

The distal portion of the oesophagus was perforated in 9 cases; in 4 cases during oesophagoscopy (3 achalasia cases, 1 carcinoma of the cardia), in 2 during a biopsy (the patient with squamous-cell carcinoma of the oesophagus and in the other case after removal of a foreign body), in 1 by a foreign body, in 1 by instrumental dilatation (the patient with a stricture after lye burns), and once spontaneously during violent vomiting (the patient with gastric carcinoma) (*Table IV*).

TREATMENT

When the diagnosis of oesophageal perforation was confirmed surgical treatment was carried out as soon as possible in the form of closure of the perforation and drainage of the pleural cavity. Antibiotics were administered both before and after surgery (usually penicillin and streptomycin in high doses).

Conservative treatment consisting of antibiotics and parenteral feeding was used in 3 cases (*Table V*). One of these was a patient with a deep mucosal tear and a small perforation of the muscular wall caused by a sharp foreign body who showed no signs of mediastinitis and recovered rapidly. In the second case, a patient with achalasia who after oesophagoscopy had a perforation located only 18 cm. from the teeth, preference was incorrectly given to conservative treatment. This patient died 2 months later despite intensive treatment with antibiotics, parenteral feeding, tracheotomy, and a jejunostomy. The third patient was treated conservatively because the diagnosis could not be confirmed by oesophagoscopy. This woman had achalasia with a complete stenosis. Since a nasal catheter could not be introduced via the oesophagoscope a gastrostomy was made for feeding. Postoperatively she developed a high fever, which was attributed to an infection of the urinary tract. Later a subdiaphragmal abscess was diagnosed, but because of the patient's poor general condition conservative treatment was instituted. The patient died and at autopsy an old perforation was found in the distal oesophagus.

The other 10 patients were treated surgically. Only 1 of these cases had a fatal course (the patient with an inoperable gastric carcinoma and a post-emetic rupture of the oesophagus).

Of the 3 cases of a perforation caused by a foreign body, 1 was only diagnosed after 3 days had elapsed. This patient was a woman suffering from lupus erythematosus and was on cortisone treatment. Primary closure of the perforation was performed, and later abscess drainage was required. The second patient had received conservative treatment elsewhere despite early diagnosis. After being referred to the University Hospital Dijkzigt he was treated initially with drainage and flushing of the abscess cavity in the thorax and later by thoracotomy with abscess drainage and exploration of the mediastinum. In the third patient, who had had a biopsy of the site from which the foreign body had been removed, the perforation was closed surgically within 24 hours.

In the 3 carcinoma patients the perforation was treated surgically. In the first patient, who had a small oesophageal polyp, the perforation had occurred during the taking of a biopsy specimen. Primary closure of the perforation was done. Three years later a definite diagnosis of squamous-cell carcinoma was made and a colon interposition was performed. The patient died a year later from metastases. The second patient, who suffered from gastric carcinoma, developed a perforation spontaneously as a result of violent vomiting. In this case the carcinoma had been diagnosed some time before, but for personal reasons the patient had consistently refused surgical treatment. Treatment consisted in the first instance of primary closure, and a primary oesophagogastrectomy was not considered (McBurney and others, 1953). Later, under much worse conditions pleural drainage and a jejunostomy were carried out and finally a total gastrectomy was performed. The patient died 50 days after the perforation had occurred. As Keighley and others (1972) have pointed out, the consequences of a spontaneous rupture are always more serious than those of an instrumental perforation. This is probably due to the autolysis of the contents of the stomach, which are forced into the mediastinum under high pressure. In the third patient, who had a carcinoma of the cardia, the perforation occurred during oesophagoscopy. Six hours later, via a left-sided thoraco-abdominal incision, the perforated part of the oesophagus and the cardia were resected with an oesophagogastrostomy. The patient made an uneventful recovery.

Two of the 4 patients with achalasia and a perforation due to oesophagoscopy were treated surgically. Within 6–10 hours the perforation was closed via a thoracotomy and a Heller's operation was performed. Both patients recovered uneventfully. The other 2 patients with achalasia were treated conservatively with a fatal result and have already been discussed.

In the 2 patients with stenosis of the oesophagus and a perforation due to dilatation, thoracotomy and primary closure of the perforation gave good results. One of these patients had a stenosis due to lye burns incurred in his youth. During dilatation of the stenosis with a mercury bougie the oesophagus was perforated just above the stricture. The second patient had a stenosis due to acid burns suffered in childhood, and was accustomed to dilate the oesophagus with a Pilling bougie, which ultimately caused the perforation. Two months after primary closure a colon interposition was performed, and at present the patient has no complaints.

CONCLUSIONS

1. Surgical treatment, consisting of closure of the oesophageal perforation and drainage of the pleural cavity in combination with high doses of antibiotics is the treatment of choice (*Table V*).

2. When perforation occurs in patients with carcinoma of the oesophagus or stomach, primary oesophagogastrectomy should be considered instead of simple closure of the perforation.

3. In patients with achalasia, diagnostic oesophagoscopy with a rigid oesophagoscope is dangerous. Because of the risk involved, oesophagoscopy, possibly with a flexible instrument, should only be considered when a malignant process is suspected.

NON-PULMONARY SURGICAL TUBERCULOSIS*

By R. G. FABER†

HIGH WYCOMBE GROUP OF HOSPITALS

Summary

Fifty-one cases of non-pulmonary surgical tuberculosis are reviewed, 29 of the cases being immigrants. Of the 44 'new' cases, tuberculosis was not among the preoperative differential diagnoses in 15. Lymph-nodes were the site of the disease in more than half the cases. In only 29 cases was an operative specimen sent for bacteriological culture, and the necessity for culturing operative specimens and the reasons for the failure of isolation of tubercle bacilli in 50 per cent of the cultures are discussed. The impression that tuberculosis is not sufficiently considered by doctors in the preoperative differential diagnosis of several surgical presentations, especially in English patients, is confirmed.

Fifty-one cases of tuberculosis who were in-patients in the surgical departments of the High Wycombe group of hospitals during the years 1966–70 are reviewed. Apart from 1966 the number of 'new' cases of tuberculosis each year has been constant in contrast to the Tuberculosis Notifications (Public Health Laboratory Service, 1971) for the same years (*Table I*). Cases of tuberculosis, including 11 gynaecological cases, who were not under the care of the surgical departments are not included. The review was prompted by the emergence of a surprising number of clinically unsuspected cases of tuberculosis in 1970, and confirmed that tuberculosis was frequently not among the differential diagnoses of several surgical presentations. In some cases this led to a delay in diagnosis since the appropriate diagnostic procedures were not employed.

---

* This paper is based on the prize-winning entry for the Oxford Regional Board Surgical Prize, 1970, and a paper presented to the Chiltern Medical Society on 23 Sept., 1970.

† Present address: Department of Surgical Studies, the Middlesex Hospital, London.

PATIENTS

The number of 'new' cases of tuberculosis presenting each year in this series is shown in *Table I*. Apart from 1966, when possibly the records were incomplete, the incidence of the disease was constant. There were no deaths in the series. Twenty-nine of the patients (58 per cent) were immigrants to the United Kingdom, the majority (22 patients) being from Pakistan. There were 22 males and 7 females among the 29 immigrants, and 9 males and 13 females among the 22 English-born cases. The ages of the patients (*Table II*) ranged from 12 to 85 years with an average of 46 years for the English cases and 28 years for the immigrants. The 12-year-old patient was the only child in the series and was born in England. There were 3 patients over the age of 70 and these were all females born in England.

Table I.—Number of Cases of Tuberculosis per Year between 1966 and 1970 in the Present Series compared with the Tuberculosis Notifications for the Same Years

	Year				
	1966	1967	1968	1969	1970
Notifications					
Total	14,616	13,223	12,984	21,162	11,907
Deaths	3,242	2,050	2,196	1,835	1,563
Present series					
Total	3	9	14	13	12
Immigrants	1	5	7	10	6
Deaths	0	0	0	0	0

Table II.—Age Distribution in the Present Series

	English	*Immigrant*
Average age	46	28
Youngest	12	17
Oldest	85	52

Seven of the 51 cases were classified as 'old' cases, as they gave a history of having had tuberculosis in the past and therefore aroused the suspicion of tuberculosis being the cause of the present admission. Only 2 of these 7 patients were immigrants. Four cases had undergone surgery for tuberculosis in the pre-antibiotic era, but the other 3 cases had received inadequate chemotherapy at the time of their previous diagnosis. There were 3 further cases in the series who received inadequate chemotherapy initially and this resulted in a protracted course to their illness. Of the 44 'new' cases (i.e., with no previous history of tuberculosis), tuberculosis was considered in the differential diagnosis in 29 (66 per cent), while in 15 patients (34 per cent) the diagnosis came as a surprise when the histology of the operative specimen was reported. Of the 15 unsuspected cases, 8 (53 per cent) were English born, while only 8 out of the 29 clinically suspected group (27 per cent) were English born.

SITE OF TUBERCULOSIS DISEASE

Table III compares the site of tuberculosis in the 51 patients with the number of cases classified as 'old' cases, 'new' cases in which tuberculosis was among the preoperative differential diagnoses, and 'new' cases in which the histological diagnosis came as a surprise. The most common site of tuberculosis was the lymph-nodes; in 23 cases the cervical region was the site of the disease, 1 case having involvement of the inguinal and axillary nodes as well. One case each of solitary axillary and inguinal tuberculous lymphadenitis occurred, and there were 2 cases of intestinal tuberculosis, in which the diagnosis was confirmed by histology and culture of the mesenteric lymph-nodes.

Of the 11 cases of genito-urinary tuberculosis, there were 6 cases with urinary-tract involvement and 5 cases of genital-tract disease. Two of the latter 5 patients had been subjected to nephrectomy in the pre-antibiotic era for renal tuberculosis but excretion urography and cystoscopy at the time of the present review showed a normal remaining kidney and bladder. Similarly, intravenous pyelography and cystoscopy were normal in the 3 cases with no previous history of urinary-tract tuberculosis. Two patients with renal tuberculosis were subjected to nephrectomy during the time of the review. In the first case nephrectomy was carried out because of a ureteral stricture and pyonephrosis despite adequate chemotherapy. The other case had a ureteral stricture and a non-functioning kidney. There was no growth of tubercle bacilli on early morning urine culture and therefore this case was not treated preoperatively with anti-tuberculous chemotherapy, because the diagnosis had not been made although it had been suspected clinically. Another case required re-implantation of the ureter into the bladder because of a fibrous stricture at the lower end.

Table III.—Site of Tuberculous Disease in Patients in the Present Series

	Lymph-nodes	Genito-urinary System	Intra-abdominal	Bone and Joint	Multiple Subcutaneous Cold Abscesses	Larynx	Breast
'Old' cases	2	3	0	1	0	0	1
'New' cases clinically suspected of having tuberculosis	16	8	3	1	1	0	0
'New' cases not clinically suspected of having tuberculosis	9	0	6	1	0	1	0
Total	27*	11	9*	3	1	1	1

* Includes 2 cases with intestinal tuberculosis as well as mesenteric tuberculous lymphadenitis

Of the 9 cases of intra-abdominal tuberculosis, there were 3 cases of intestinal disease, 2 having localized tuberculous appendicitis, of which 1 had enlarged tuberculous mesenteric lymph-nodes. One case presented with small-bowel obstruction due to an active tuberculous stricture of the ileum approximately 1 m. from the ileocaecal valve. This patient also had enlarged tuberculous mesenteric lymph-nodes. The other 6 cases had tuberculous peritonitis, 5 patients presenting with generalized peritonitis and being submitted to emergency laparotomy, while the sixth patient was also noted to have a pleural effusion and the diagnosis was made from the pleural biopsy. Despite a clinical suspicion of tuberculosis in only 3 of the 6 patients, in none was there any delay in operating and obtaining biopsy material from which an early diagnosis was made.

The sites of disease in the 3 cases of bone and joint tuberculosis were the spine, knee, and ankle respectively. The first case was diagnosed on the classic radiographic appearance of the collapse of two adjacent thoracic vertebral bodies with a surrounding paravertebral abscess, and was treated for 3 weeks before drainage of the abscess. The other 2 cases were diagnosed from the biopsy of discharging sinuses.

The case with multiple subcutaneous cold abscesses was suspected initially to be suffering from tuberculosis, but several abscesses had to be biopsied and aspirated before a positive culture of *Mycobacterium tuberculosis* was obtained. The patient with tuberculosis of the larynx was thought to have a carcinoma of the vocal cords before the histology of the biopsy was seen. The tuberculous breast abscess occurred in an 85-year-old woman who had had a tuberculous lymph-node many years before and had received no chemotherapy.

INVESTIGATIONS

Chest Radiography.—Thirty-five patients (69 per cent) had normal chest radiographs even though some of these cases had generalized disease (*Table IV*). In 11 cases the chest radiograph showed evidence of active pulmonary tuberculosis. However, 10 cases did not have a chest radiograph performed preoperatively, and on reviewing the postoperative films it was seen that in 3 of the cases the diagnosis could have been made from the chest radiograph alone. Five cases showed evidence of old healed tuberculosis and in all of these cases this aroused the suspicion that tuberculosis was the cause of the disease at the present time.

Table IV.—Findings of Chest Radiography in the Present Series

	Normal	Evidence of Old Tuberculosis	Evidence of Active Tuberculosis
Performed preoperatively	28	5	8
Not performed preoperatively	7	0	3
Total	35	5	11

Mantoux or Heaf Test.—This was performed preoperatively in only 8 cases and was positive in 7 and negative in only 1 patient who was severely ill with tuberculous peritonitis.

Erythrocyte-sedimentation Rate.—This was measured preoperatively in 21 cases, being normal in 4 and raised in 17.

Bacteriological Culture.—In only 29 cases (57 per cent) were either an operative specimen or early morning urine specimens (in the case of genito-urinary tuberculosis) sent for bacteriological culture (*Table V*).

Table V.—Bacteriology of the Operative Specimens from Patients in the Present Series

Result	*No of Cases*
Specimens not sent for culture	22
Isolation of *M. tuberculosis* on culture	15
No growth of *M. tuberculosis* on culture	14

Of those specimens which were sent for culture, *M. tuberculosis* was isolated in only 15 cases.

DISCUSSION

The number of cases presenting each year remained constant, apart from 1966 (*Table I*), and this contrasts with the falling incidence of National Notifications (Public Health Laboratory Service, 1971). The incidence of tuberculous disease in immigrants of 58 per cent in the present series is considerably more than the figure of 16·5 per cent of the notifications in England and Wales during a 3-month period in 1965, at which time immigrants formed 4 per cent of the population (British Thoracic and Tuberculosis Association, 1971). The large proportion of immigrants in the present series is simply a measure of the large immigrant population in the area served by the High Wycombe group of hospitals, and contrasts strongly with the 4 immigrant cases out of 71 patients (6 per cent) reported in the Edinburgh series for the years 1964–8 inclusive (Stack, 1971). Although the average age of the immigrant cases was appreciably lower than that of the native population the range of ages in both groups prevents this being used as a diagnostic criterion, and probably merely reflects the younger age of the immigrant population in general.

Six cases received inadequate chemotherapy; 3 before the period covered by the review, and 3 who were initially diagnosed during the period of this review. For chemotherapy to be considered adequate it must be continued for about 2 years to ensure freedom from relapse (Leading Article, 1970b). There are two reasons for inadequate chemotherapy. First, there is the natural reluctance of surgeons to condemn a patient to 2 years of treatment with drugs which sometimes have unpleasant side-effects, and it needs the enthusiasm of the physician specializing in tuberculosis to ensure that the drugs are taken. Gabriel (1971) made a plea for co-operation between surgeon and physician in this respect. Secondly, there is frequent 'patient-failure', especially among some immigrants whose mobility and language problems make follow-up very difficult. However, there is a medical responsibility to impress upon the patients the seriousness of the condition and the necessity for continued chemotherapy.

The inclusion of tuberculosis in the initial differential diagnosis of 66 per cent of the 'new' cases compares with the figure of 69 per cent in non-thoracic cases of tuberculosis reported by Stack (1971).

There were no deaths in the present series compared with 5 in Stack's review. Although the percentage of cases in which tuberculosis would have been included in the initial differential diagnosis must have been much higher 25 years ago when surgeons saw many more cases and were more aware of the incidence of the disease, it is hard to believe that any similar series then could have had no deaths. The relatively high incidence of English-born cases in the group of patients in which tuberculosis was not included in the differential diagnosis (53 per cent), compared with only 27 per cent of English-born patients occurring in the group in which tuberculosis was considered in the differential diagnosis, suggests that in the High Wycombe area especially doctors are not aware of the amount of tuberculosis in the native population.

More than half of all the cases had tuberculous lymphadenitis. There were 318 lymph-node biopsies in the High Wycombe group of hospitals during the years of the review, giving an incidence of tuberculous disease in 8 per cent. This incidence is far greater than that in Stack's (1971) series from Edinburgh (12 out of 71 cases), but the distribution of the disease in his series is similar with all the cases having cervical lymph-node involvement, which was true in all but 4 of the cases in this series.

The fact that in the present series only 2 out of the 5 cases with genital-tract disease, all having tuberculous epididymitis, had suffered from urinary-tract disease would seem to support the theory that genito-urinary tuberculosis is not a single entity (Konstam, 1966). However, Wells (1938) clearly showed over 30 years ago that the commonest route of infection of the genital tract is the urinary tract, and it is possible that the urinary-tract disease was either healed or dormant, which in the latter case would have been cured by an adequate course of chemotherapy.

The finding of 2 cases of tuberculous appendicitis with no associated general disease is surprising, and Bochus (1969) quoted only 4 cases in 7847 appendices removed from 1928 to 1948. However, with tuberculous disease elsewhere in the body, tuberculous appendicitis becomes more common, rising to 24 per cent in sanatoria. A review of intra-abdominal tuberculosis, including the 9 cases in this series, is in preparation.

The case with multiple cold abscesses was typical of the description of these cases given by Shaw and Bassu (1970) and in a Leading Article in the *British Medical Journal* (1971). The patient was a Pakistani immigrant who developed multiple subcutaneous abscesses of the scalp and both arms. The diagnosis was made clinically, but the histology was non-specific and confirmation was only obtained by a very weak growth of tubercle bacilli on a culture of the third abscess drained.

The high percentage of normal chest radiographs shows that it is necessary to be aware of the possibility of non-pulmonary tuberculosis in the absence of radiological pulmonary changes. However, it is regrettable that in 10 cases a chest radiograph was not performed preoperatively, and ironic that in 3 of these cases there was evidence of active pulmonary tuberculosis.

Only 8 of the 51 cases had a Mantoux or Heaf test performed. In patients with active tuberculosis the tuberculin test is only negative during the incubation period of 3–9 weeks while cell-mediated delayed hypersensitivity is being built up. In critically ill patients the test may become negative, and revert to positive on the recovery of the patient with treatment, as occurred in this series in 1 patient with tuberculous peritonitis (Howard, Klopfenstein, Steininger, and Woodruff, 1970; Leading Article, 1970c). As a method of clinical diagnosis the tuberculin test is only of value in an area where there is a low infection rate and B.C.G. vaccination is not used extensively, as it is in England (Crofton and Douglas, 1969a). However, if the patient is not critically ill a negative tuberculin test excludes tuberculosis as the cause of the disease, and it should therefore have been performed more frequently.

The erythrocyte sedimentation rate (E.S.R.) was carried out preoperatively in only 21 cases, being normal in 4 (20 per cent) and raised, sometimes only slightly, in 17 (80 per cent). It has been suggested by Kay (1970) that E.S.R. surveys can be of diagnostic value despite their lack of specificity. However, the 20 per cent normal figure in the present series supports the contention of Crofton and Douglas (1969c) that active lesions may be associated with a normal E.S.R. and that the investigation is of little diagnostic value.

It is regrettable that in only 29 cases (57 per cent) were operative specimens sent for bacteriological culture. When the diagnosis was not suspected preoperatively it was the rule that no specimens were cultured. When the diagnosis was suspected, specimens have occasionally been put into formalin by mistake when it had been the surgeon's intention to send some for culture, and he must accept responsibility for not informing the nursing staff clearly in advance (author's own experience). Furthermore, it must be said that some surgeons have not appreciated the necessity of sending a good specimen for bacteriological culture as well as for histology. One reason for having all specimens cultured is that it is impossible to be sure of the diagnosis of tuberculosis in every case on histological grounds alone and in 2 cases in this series, when the histology was non-specific, the diagnosis was made by the growth of tubercle bacilli on a culture. One cannot help considering whether in this 5-year period there may have been other cases in which the diagnosis was not made on histological grounds and an operative specimen was not sent for culture. Secondly, without culturing the tubercle bacilli it is impossible to be sure that the lesion has not been caused by one of the atypical mycobacteria. Finally, it is not possible to know the drug sensitivities of the tubercle bacilli if it has not been cultured. Springett (1972) stated that in Asian immigrants with tuberculosis in Birmingham between 1961 and 1963, 3 per cent per year excreted resistant bacilli on the first diagnosis, but between 1968 and 1970 13 per cent excreted resistant bacilli. There is controversy about the value of sensitivity tests in the individual patient—a Leading Article in the *British Medical Journal* (1970a) and Citron (1972) decrying their value, especially as performed outside central specialized laboratories—except in cases which relapse or which have had previous chemotherapy with a recurrence of the disease. However, Bruce (1970) and Marks (1970) strongly disagreed but stated that they believe that the best results are obtained at reference laboratories.

It is apparently disappointing that in only 15 of the 29 operative specimens sent for bacteriological culture in the present series was a growth of *M. tuberculosis* obtained. Medlar, Bernstein, and Steward (1952) and Medlar (1955) found that in 356 solid pulmonary lesions or filled-in cavities which were resected only 20 (5 per cent) grew tubercle bacilli. They concluded that although definite proof of the reasons for this was lacking there were several factors which adversely affected the isolation of the tubercle bacilli under laboratory conditions. First, in any patient who had been submitted to chemotherapy the drugs may have killed the bacilli in the operative specimen. Secondly, as a result of the host-immune response there may be a decreased pathogenicity of *M. tuberculosis*, and this is confirmed by tubercle bacilli being seen on microscopy but being non-pathogenic in guinea-pigs. In closed lesions tubercle bacilli can remain alive for many years without the ability to grow on a culture medium or in a guinea-pig, but the patient in whom this has occurred may relapse many years later. It is suggested that changes in the life process enabling these bacilli to survive hypoxia and the host-immune response render them incapable of reproducing on artificial media. Thirdly, specimens in which there are only a few tubercle bacilli require culturing for 3 months and the routine laboratory period of time of 6 weeks is insufficient. Fourthly, some viable tubercle bacilli are not capable of reproducing on artificial media. Better results may be obtained with the use of fluid media reinforced with glycerol which enhances the growth of sick *M. tuberculosis*. *Mycobacterium bovis* grows better in the absence of glycerol but with the media having added pyruvate (Crofton and Douglas, 1969a), and it is possible that some of the cases of cervical tuberculosis in the present series may have been caused by this organism. Davies (1971) noted that, curiously, caseous material from tuberculous lymph-nodes frequently shows no acid-fast bacilli on a smear or culture, but only suggested that the surgical practice of putting specimens into formalin may be a cause. The figure of 50 per cent of the operative specimens growing a culture of *M. tuberculosis* in the present series compares with the recent results from the Bacteriology Department at St. George's Hospital (Hilson, 1972).

Acknowledgements.—I am grateful to the late Mr. K. H. Taylor for suggesting carrying out this review, and to him and the other surgeons in the High Wycombe group of hospitals for permission to present their cases. I wish to thank Dr. A. O. Robson, Dr. D. A. Leigh, and Professor G. R. F. Hilson for their advice and help, and Dr. C. R. Tribe without whose excellent pathology records this review would have been impossible.

SIGNIFICANCE OF RECTAL BLEEDING IN DIVERTICULAR DISEASE IN PATIENTS AT ST. MARK'S HOSPITAL

BY J. C. B. PENFOLD*
ST MARK'S HOSPITAL, LONDON

SUMMARY

The site of the rectal bleeding in diverticular disease was sought by examination of the surgical specimen and found in 28 of 49 cases examined. It was related to the diverticular disease in 9 cases and to other pathological conditions in 19 (39 per cent), 16 of which were polyps. Fourteen of the polyps were demonstrated by preoperative barium-enema examination.

Adequate clinical and radiological examination demonstrated these other colonic conditions preoperatively in most of the patients.

RECTAL bleeding in the presence of known diverticular disease is a difficult clinical problem. The significance of the rectal bleeding is unclear as it is now recognized that non-inflamed diverticula may bleed and that other pathological conditions may be present in the bowel, the diverticular disease being a red herring. The present investigation was undertaken to determine the incidence and nature of these other pathological conditions in patients with diverticular disease in whom there was a preoperative history of rectal bleeding and to see whether any clinical features or investigations will distinguish these patients from those in whom the rectal bleeding is related to the diverticular disease.

Bleeding is usually of two distinct types: minimal and massive. The second variety has been the subject of many communications and will not be considered further.

METHODS

All the cases of sigmoid diverticular disease which had undergone resection at St. Mark's Hospital from 1964 to 1969 were reviewed. The cases in which there was a preoperative history of minimal rectal bleeding were selected. The operative specimens had been specifically examined for a site of the bleeding. The results of these examinations were studied and correlated with the nature of the rectal bleeding and the preoperative diagnosis. Specimens containing malignant neoplasms were excluded as they all had been suspected preoperatively.

RESULTS

Forty-nine specimens (one-third of the specimens of diverticular disease resected over this period) were reviewed. The indication for the resection was to determine whether cancer was present in 27 cases, persistent abdominal pain in 15, and a specific complication of the disease (fistula, abscess, perforation, or previous proximal colostomy) in the remaining 7 patients.

Site of the Bleeding.—In 28 specimens (57 per cent) a site for the bleeding was found. In 9 patients there were ulcerated diverticula, some containing granulations, and no other pathological condition. In the other 19 specimens (an incidence of 39 per cent) the bleeding was from an associated pathological condition (*Table I*). The metaplastic polyp was 1 cm. in diameter, which is unusually large in our experience. The 2 cases of ulcerative colitis were mild and not suspected preoperatively but were confirmed histologically.

Table I.—NATURE OF OTHER PATHOLOGICAL CONDITIONS FOUND IN SIGMOID COLON SPECIMENS

Pathology	*No. of Cases*
Polyps	
Adenomas	13
Hamartomatous	1
Peutz-Jegher's	1
Metaplastic	1
Ulcerative colitis	2
Endometriosis	1

Nature of the Rectal Bleeding.—There was no correlation in the incidence of other pathological conditions in the specimens of patients in whom the rectal bleeding was only seen once or twice and in those in whom it was a more frequent occurrence.

Preoperative Diagnosis.—All the patients had had a double-contrast barium-enema examination preoperatively. Of the 15 patients who showed a polypoid filling defect suggestive of a polyp as well as the diverticular disease, only 1 was found to be a false positive. In 2 patients a polyp, each 7 mm. in diameter, was missed. The 2 cases of ulcerative colitis showed no suggestion of colitis on a roentgenogram. Unfortunately neither patient had had a rectal biopsy.

DISCUSSION

In the patients in whom no source of the rectal bleeding could be found the possibility of bleeding from haemorrhoids exists. It is impossible to tell whether the haemorrhoids were the cause of the bleeding.

Many different opinions have been expressed regarding the significance of minimal rectal bleeding, particularly since the conclusive recognition that uncomplicated diverticula may bleed (Maynard and Voorkees, 1956; Mobley, Dockerty, and Waugh, 1957). Some workers have concluded that other pathological conditions are the cause of bleeding in most cases (Smith, 1951; Gilchrist and Economou, 1955; Scarborough, 1958). Yet Mobley and others

---

* Present address: Colon and Rectal Surgery Department, Ochsner Clinic, New Orleans, U.S.A.

(1957) found ulceration related to diverticula in over 56 per cent of their cases and felt that more careful examination of specimens would reveal an even higher incidence, and Greene (1957) examined 60 specimens and was unable to find other pathological conditions in any. Noer (1955) demonstrated the closeness of blood-vessels to diverticula, suggesting their vulnerability to trauma. Other workers have been undecided as to the site of the bleeding but stressed the importance of looking for a neoplasm (Lloyd-Davies, 1953; De Cosse and Amendola, 1957; Colcock, 1965). Rigg and Ewing (1966), in reviewing the literature, came to a similar conclusion. Our results agree with the latter findings—associated disease is the source of rectal bleeding in many of these patients but a similar proportion of patients have no demonstrable site despite meticulous examination of operative specimens. Ulcerated diverticula are found in only a small percentage of cases.

Thorough anorectal and barium-enema examinations have demonstrated the presence of polyps in most of the colons which were subsequently found to contain them. The high success rate in detecting these polyps preoperatively is to a large extent due to the excellence of the radiology. If a biopsy of rectal mucosa is included in all suspicious cases most of the other pathological conditions will be detected. The remainder of these cases present a clinical problem. However, since the introduction of the colonoscope it would seem that they would have been accurately diagnosed preoperatively by its use. A patient who has known diverticular disease and a history of rectal bleeding should in our opinion be investigated for the rectal bleeding as if the diverticular disease were not present.

Acknowledgements.—I would like to thank the staff of St. Mark's Hospital, London, for allowing me to study their records, and especially Dr. Basil Morson and Mr. Charles Mann for helpful criticism in the preparation of this paper.

PRESSURE MEASUREMENTS IN THE CERVICAL PORTION OF THE THORACIC DUCT IN MAN

By P. KINNAERT

DEPARTMENT OF SURGERY, HÔPITAL BRUGMANN, UNIVERSITÉ LIBRE DE BRUXELLES, BRUSSELS, BELGIUM

SUMMARY

Pressures were measured in the cervical portion of the thoracic duct during a surgical procedure performed to drain lymph in 8 male patients. Cyclic variations depending on respiration were observed. Smaller oscillations in pressure were synchronous with the pulse-rate and result from rhythmic compression of the thoracic duct by the aorta in the thorax. In 2 patients the recordings showed superimposed pressure waves which were independent of breathing and the heart-rate and which are thought to be due to spontaneous contractile activity of the duct.

During the past 4 years we have cannulated the thoracic duct in the neck of 50 patients in terminal chronic renal insufficiency. Usually, lymph-flow in the catheter depends on respiration and is maximal at the end of expiration. However, in some patients gushes of lymph could be observed which were independent of breathing. This suggested a spontaneous contractile activity of the duct. Reports on this subject are scarce and the published results are discrepant. Pflug and Calnan (1968) did not observe peristalsis in the thoracic duct of dogs, and Pomerantz, Herdt, Rockoff, and Ketcham (1963) stated that there was no intrinsic motor activity in the duct of 115 patients undergoing lymphography. On the other hand, in a radiographic study conducted in dogs Browse, Lord, Rutt, and Taylor (1969) described rapid forward movements of the contrast medium which sometimes occur without any detectable changes of pressure gradiants. Nusbaum, Baum, Hedges, and Blakemore (1964) noted segmental contractions of the upper part of the thoracic duct in man, and Kinmonth and Taylor (1956) described spontaneous rhythmic contractions of the duct. These results prompted the present study.

MATERIAL AND METHODS

Eight male patients were studied during a surgical procedure performed to drain the thoracic duct lymph. Their ages ranged from 16 to 49 years. All were in chronic terminal renal insufficiency and were treated by regular haemodialysis. They had been dialysed 2 days prior to operation and were in good physical condition; in particular, there was no sign of cardiac failure and they were in a good nutritional state.

At 7.30 a.m. on the day of the operation 6 of the 8 patients received a premedication consisting of 0·25 mg. of atropine i.m. and 50 mg. of pethidine or 1 ml. of a mixture containing 2·5 mg. of droperidol and 0·0785 mg. of fentanyl per ml.* (*Table I*). Succinylcholine was injected to intubate the patients. After recovery from curarization the patients were allowed to breathe spontaneously in the anaesthetic circuit. Anaesthesia was maintained with a mixture of droperidol and fentanyl and with 2-bromo-2-chloro-1,1,1-trifluoroethane (halothane) and nitrous oxide in 5 cases. Nitrous oxide was not administered in 3 cases, 2 of which received supplements of fentanyl (*Table II*).

* Thalamonal.
† Patients showing spontaneous activity of the thoracic duct.

The patients were laid supine, the neck being slightly extended and the head rotated to the right. The thoracic duct was approached through a small incision made above the medial extremity of the clavicle. The lymphatic vessels and the veins were dissected sufficiently to allow easy puncture by a small needle. Manipulation of the lymphatic ducts was avoided as much as possible prior to pressure measurements. The location of the lymphovenous junction for each subject is given in *Table III*. Seven of the thoracic ducts ended in a single orifice in the venous system and one duct divided into two branches, both entering the subclavian vein (*Fig.* 1). Nevertheless, in all the cases there was a common channel which usually resulted from the junction of two or more lymphatic vessels (*Fig.* 2). This portion of the duct was punctured with a 25-gauge needle.* Pressures were recorded continuously for several minutes using an Elema or a Sanborn venous strain-gauge transducer. In 5 cases the venous pressure close to the lymphovenous junction was recorded simultaneously. After this procedure the thoracic duct was further dissected and cannulated in order to create a thoracic duct fistula.

RESULTS

Pressure curves in the thoracic duct showed cyclic oscillations with respiration. The highest values were registered during expiration and ranged from +2·6 mm. Hg to +22 mm. Hg, while the lowest occurred at the peak of inspiration and ranged from −5 mm. Hg to +17 mm. Hg (*Table IV*). Smaller oscillations up to 4 mm. Hg were synchronous with the heart-rate and are probably due to compression of the thoracic duct by the aorta in the thorax (*Fig.* 3). In 6 of our 8 patients no other pressure variations were observed. In 2 individuals superimposed pressure waves were seen which were independent of respiration and the pulse-rate. In the first patient they occurred every 5–7 seconds at the beginning of the recording (*Fig.* 4). A few seconds later their frequency had dropped to 4–5 per minute. In the second patient autonomic pressure waves were noted every 12–15 seconds. No contraction of the thoracic duct was observed in the neck throughout the procedure.

* Thalamonal, Janssen Pharmaceutica.

* Minicath 25 infusion set, Deseret.

The thoracic duct pressure varies with the venous pressure, higher values being recorded when the venous pressure is elevated (*Table IV*). However, various patterns can be observed, as was shown in 5 patients where the venous pressure and the thoracic duct pressure were measured simultaneously. In 2 cases the thoracic duct was continuously higher than the venous pressure (*Fig.* 5). One subject had a higher pressure in the thoracic duct than in the adjacent vein during expiration, but at the peak of inspiration the gradient was inverted and the difference between the two pressures amounted to as much as 7 mm. Hg (*Table IV*). Nevertheless, no venous reflux was noted in the thoracic duct, demonstrating that the valves at the lymphovenous junction were in this case perfectly competent with very low pressures. Finally, in the 2 patients where autonomous activity of the thoracic duct was found the pressure curves showed, besides the peaks of spontaneous contractile activity, higher values in the thoracic duct than in the vein during inspiration but lower values during some of the expiration movements (*Fig.* 4).

‡ Venous pressure and thoracic duct pressure were measured successively.

DISCUSSION

Several authors have cannulated the thoracic duct in the neck and determined maximum end-pressures. Shafiroff and Kau (1959) reported values ranging from 10 to 28 cm. saline, while Werner (1965) obtained figures which ranged from 6 to 28 cm. Dumont and Mulholland (1962) and Dumont, Clauss, Reed, and Tice (1963) measured pressures of 15–70 cm. saline in cirrhotic patients, 17–80 cm. in patients in cardiac failure, and 6–15 cm. in normal individuals. These figures do not necessarily represent the true values in the intact thoracic duct. Indeed, because of the cannulation the thoracic duct is disconnected from the venous system. The possible influences of venous pressure and the lymphovenous junction are therefore suppressed. Dumont and Mulholland (1962) found side-pressures of 4–6 cm. saline in the unopened duct. The higher values that we noted in some patients are probably due to an increased extracellular fluid volume 2 days after dialysis, as is suggested by the concomitant elevated venous pressure.

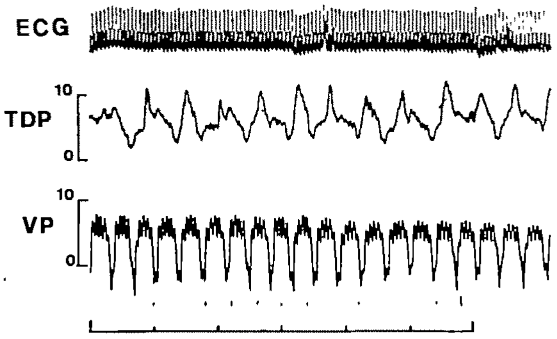

FIG. 4.—Electrocardiogram, thoracic duct pressure, and venous pressure (VP) tracings showing autonomous pressure waves in the thoracic duct which are independent of respiration and the heart-rate. Pressure values are given in mm. Hg. Time is divided in to units of 10 seconds.

Oscillations due to respiration and aortic percussion have been described in the pressure curves of dog thoracic ducts (Pflug and Calnan, 1968; Browse and others, 1969). No pressure variation due to intrinsic contraction of the duct was noted in the anaesthetized animals. On the contrary, we observed spontaneous contractile activity in 2 patients, thus confirming previous studies in man (Kinmonth and Taylor, 1956; Nusbaum and others, 1964; Edwards, Gough, Kinmonth, and Pierce, 1965). The question remains why only 2 of our 8 subjects showed autonomous activity of their thoracic duct. Anaesthesia could be incriminated; however, it can be seen from *Tables I* and *II* that there was no significant difference in the drugs which were administered to both groups of patients. Tilney and Murray (1967) measured end thoracic duct pressures in 2 waking patients and found no intrinsic activity in 1. From the present data pressure in the thoracic duct and eventual stretching of its muscular fibres do not seem to be determinant factors (*Table IV*). Increase in flow and variations in lymph biochemical content could be responsible factors; these are commonly seen after a meal. Our patients had all fasted for 12 hours before cannulation, but some surgeons administer milk or cream prior to operation in order to visualize the lymphatic vessels better. This could explain the fact that some authors (Sharpey-Schafer and Kinmonth, 1957; Edwards and others, 1965) observed constant waves of contractions. This possibility has not been explored in the present study.

From our data it is impossible to draw any conclusion on the exact nature of the autonomic activity of the thoracic duct: whether it is peristalsis or segmental contractions (Nusbaum and others, 1964; Edwards and others, 1965). It is not surprising that we did not observe any contraction in the neck. Kausel, Reeve, Stein, Alley, and Stranahan (1957) have shown that the amount of muscular fibres in the thoracic duct wall is reduced in the proximal part. The absence of any visible motor activity in the neck does not exclude the possibility of peristaltic waves in the thoracic portion of the duct.

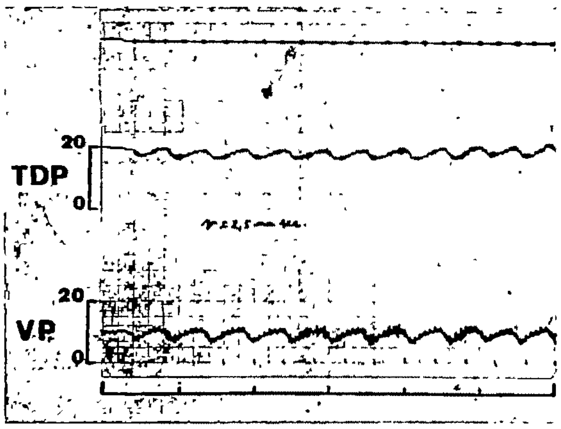

FIG 5.—Thoracic duct pressure and venous pressure tracings showing parallel variations. Units are as in *Fig*. 3.

Finally, blood reflux in the thoracic duct was seen in all except 2 cases. Pflug and Calnan (1968) stated that the valves at the lymphovenous junction close when the vein is distended by an increase in pressure. However, 1 patient in the present series had a negative duct pressure at the peak of inspiration while venous pressure remained positive. There was no blood reflux in this case. Consequently, it must be admitted that the valves were perfectly competent and that their closure occurred during the phase of lowest venous pressure. Further information is needed to elucidate the exact mechanism of the valves of the lymphovenous junction.

RENOVASCULAR HYPERTENSION: THE PLACE OF RENAL AUTOTRANSPLANTATION

By G. J. A. CLUNIE, L. C. J. HARTLEY, G. M. COLLINS, AND R. D. GORDON

DEPARTMENTS OF SURGERY AND MEDICINE, UNIVERSITY OF QUEENSLAND, PRINCESS ALEXANDRA HOSPITAL AND REPATRIATION GENERAL HOSPITAL, BRISBANE

SUMMARY

Six cases of hypertension due to renal artery stenosis were treated by renal autotransplantation, with cure in 4 cases and significant improvement in the other 2 cases. The procedure allows reconstruction of complex arterial lesions before revascularization, and should be preferred to nephrectomy whenever technically possible.

THE place of surgery in the management of hypertension of renovascular origin is now well established (Smith, Muller, and Beckwith, 1968; Foster, Oates, Rhamy, Klatte, Burko, and Michelakis, 1969; Buda, McAllister, and Sommers, 1970), but the standard surgical procedures of by-pass grafting or thrombo-endarterectomy have been performed almost entirely for lesions involving the main renal artery itself. Where the disease process has affected more distal renal vessels the usual alternative has been nephrectomy. The condition is frequently bilateral (Foster and others, 1969), and even when this is not the case primarily, the other kidney has usually been affected secondarily by hypertensive vascular disease. Thus, every effort should be made to avoid nephrectomy and to preserve functioning renal tissue. When disease of major vessels occurs beyond the bifurcation of the main renal artery, or where there are multiple arteries supplying the affected kidney, we believe that correction of the lesion can be achieved most satisfactorily by removal of the kidney, correction of the defect, and revascularization by anastomosis to the pelvic vessels of the same side. Five such cases have been treated by renal autotransplantation over a 3-year period, and the procedure has proved so satisfactory that it has been applied to a sixth patient suffering from a less complicated stenosis of the renal artery.

CASE REPORTS

Details of the 6 patients are summarized in *Table I.*

Table I.—SUMMARY OF THE DETAILS OF THE 6 CASES WITH RENOVASCULAR HYPERTENSION IN THE PRESENT SERIES

* The ratio of plasma renin measured in blood-samples taken simultaneously from both renal veins. A ratio of 1 : 5 was considered positive (Pawsey, Vandongen, and Gordon, 1971).

Case 1.—This patient has been reported in detail previously (Clunie, Murphy, Lukin, Nicoll, and Marsden, 1971).

C. N., a 25-year-old woman, presented in late 1968 with severe hypertension which was poorly controlled by medical therapy, and investigations revealed a functional stenosis of the right renal artery owing to fibromuscular hyperplasia. Both kidneys were explored through a right paramedian incision on 13 March, 1969. The stenosis of the right renal artery extended to the point of bifurcation near the hilum, and the lower pole of the kidney was supplied by a small accessory vessel. Direct reconstruction of the main artery was not considered possible because of the extent of the disease, and it was felt that the vessels beyond the bifurcation were too small to allow for adequate by-pass. Autotransplantation was therefore performed. The two renal arteries were divided, the larger at the point of bifurcation where it was macroscopically free from disease, and the renal vein was divided flush with the inferior vena cava. End-to-end anastomoses were carried out between the renal arteries and the cut ends of the mobilized right internal iliac artery, which had been divided just distal to its first division. The renal vein was anastomosed end to side to the common iliac vein. The ureter was gently freed in its middle third without disturbing its blood-supply, and was allowed to take up a redundant course without reimplantation. There was immediate control of the patient's hypertension, and the patient has remained normotensive without further therapy in the 4 years since operation.

Case 2.—K. D., a 25-year-old woman, was seen in early 1970 with severe hypertension, which was poorly controlled by medical therapy. Investigations revealed a functional stenosis at the bifurcation of the right renal artery as a result of fibromuscular hyperplasia. Autotransplantation was carried out on 5 Feb., 1970, the renal artery anastomosis in this case being carried out well into the hilum beyond the bifurcation of the artery because of the extent of the disease. The blood-pressure remained slightly elevated for 1 year following operation, but 3 years later it is within normal limits without therapy.

Case 3.—K. D., a 14-year-old boy, was found to have hypertension at a routine medical examination in 1970. The presence of a functional congenital stenosis at the origin of the left renal artery with a marked ureteric collateral supply was demonstrated (*Fig.* 1). On 10 June, 1970, direct reimplantation of the artery into the aorta was carried out, with an immediate reduction of the blood-pressure to normal. However, on 13 June there was a recrudescence of the hypertension, and an aortogram showed occlusion of the renal artery with marked collateral flow. At a re-exploration thrombus was found adherent to and extending beyond the bifurcation. Since there was some dilatation of the duplex right collecting system, it was felt important to preserve function in the left kidney of this young patient. Autotransplantation was therefore performed, the kidney in this instance being inverted since the vascular anastomosis lay most conveniently in this position. The blood-pressure was immediately controlled and has remained within normal limits in the 3 years since operation. An intravenous pyelogram taken 2 years after operation demonstrated satisfactory function without dilatation of the collecting system of the transplanted left kidney in spite of the unusual position (*Fig.* 2).

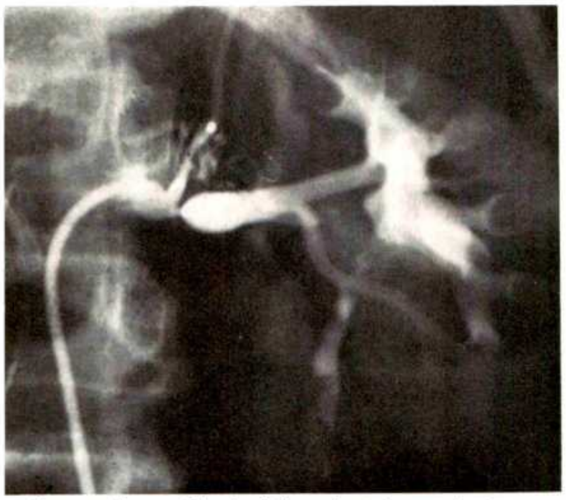

FIG. 1.—*Case* 3. Selective left renal arteriogram showing a congenital stenosis with post-stenotic dilatation.

Case 4.—H. H., a 59-year-old man, had been treated for mild hypertension for some years before his emergency admission with malignant hypertension in December, 1970. An intravenous pyelogram at that time showed no function of the right kidney and an aortogram revealed marked atheroma of the aorta with no apparent right renal artery. The serum creatinine was raised, and it was felt important to attempt to restore function to the right kidney, which was presumed to be viable and to be primarily responsible for the hypertension and its exacerbation. At exploration on 3 Feb., 1971, the right kidney was found to be atrophic, but there was a well-developed ureteric collateral circulation. The renal artery was completely occluded with recent thrombus up to and beyond its bifurcation. Autotransplantation was carried out with a satisfactory appearance of the kidney on revascularization. Hypertension has been easily controlled medically in the 2 years since operation, and the serum creatinine has returned to normal levels. An intravenous pyelogram and an isotope scan taken 1 year after operation showed satisfactory function in the transplanted kidney.

Case 5.—J. P., a 37-year-old woman, presented with poorly controlled hypertension due to an atheromatous plaque at the origin of the larger of two left renal arteries. Autotransplantation was carried out on 20 Jan., 1972, with good immediate control of hypertension. The blood-pressure gradually rose in the month after operation but is now easily controlled within normal limits by medical therapy.

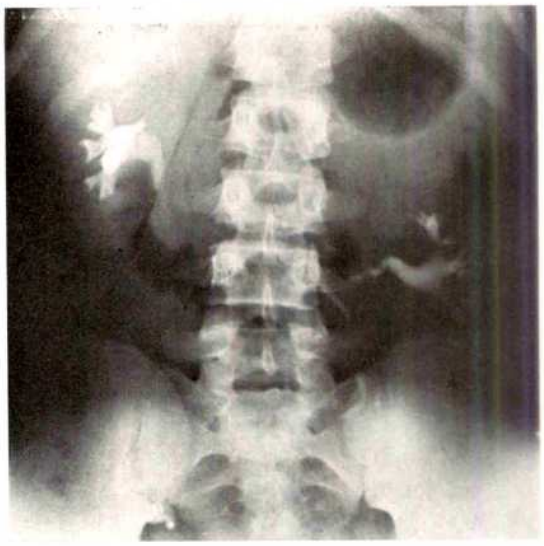

FIG. 2.—*Case* 3. Intravenous pyelogram taken 1 year post-operatively showing the redundant left ureter without proximal dilatation, and the duplex right collecting system.

Case 6.—G. H., a 50-year-old woman, presented with uncontrolled severe hypertension. Although the renal vein renin ratio was not significantly altered (*Table I*), divided renal function studies indicated a functional right renal artery stenosis. Arteriography demonstrated a fibromuscular hyperplasia of the right renal artery. This lesion would normally have been treated by by-pass grafting from the aorta, but autotransplantation was considered to be preferable in the light of experience with the previous cases. This procedure was performed on 19 Aug., 1971, with immediate and persisting control of the hypertension without further therapy in the 18 months since operation.

DISCUSSION

Autotransplantation of the kidney was first performed by Hardy (1963) for a complicated ureteral injury involving a single kidney, the shortened ureter being reimplanted into the bladder after vascular anastomosis in the pelvis. A similar case was reported by Marshall, Whitsell, McGovern, and Miscall (1966), and the technique has also been used in a patient with multiple ureteral tumours (Murphy, Staubitz, and Kenny, 1971). The procedure was first performed for the relief of renovascular hypertension by Woodruff, Doig, Donald, and Nolan in 1963, and later reported briefly in 1966 following descriptions of similar cases by

Marshall and others (1966) and Serrallach-Mila, Paravisini, Alberti, Mayol-Valls, Casellas, Torner-Soler, and Nolla-Panades (1966). Further single cases have been described since (Kuss, 1967; Kauffman, Alferez, and Vela Navarette, 1969; Whitsell, Goldsmith, and Nakamura, 1970; Clunie and others, 1971). Gil-Vernet, Caralps, Revert, Vidal, and Carretero (1969) reported 5 cases of renovascular hypertension treated in this fashion with excellent early results.

The operative technique used in the present 6 cases has been described previously (Clunie and others, 1971) and presents no difficulty for surgeons familiar with the operation of renal allotransplantation. In order to minimize ischaemic damage the kidneys were perfused with 200–300 ml. of solution C3 (Collins, Hartley, and Clunie, 1971) at 4° C. from a height of 1 m., the ureter being lightly clamped to prevent escape of this high potassium content solution into the general circulation. None of the operations in this series involved renal ischaemic intervals of greater than 40 minutes, and the degree of protection against ischaemic damage reported by such a cold flush in renal allotransplantation (Hartley, Collins, and Clunie, 1971) suggests that this simple procedure is preferable to the more complex continuous perfusion proposed by Belzer, Keaveny, Reed, and Pryor (1970) in reconstruction prior to renal autotransplantation. Reimplantation of the ureter into the bladder appears to be unnecessary in the correction of renal artery stenosis, and the ureter has simply been freed while retaining its normal blood-supply in all the reported cases. There has been no evidence of dilatation of the collecting system in the 6 cases reported here, although long-term follow-up is clearly necessary before such a complication can be excluded.

The procedure has proved so simple technically and so satisfactory in terms of immediate and late results in the control of hypertension that it may have a wider application. It allows reconstruction of extensive lesions involving the bifurcation of the renal artery, and there can be no doubt that it is preferable to nephrectomy whenever it is technically feasible. Revascularization with a by-pass vein autograft running from the aorta to the distal renal artery is at present the standard procedure for the relief of renovascular hypertension. In cases of atheroma where the aorta may well be extensively involved by the disease, surgery involving the aorta itself is clearly hazardous and we believe that autotransplantation offers significant advantages for this reason. With the increasing numbers of surgeons familiar with techniques of renal allotransplantation, we suggest that renal autotransplantation may in time come to be the procedure of choice in the surgical treatment of the majority of cases of renovascular hypertension.

Acknowledgements.—We wish to thank our colleagues for referral of patients and Dr. E. R. Jay of the Department of Radiology, Princess Alexandra Hospital, for the radiological investigations in these patients.

Now, to simplify treatment of pseudomonas urinary infections:

Pyopen

Penicillin safety and a published 76% success rate in 543 patients of varying renal status confirm Pyopen as a simple solution to a difficult problem.

For patients with normal kidneys 5G. 6 hourly is easily given using Pyopen infusion. For patients in renal failure or with impaired renal function a simple dosage of 2G. 8 hourly, by infusion or into the dialysate, is often sufficient.

Whether the kidneys are impaired or not, Pyopen provides the answer in pseudomonas urinary tract infections.

Adult dosage: Chronic urinary tract infection: 5G. 4–6 hourly
Acute uncomplicated infections: 2G. 6 hourly
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

You may not know about Avon sets, but you'll know someone who does.

If you're a newcomer to the medical profession there's a chance you may not know about us, after all, we haven't been around so long ourselves.
Well, very briefly, Avon Medicals manufacture a whole range of disposable products for transfusion and dialysis.

In many hospitals, all over the world, they're an accepted way of life.
Most of the more experienced people you work with will be able to tell you a good deal about us. And if they feel they'd like to know even more, drop us a line, and we'll get someone to call.

THE SURGICAL MANAGEMENT OF PRIMARY HEPATOCELLULAR CARCINOMA IN UGANDA

By N. W. HARRISON, D. DHRU, A. PRIMACK, D. BHANA, and S. K. KYALWAZI
THE SOLID TUMOUR CENTRE, UGANDA CANCER INSTITUTE, AND THE DEPARTMENT OF SURGERY, MAKERERE UNIVERSITY MEDICAL SCHOOL, KAMPALA

SUMMARY

Hepatocellular carcinoma is a common tumour in Uganda. Thirty-six of 120 patients with hepatoma admitted during a 2½-year period were submitted to surgery. Major hepatic resections were performed in 10 patients and a further 10 cases had placement of a hepatic artery catheter for regional infusion chemotherapy. In the surgically resected and regionally infused patients survival was improved compared with those receiving either systemic chemotherapy or no treatment. Hepatic resection offers a chance of cure for a small minority of patients with hepatoma, whilst regional chemotherapy via a directly placed arterial catheter at the time of exploratory laparotomy may benefit others and is being further evaluated by a controlled trial.

THE treatment of liver cancer by partial hepatic resection is not new (Keen, 1899). Only in recent years, however, has this approach been widely practised following advances in the understanding of hepatic anatomy and physiology (Hobsley, 1958; McDermott, Greenberger, Isselbacher, and Weber, 1963), together with improvements in anaesthesia and intensive care of patients. Treatment by partial hepatic resection appears to have met with limited success, whereas untreated hepatocellular carcinoma usually runs a rapidly fatal course (Foster, 1970).

In Uganda hepatocellular carcinoma is common; in a large part of the country it is the second most frequently encountered cancer in males (Davies, Knoweldon, and Wilson, 1965). The following report is based on patients with this tumour who were treated surgically at Mulago Hospital during a 2½-year period since the opening of the Uganda Cancer Institute in 1969.

MATERIAL AND METHODS

One hundred and twenty patients with primary hepatocellular carcinoma were admitted to the Uganda Cancer Institute between August, 1969, and March, 1972. On admission all the patients were evaluated from their history, physical examination, chest radiographs, radiographs of painful bones, complete blood-count, liver-function studies, blood-clotting studies, blood-urea, total proteins and protein electrophoresis, α-fetoprotein, and liver scan.

After evaluation, 36 patients who were thought to have potentially resectable lesions were submitted to laparotomy. Preoperative coeliac axis arteriography was carried out in the majority of this group. There were 24 males and 12 females with a mean age of 38 years (range 16–65 years). The diagnosis of hepatocellular carcinoma was confirmed histologically in all but 2 patients who have been excluded from further discussion. The subsequent management of the remaining 34 patient is shown in *Table I*. Partial hepatic resection was carried out in 10 patients. Ten patients with unresectable tumours had a catheter placed in the hepatic artery for subsequent infusion with anti-tumour drugs. The other patients were treated by either systemic chemotherapy or a placebo.

OPERATIVE TECHNIQUES

The techniques of major hepatic resection and hepatic artery catheterization are well documented (McDermott and Ottinger, 1966; Pack and Islami, 1970; Watkins, Khazei, and Nahra, 1970). Those used in the present series are briefly summarized.

Table I.—MANAGEMENT OF PATIENTS WITH HEPATOCELLULAR CARCINOMA WHO WERE ADMITTED TO THE UGANDA CANCER INSTITUTE BETWEEN AUGUST, 1969, AND MARCH, 1972

	No. of Patients
Patients admitted with hepatocellular carcinoma	120
Patients submitted to surgery	36
Subsequent treatment of 34 surgical patients:—	
Partial hepatic resection	10
Hepatic artery catheter placement	10
Systemic chemotherapy	7
None	7

1. Partial Hepatic Resection.—Left hepatic lobectomy was carried out through an upper abdominal incision. The left lobe of the liver was mobilized and the left branches of the hepatic artery, portal vein, and hepatic duct were ligated in the porta hepatis. The left hepatic vein and sometimes the middle hepatic vein were ligated and the liver was resected through a line joining the inferior vena cava superiorly and the gall-bladder fossa inferiorly. For division of the liver substance cutting diathermy or finger dissection was used with additional ligature of vessels as necessary. The cut surfaces of the liver were approximated and, where possible, re-peritonealized by utilizing the falciform ligament.

For right hepatic lobectomy an extended lobectomy or a thoraco-abdominal approach was used. An upper abdominal incision was made initially to assess the extent of the tumour, and if deemed resectable the incision was extended into the chest through the eighth or seventh intercostal space and the diaphragm was incised radially to the inferior vena cava. After mobilization of the right lobe and division of the cystic duct, right hepatic duct, and right hepatic vessels, liver resection was carried out in the line of the gall-bladder fossa in a right lobectomy or just medial to the falciform ligament in an extended resection.

2. Hepatic Artery Catheterization.—A careful dissection was made to expose and identify the common hepatic artery and its right and left branches and the gastroduodenal artery. A fine Teflon catheter (external diameter 1·0 mm.) was placed in the hepatic artery towards the coelic axis via an arteriotomy in the gastroduodenal vessel. The extent of perfusion was checked by injecting fluorescein through the catheter and observing the distribution of the dye under ultra-violet light. Adjustments were made in the position of the catheter until an optimum distribution was obtained. On occasions when it was not possible to identify the gastroduodenal artery the catheter was inserted into the right gastro-epiploic vessel. In 1 case where the anatomical variation of a replaced left hepatic artery was encountered the splenic artery was utilized. Infusion was carried out by gravity or, more recently, by means of a Watkins Chrono-Fusor (U.S. Catheter & Instrument Corp.) which delivers 5 ml. of infusate in 24 hours.

RESULTS

Table II shows the duration of symptoms before diagnosis and survival in the 34 patients who underwent surgical exploration. The median duration of symptoms was similar in all the groups. The median survival of the patients whose tumour was resected was 7 months and that of the other groups between 1 and 1·5 months. However, of the 10 patients who underwent hepatic artery catheterization only 6 actually received chemotherapy and in these patients the median survival was 6 months.

Table II.—LENGTH OF HISTORY BEFORE DIAGNOSIS AND DURATION OF SURVIVAL AFTER SURGICAL EXPLORATION

TREATMENT	NO. OF PATIENTS	LENGTH OF HISTORY (mth.)		NO. OF PATIENTS STILL ALIVE	SURVIVAL AFTER EXPLORATION (mth.)	
		Median	Range		Median	Range
Resection	10	3·0	1–7	3	7·0	0–34
Hepatic artery catheterization		2·5	1–24			
a. All patients	10			1	1·5	0–22
b. Patients who received chemotherapy	6			1	6·0	1·5–22
Systemic chemotherapy	7	2·0	1–9	1	1·0	0·25–4
None	7	3·0	0·5–12	1	1·0	0–11

Table III.—DETAILS OF THE 10 PATIENTS WHO UNDERWENT HEPATIC RESECTION

AGE AND SEX	SITE OF LESION	PROCEDURE	COMPLICATIONS	RESULT
18 M.	Right lobe; superficial nodule in the left lobe	Right lobectomy; wedge resection of the nodule on the left side	Jaundice; pleural effusion	Alive 29 months after surgery
53 M.	Right lobe	Right extended lobectomy	—	Died on first postoperative day
59 M.	Right lobe	Right lobectomy	—	Operative death
31 M.	Right lobe	Right lobectomy; right extended lobectomy 4 months after first operation	Subphrenic abscess	Died 18 months after surgery
37 M.	Right lobe	Right lobectomy	Pleural effusion; subphrenic abscess	Died 4 months after surgery
40 F.	Left lobe	Left lobectomy	Jaundice; pleural effusion	Died 10 months after surgery
45 M.	Left lobe	Left lobectomy	Portal hypertension and haematemesis 2 years after lobectomy; gastric transection performed	Alive 34 months after surgery
28 M.	Left lobe; two nodules in the right lobe	Left lobectomy; wedge resection of one nodule in the right lobe	Jaundice; chest infection; wound infection	Died 6 months after surgery
22 F.	Right lobe	Right lobectomy	Hepatic failure	Died 2 weeks after surgery
33 M.	Caudate lobe	Caudate lobectomy	—	Alive 9 months after surgery

The main features of the 10 patients who underwent resection are summarized in *Table III*. The right lobe was resected in 6 patients and the left in 3. The tumour was confined to the caudate lobe in 1 patient. Two patients had apparently isolated tumour nodules in the remaining lobe, and these were removed by wedge resection. There were 2 operative deaths and a third patient died in the early postoperative period. Three patients are still alive—9, 29, and 34 months after surgery.

Ten patients who were found at laparotomy to have unresectable tumours had placement of a catheter into the hepatic artery (*Table IV*). There were 3 deaths in the early postoperative period. Two other patients did not receive chemotherapy by this route as the catheter was found to be unsatisfactory, although 1 subsequently received treatment by a percutaneously placed catheter. The percutaneous method was used to give further courses of chemotherapy in 3 patients after the operatively placed catheter blocked. Catheter position and patency were maintained for up to 1 month with a mean of 13 days.

Thus, 6 patients received intra-arterial chemotherapy in the form of dichloromethotrexate (DCM) at a dose of 10 mg. per m.^{2} for 7–10 days according to toxicity.

Table IV.—DETAILS OF THE 10 PATIENTS WHO UNDERWENT HEPATIC ARTERY CATHETERIZATIONS

AGE AND SEX	PLACEMENT OF CATHETER	NO. OF COURSES OF CHEMOTHERAPY	COMPLICATIONS	RESULT
40 M.	Via right gastro-epiploic artery	0	—	Died on third post-operative day
26 F.	Via gastroduodenal artery	2	Diarrhoea; catheter removed after 3 weeks; subsequent percutaneous catheterization and infusion	Died 22 months after surgery
24 M.	Via right gastro-epiploic artery	0	Diarrhoea; catheter removed after 5 days as distribution unsatisfactory	Died 5 weeks after surgery
50 M.	Via splenic artery	0	Ascites; oliguria	Died on third post-operative day
26 F.	Via gastroduodenal artery	0	Acute tubular necrosis	Died on first post-operative day
40 M.	Via gastroduodenal artery	3	Catheter removed after 9 days because of infection; subsequent percutaneous catheterization and infusion (× 2); left subphrenic abscess	Died 8½ months after surgery
27 M.	Via gastroduodenal artery	3	Catheter removed after 1 month; subsequent percutaneous catheterization and infusion (× 2)	Died 7 months after surgery
52 M.	Via gastroduodenal artery	1	Catheter removed after 2 weeks; developed pulmonary metastases	Died 6 weeks after surgery
28 M.	Via right gastro-epiploic artery	3	Catheter removed after 10 days as not in position; subsequent percutaneous catheterization and infusion (× 3)	Died 5 months after surgery
26 F.	Via gastroduodenal artery	1	Catheter removed after 8 days as not in position	Alive 6 weeks after surgery

Of the remaining 14 patients with unresectable tumours, 7 received systemic chemotherapy in the form of DCM,* CCNU,† or a combination of BCNU,‡ and 5FU,§ and 7 received no treatment. There were no responses in the sytemically treated group and no increase in survival compared with untreated patients (*Table II*).

DISCUSSION

In assessing the results of treatment in hepatocellular carcinoma the survival after surgical exploration may be compared with the natural history of the disease from diagnosis to death in untreated patients (*Table II*). In the present series patients whose tumour was resected survived considerably longer than those receiving no treatment (median, 7 months and 1 month respectively), as did those who received intra-arterial chemotherapy (median, 6 months). Since no patient who succumbed within 1 month of catheter placement received chemotherapy, early postoperative deaths are automatically excluded from this group. These figures suggest a favourable response to surgery and regional infusion chemotherapy. This is in contrast to systemic chemotherapy which has, so far, proved unsuccessful (Chan, 1967; Geddes and Folkson, 1970; Vogel, Adamson, Devita, Johns, and Kyalwazi, 1972). In Chan's (1967) series of 108 cases of hepatoma the patients who were treated surgically had a mean survival of 22·5 months compared with 0·5 month for those who were untreated. Admittedly these figures, as in the present series, are biased in that patients who underwent resection had more limited disease than the untreated patients or those receiving other forms of treatment. However, results expressed in this way fail to emphasize patients who are still alive. *Fig.* 1 is a life-table analysis for the 34 patients who underwent surgical exploration in the present series and clearly shows the superior results of surgical resection.

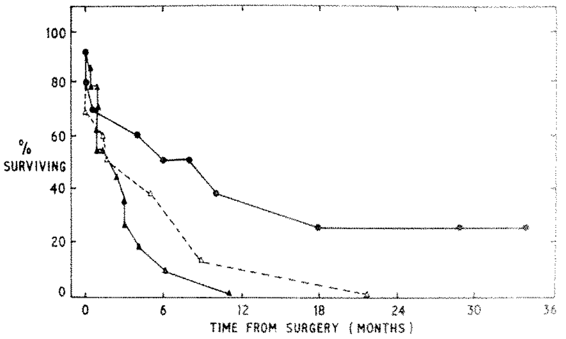

FIG. 1.—Survival curves following surgical exploration. Type of treatment: ●——●, resection, △ - - - -△, catheterization; ▲——▲, systemic chemotherapy or none.

§ NSC 19893; 5-fluorouracil.

Foster (1970) reviewed the surgical treatment of primary liver cancer in 227 patients from 35 different sources and calculated a mean 5-year survival of 14 per cent in patients who underwent hepatic resection. There is thus evidence to encourage an aggressive surgical approach to this tumour.

Major hepatic resection carries a considerable mortality. In Foster's (1970) review of hepatoma series reported within the past 10 years there was an overall mortality of 24 per cent. The operative mortality in the present series was 30 per cent. In an attempt to reduce the surgical mortality the pre- and postoperative management of our patients now follows a careful protocol. All the patients selected for surgical exploration are potential candidates for a major resection and are prepared as such. Intravenous fluids and measurement of the urine output are commenced the day before operation. A minimum of 10 units of blood must be available. A central venous pressure line is established and the central venous pressure is closely monitored during and after surgery. A urine output exceeding 50 ml. per hour for the first 48 hours is aimed at. Metabolic disturbances which follow major hepatic resections (McDermott and others, 1963; McDermott and Ottinger, 1966) should be anticipated. Thus, albumin levels which tend to fall progressively during the first 7–10 days and may result in significant shifts in body fluids can be maintained by giving albumin intravenously in the following arbitrary amounts: 75 and 50 g. in the first and second 24 hours after surgery, and 25 g. daily for the subsequent 4–7 days. Hypoglycaemia is another potential, if more theoretical, problem and can be prevented by incorporating 10 per cent glucose solution into the postoperative fluid régime. Intensive physiotherapy and early mobilization are directed at reducing the risks of respiratory and other complications.

Subphrenic abscess is a particular hazard of right hepatic lobectomy and 2 patients in the present series developed abscesses, 1 patient requiring drainage on three occasions. The importance of establishing and maintaining adequate drainage of the subdiaphragmatic space after resection is illustrated by a case reported by Lloyd-Davies and Angell (1958) in which the subdiaphragmatic drain was not finally removed until 7 months after surgery.

The high mortality of hepatic resection and the demanding postoperative care make it essential to select patients carefully for surgery. In Uganda, where medical resources are limited and overburdened, this is even more pertinent. Ideally only patients with localized disease which is potentially curable by resection should be submitted to surgery. A staging system (*Table V*) has recently been devised (Vogel and Linsell, 1972) and its prognostic value is currently being evaluated in a prospective study. On this system only Stage IA – lesions (or IA +, if in the left lobe) are considered resectable. The corollary to more strictly defined criteria for selection is fewer patients undergoing surgery. In the present series the 36 patients submitted to laparotomy represent only 28 per cent of the patients presenting with hepatoma. However, though fewer patients may be explored it is hoped that more of these will have operable tumours.

Although systemic chemotherapy has not met with success, regional perfusion has been more encouraging (Chan, 1967; Provan, Stokes, and Edwards, 1968; Geddes and Folkson, 1970; Vogel and others, 1972). The life-table analysis of the present series (*Fig.* 1) also suggests a favourable response. In addition to any improvement in survival, regional chemotherapy often produced relief of symptoms. The operative procedure of catheter placement is a relatively minor procedure although enlargement of the liver by tumour may distort the anatomy and make dissection of the coeliac axis difficult. The postoperative mortality in patients having catheter placement was similar to that for resection, but the results of more recently performed catheterizations suggest that a much lower mortality can be anticipated for this procedure. Hepatic artery catheters have been placed only in patients found at surgery to have a localized but unresectable tumour. Selection was initially on an arbitrary basis but a controlled trial is now in progress in which patients are randomized on the basis of the stage of the disease at the time of surgery into receiving either catheter chemotherapy or no chemotherapy. If the controlled results substantiate the trends of the present series it will then be possible to offer alternative treatment to those patients who, in spite of careful selection, are found at surgery to be inoperable. Percutaneous catheter placement via the femoral artery is a useful alternative to operative placement, but is less accurate and reliable (Watkins and others, 1970).

Table V.—FUNCTIONAL/ANATOMICAL STAGING. OF HEPATOCELLULAR CARCINOMA

FUNCTIONAL (Assessed on General Condition and Liver-function Studies)	ANATOMICAL (Extent of Tumour)
I = Good	A = One lobe
II = Moderate	B = More than one lobe
III = Poor	C = Metastatic

In addition the presence or absence of cirrhosis is denoted by the symbols + and –. The stage is modified if necessary at surgical exploration.

It has been estimated that only 1 per cent of all patients with hepatocellular carcinoma may be cured by surgery (Vogel and Linsell, 1972). In the present series 10 patients (8·5 per cent) had resectable disease of whom 3 are still alive, although only 1 appears to be tumour free. The majority of patients have advanced disease by the time the diagnosis has been made; surgery has nothing to offer these patients. The discovery of biochemical abnormalities in liver cancer, such as α-fetoprotein, proline hydroxylase, and fibrinogen (McIntire, Vogel, Princler, and Patel, 1972; Alpidovsky, Vogel, Sadikali, and Primack, 1973; Keiser, Vogel, and Sadikali, 1973), may make it possible to detect the tumour earlier, at a time when more patients have resectable disease. Similarly, biochemical markers may help to detect relapse and enable re-exploration or the initiation of further therapy at an opportune moment.

CONCLUSIONS

Although it must be accepted that the treatment of hepatocellular carcinoma is far from satisfactory, surgery continues to play a small but significant rôle in the management. Since this tumour is common in

Uganda controlled clinical trials with large numbers of patients are now possible. There is hope that in this way further progress will be made in rationalizing the treatment of this challenging tumour.

Acknowledgements.—The study of hepatoma is a team effort and we gratefully acknowledge the contribution of many others to this project: in particular, Dr. Margaret Dodson (Anaesthetics), Dr. C. L. Vogel and Dr. J. L. Ziegler (Uganda Cancer Institute), Dr. D. Truscott and Dr. P. Briers (Radiology), and Dr. B. Cady (Lahey Clinic Foundation, Boston, U.S.A.). Our thanks are also due to the sisters and nursing staff of the Intensive Care Unit, Mulago Hospital, and of the Uganda Cancer Institute.

THE MANAGEMENT OF CARCINOMA OF THE BREAST BY RADICAL SUPERVOLTAGE RADIATION

BY PAUL STRICKLAND
REGIONAL RADIOTHERAPY CENTRE, MOUNT VERNON HOSPITAL, NORTHWOOD, MIDDLESEX

SUMMARY

A high-dose radiation technique for the management of inoperable carcinoma of breast is described, and the results of the treatment of 385 consecutive cases are outlined. The morbidity is considerable. Supervoltage radiotherapy can usually arrest the primary disease and cure a substantial number of cases. The quality of life enjoyed by the survivors is good.

'THE best treatment for a patient with early cancer of the breast is not known' (Editorial, 1969). Four years later most surgeons would still agree with this statement, though the next decade may do something to sharpen our ideas. In any unselected series of patients with operable breast cancer the same salvage rate is achieved by a variety of surgical techniques, ranging from restricted removal to ultraradical resection.

The present paper describes the treatment of 385 personally observed breast cancers which were deemed to be too advanced for surgical cure or were unsuitable for surgery on general grounds.

HISTORY

Breast cancer has been treated by ionizing radiation since the pioneer days of radiotherapy. Early published accounts were few and unreliable; moreover, the classic Halsted dissection so dominated the clinical scene that radiotherapists saw only the hopeless stages of the disease. It is thus not surprising that the early impressions of radiotherapy were discouraging. In addition, methods of dose estimation were primitive, so if an occasional good tumour response was obtained it was impossible to say what order of dose had achieved it.

It was left to Geoffrey Keynes to show that if enough radium were used, the response in selected cases was excellent. Keynes carried out meticulous radium implants 'to the breast itself, beneath the pectoral muscles, in the axilla, on the costocoracoid membrane, above the clavicle and in the upper three or four intercostal spaces' (Keynes, 1930, 1932, 1937), though he doubted the value of these last needles. The radiation dose received by the operator is not recorded, but it must have been high, bearing in mind that up to 100 mg. of radium were used in needles of 1–3 mg. strength per needle.

The art of Keynes's technique was that the whole volume of tissue likely to be involved in the disease was implanted. A typical Keynes-style implant is shown in *Fig.* 1. A degree of radiation soft-tissue damage had to be accepted, but Keynes showed that many breast cancers responded well if the dose were right. This justified the later use of high-energy X-ray beams which have the enormous advantage of not irradiating the surgeon or the theatre and ward staff.

Until about 20 years ago so-called orthovoltage X-ray therapy with beams generated at about 250 kV. was the standard radiotherapy treatment. The main dose fell on the patient's skin which, even at moderate levels, reacted to the point of moist desquamation. This often occurred at a dose level below that known to be cancericidal and was the practical limiting factor in treatment, that is, irradiation had perforce to be stopped at a dose known to be ineffective for most breast cancers.

Supervoltage X-ray therapy uses beams generated at more than a million volts. These beams have the great advantage of sparing the skin and because of the laws of physics that govern them, the maximum radiation dose occurs at 0·5–2·0 cm. below the skin. Skin desquamation is therefore no longer the forced end-point of treatment and a higher and therefore more effective dose can be given to the depths of the breast substance and to the apex of the axilla. The brunt of the dose falls in the soft tissues and the problems caused by this are deferred.

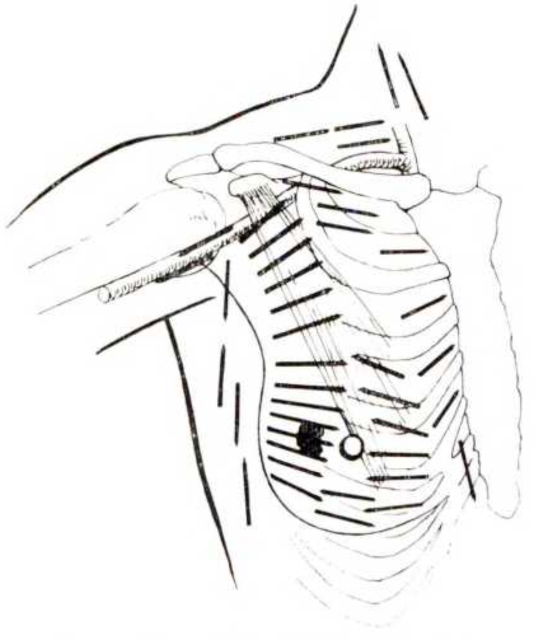

FIG. 1.—A Keynes-style radium implant to a breast.

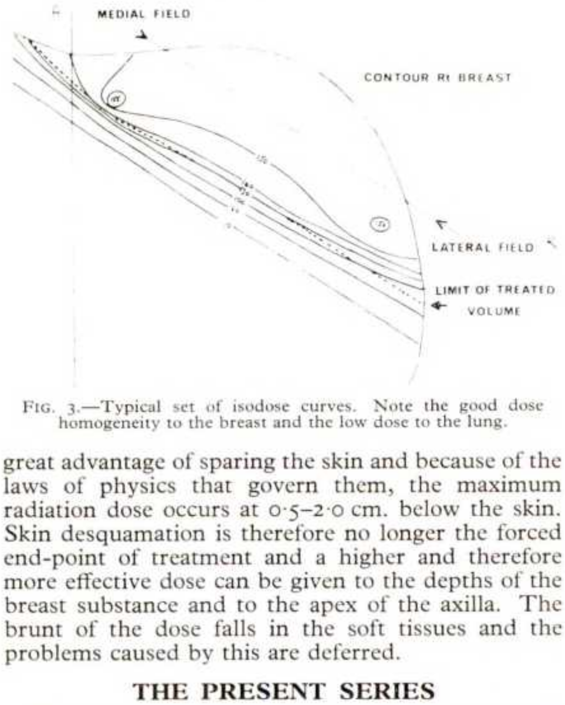

FIG. 3.—Typical set of isodose curves. Note the good dose homogeneity to the breast and the low dose to the lung.

THE PRESENT SERIES

Whenever high-dose radiation is used agreement on a management plan with the group of referring surgeons must be sought in advance. Routine mastectomy, whether 'toilet' or otherwise, becomes a hazardous procedure because of the risk of delayed wound healing and tissue sloughing. It has been the author's good fortune to work with colleagues who accepted this view.

Between 1955 and 1966, 429 consecutive cases of carcinoma of the breast were referred with a view to radical radiotherapy as the definitive treatment. Of these, 44 had metastases beyond the lymph-drainage area when first seen and were therefore rejected, leaving a group of 385 cases on which the present report is based. The TNM Classification of Malignant Tumours (1968) was used retrospectively; there were 86 T.2 cases, 275 T.3 cases, and 24 T.4 cases. If this is translated into conventional staging, then there were no Stage I cases, 56 stage II cases (27 T.2 N.1a and 29 T.2 N1b), with all the rest Stage III and beyond. In ordinary clinical terms most cases were large primary growths with substantial skin involvement and ulceration and evidence of fixation to underlying muscle. Supraclavicular nodes were occasionally palpable. Every case was histologically proved. In no case was later mastectomy performed.

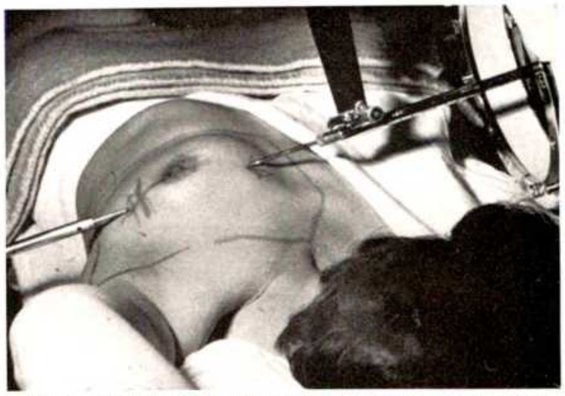

FIG. 2.—Medial breast field with a patient in the treatment position.

TECHNIQUE

The X-ray beam deriving from a 4 million volt Metropolitan Vickers linear accelerator was used in all the cases. The breast and its lymph-drainage areas were included within three X-ray fields. Two of the three fields were truly opposing and covered the breast, the internal mammary chain on the affected side, and the axillary contents. A third small field covered the supraclavicular fossa and that part of the axillary apex not adequately covered by the opposing field pair.

Radiation homogeneity is essential if underdosage or high-dose effects are to be avoided, so the opposing fields must be accurately opposing. This was achieved by tilting the patient and maintaining the angle of tilt constant for all three fields. The lateral beam was brought in 15° above the horizontal and the medial 15° below the horizontal. A high degree of accuracy was vital, and front and back pointers helped to secure it (*Fig.* 2). A typical set of isodose curves is shown in *Fig.* 3; it will be noted that dose homogeneity to the whole breast volume is good and that the dose to the lung parenchyma is low.

A tumour dose to the whole breast of 6500–7000 rad was given by daily fractions (5 per week) in an overall time of 35–42 days. During the same time an applied dose of 6500 rad was given to the third field, shielding the trachea and shoulder-joint.

Towards the end of the treatment course, retrosternal soreness was usual and was sometimes severe. Some degree of oesophagitis was invariable and gave moderate dysphagia that could take several weeks to settle down. Skin reactions were usually trivial but the skin was sometimes moist in the hollow of the axilla and beneath a pendulous breast. These complications resolved rapidly.

RESULTS

Typical cases submitted can be seen in *Figs.* 4 and 5. The results of the treatment technique described are shown in *Table I*. The 'disease-free' rate of 34 per cent for the whole group is acceptable and it is not surprising that 48 per cent of the mixed T.2 group survived. Only a single T.4 case survived for 5 years.

In *Table II* the T.4 cases have been excluded and the results for the T.2 and T.3 groups are summarized. The survival of 89 out of 275 T.3 cases (32 per cent) happens by chance to be close to the survival of the whole series.

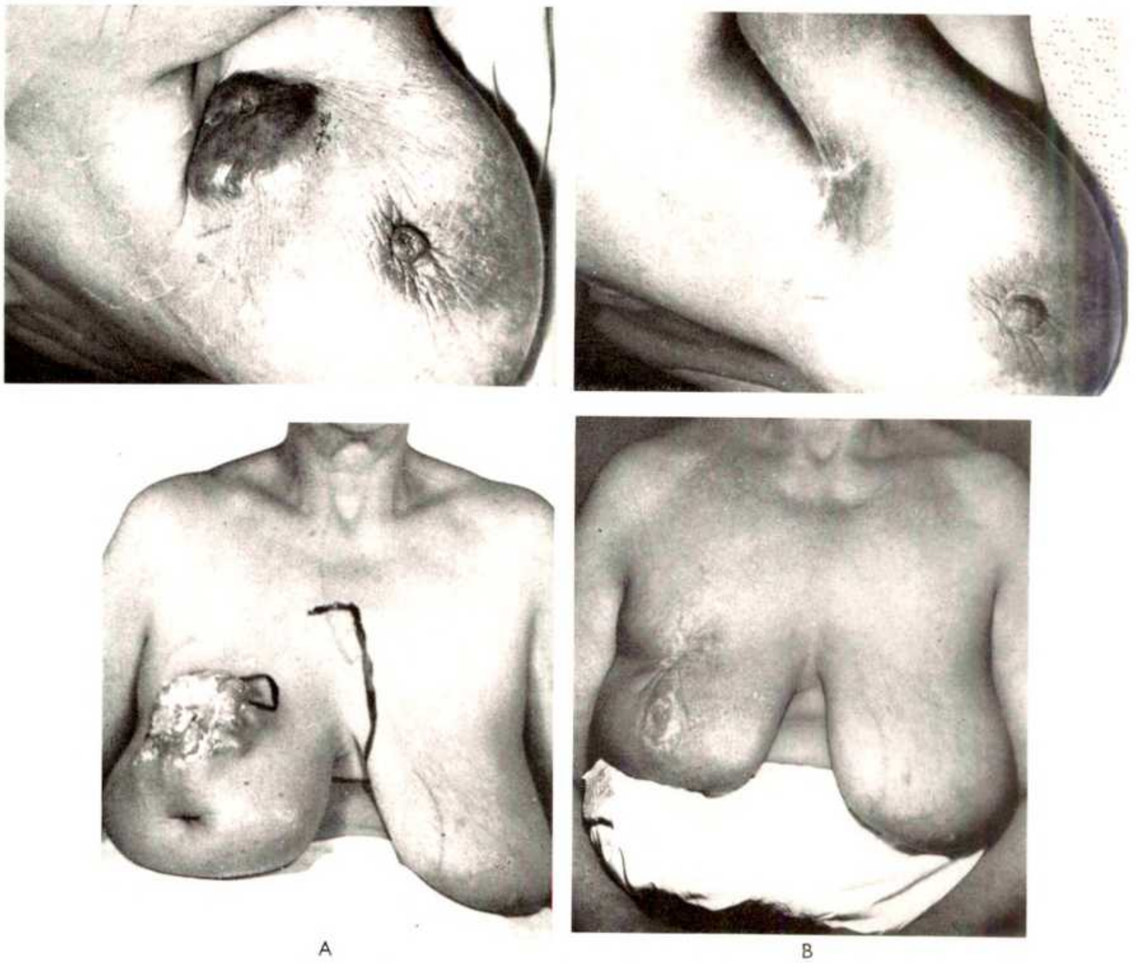

FIG. 4.—A, Typical advanced cases. B, The results 12 years later.

MORBIDITY OF TREATMENT

The price paid by the survivors is considerable. Soft-tissue deformity due to fibrosis is very common and may be severe. It starts within 6 months of completing the course of radiation and is progressive for 2 or 3 years. Fortunately it is usually painless even when the appearance is grotesque (*Figs.* 6, 7). In perhaps 20 per cent of this group the residual 'breast' is plastered on to the rib cage so firmly that when the remnant is grasped and moved, it is the patient who is rocked! The presence of large fibrous lumps and iron-hard plaques in and below the axilla closely mimic carcinoma and confuse the uninitiated.

Worrying inflammatory episodes may be seen in the irradiated breast for many years. As a result of minor trauma the breast becomes pink and painful, resembling one type of erysipelas which was so familiar to an earlier generation of surgeons. The condition settles down in a few weeks, despite rather than as a result of antibiotics, but it may recur several times. When there is no history of trauma or infection, and no constitutional disturbance or pyrexia—a common pattern—the signs are indistinguishable from massive local recurrence. In such circumstances, time must be allowed to decide.

T.2 N.1b	29	16	
T.2 N.2	27	11	
T.2 N.3	3	0	
T.3 N.1a T.3 N.1b	187	76	32 per cent
T.3 N.2	71	11	
T.3 N.3	17	2	
T.4 N.1a	—	—	
T.4 N.1b	—	—	
T.4 N.2 T.4 N.3	24	1	
Total	385	131	(34 per cent)

There is no correlation between breast deformity and local pain and stiffness. Acute local pain usually indicates the presence of rib fractures due to avascular bone necrosis, which in turn is due to post-irradiation endarteritis obliterans. Many ribs may sometimes be seen to be fractured as a chance finding on radiographic examination and it is as well not to inform the patient of this. Callus formation after fracture is usually good and healing is uneventful but some fractures produce no callus at all. In this series the sternum was fractured on two occasions and both cases healed uneventfully.

Late skin damage is usually trivial and is totally overshadowed by the soft-tissue changes. Lung damage is slight because only small volumes of lung parenchyma are caught in the X-ray beams. A few

Table II.—SURVIVAL OF PATIENTS WITH STAGE T.2 AND T.3 CARCINOMA OF THE BREAST AFTER HIGH-DOSE RADIATION

STAGE	NO. OF CASES	'DISEASE-FREE' AT 5 YEARS	PERCENTAGE 'DISEASE-FREE' AT 5 YEARS

T.3	275	89	32
Total	361	130	36

patients develop dyspnoea out of proportion to the extent of pleural thickening and pulmonary fibrosis may be shown on chest radiographs, but respiratory cripples as a result of treatment have not occurred. No satisfactory explanation of this disproportionate dyspnoea can be found. Some degree of lymphoedema is common but it is rarely severe; it is commonest in a plump arm and where the axilla has been extensively infiltrated. Its appearance several years after radiation often indicates active carcinoma though a symptomless axillary vein thrombosis may give an identical picture. Brachial neuritis is occasionally encountered and is quite resistant to treatment.

DISCUSSION

The justification for radical high-dose irradiation must lie in the balance between the cure rate and the damage done to the patient in securing it, which means that subjective judgement is inevitable. The patient's own opinions are important here. Most of these women would much sooner possess a small contracted breast than no breast at all, particularly if they have no pain in it. Therefore the aesthetic argument as judged by 'patient satisfaction' answers itself.

The disease-free rate of 36 per cent for all T.2 and T.3 cases is open to all the usual legitimate objections to 5-year survival figures in breast carcinoma; this figure certainly drops to 21 per cent at 10 years (51 survivors out of 245 cases treated for the years 1955–61 inclusive), which is still not negligible. What is often forgotten is the *quality* of survival, rather than its duration.

This group of women has advanced disease; those who do not perish from metastatic disease have an excellent quality of life, without discharge and fungation or any of the other signs of uncontrollable breast cancer. Their survival without mastectomy and their almost invariable knowledge of the true diagnosis add an extra dimension of sweetness to life that cannot be quantified. To hear such patients explaining this is a moving experience.

What high-dose radiation can almost always achieve is the *local* eradication of the majority of breast cancers, or at least their local arrest. During the first 5 years after treatment roughly one-half of the group die of distant metastases but without return of the primary growth. During the next 5 years a further number succumbs but the primary cancer, once arrested, does not recur.

In an important but neglected paper by Ross (1939) simple mastectomy was performed routinely in 50 patients after the radium implantation of their breast carcinoma by Keynes's technique. Careful histological analysis showed that 'about half of them contained carcinoma cells, the remainder showed only dense scar tissue and we noted that among the latter group there were several cases in which a heavy dose of radium had been used'. The radiation dose received by these tumours was not known accurately but it must have been substantially less than the doses quoted in the present report. As there is a roughly linear relationship between applied dose and tumour-cell death, it is not surprising that our local recurrence rate after the high doses used is so low. It is part of our deliberate policy that the breast should be conserved so we have to rely on the absence of macroscopic evidence of local recurrence over the course of time. Opportunities for autopsy have been few but these have usually failed to show viable carcinoma cells; even when clumps of apparently healthy cancer cells are found they are walled off in dense layers of mature fibroblasts and their ability to 'escape' is uncertain.

The high-dose technique described (about 6500 rad in 5–6 weeks) cannot be further increased without producing an unacceptable morbidity. Unfortunately breast cancer is a disease of limited radiosensitivity and there is no reliable way of assessing in advance those that will respond to lower doses. Thus, all the cases selected need a high dose and will therefore share in the morbidity.

After 17 years' experience of this technique it is clear that certain types of case which were formerly included should not be included in the future. A palpable supraclavicular node is nearly always a death sentence so that such patients should be excluded from 6 weeks' arduous radiation and treated more simply. The same is true if the primary cancer is large—10 cm. or more in diameter—since very few patients in this group survive even 5 years. If these two groups of cases are excluded in future, survival figures will be more encouraging.

Mastectomy is still carried out on many women who would be far better off left to the radiotherapist. Operation is contra-indicated not merely because it may disseminate tumour but because it is irrelevant, for example, in the management of sizeable inner-quadrant primary tumours, or large primary tumours anywhere, or where there is marked skin involvement or any degree of fixation to muscle. This is equally true when the topmost axillary nodes are hard or semi-fixed. The surgical management of breast cancer will rightly remain the mainstay of treatment for many years ahead, particularly if it is used more selectively than in the past.

Radical radiation provides a good alternative treatment in many cases and is the treatment of choice in many more. Low-dose radiation techniques achieve next to nothing, apart from the simple palliation of bleeding and fungating masses. High-dose radiation is an ordeal for most patients and carries a high rate of morbidity; for these reasons alone patients should be selected as rigidly for it as our imperfect criteria permit.

Acknowledgements.—I am indebted to the group of surgeons who have referred cases to me over many years and to Dr. Max Hulbert, St. Mary's Hospital, Paddington, for helpful criticism. I am obliged to Mr. R. N. Blake for the illustrations, Mrs. C. Hardstaff for secretarial help, and the staff of the Regional Radiotherapy Centre for the 100 per cent follow-up.

BLADDER FUNCTION FOLLOWING ABDOMINOPERINEAL EXCISION OF THE RECTUM FOR CARCINOMA

By J. W. FOWLER
DEPARTMENT OF UROLOGY, ROYAL INFIRMARY, EDINBURGH

SUMMARY

Denervation of the bladder was demonstrated in 8 of 28 patients following abdominoperineal excision of the rectum. It is suggested that routine postoperative bladder-function studies be performed to detect this complication and thus to enable suitable postoperative care and long-term follow-up to be undertaken.

URINARY retention occurs in a significant number of patients following abdominoperineal excision of the rectum for carcinoma (Lockhart-Mummery, 1932; Buckwalter, Shropshire, and Joiner, 1955); its cause may be mechanical obstruction or neurological injury (Watson and Williams, 1952). It has been suggested that satisfactory voiding is regained spontaneously in the majority of cases (Watson and Williams, 1952; Roberts, 1961) and little attention has been paid to the need for routine bladder-function studies either in the immediate or late postoperative period.

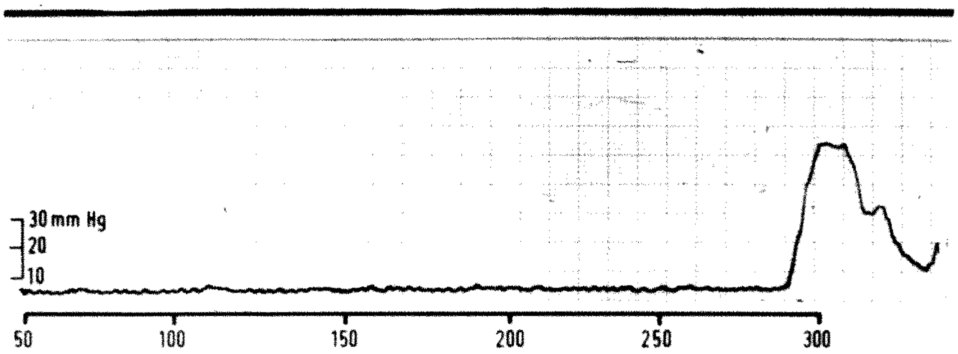

FIG. 1.—Cystometrogram of a normal innervated bladder.

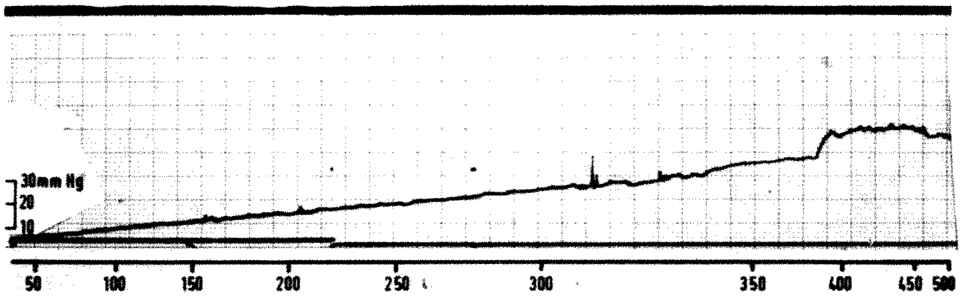

FIG. 2.—Cystometrogram of a denervated bladder.

During a period of 18 months 7 patients presented with urinary difficulties between 3 and 28 years after abdominoperineal excision. Investigation suggested that their bladder symptoms were occasioned by the operative procedure. For this reason routine screening of patients undergoing abdominoperineal excision of the rectum was instituted.

MATERIAL

Group A.—This group comprised 7 patients with long-term complications of excision of the rectum.

Group B.—Twenty-eight patients underwent vesical function studies. Fourteen patients were studied both pre- and postoperatively and the other 14 cases were investigated postoperatively only.

METHODS

Bladder symptomatology was noted. Intravenous pyelography, residual urine estimation, cystometrography, and (where indicated) cystoscopy were carried out. The cystometrogram was performed with a 16F three-way Foley catheter, using 1 : 5000 chlorhexidine as the irrigating fluid. The pressure changes were recorded via a transducer on a Devices recorder. The results were classified as normal (*Fig.* 1) or denervated (*Fig.* 2). No attempt was made to classify the subjective sensory changes. The postoperative cystometrogram was carried out on the day that the surgeon elected to remove the catheter. The three-way Foley catheter was used for postoperative drainage and thus avoided a catheter change before performing the cystometrogram.

RESULTS

Group A.—Group A consisted of 7 patients presenting 3–28 years (average 7–8 years) after abdominoperineal excision of the rectum for carcinoma. The case details are given in *Table I.*

Two male and 3 female patients were found to have denervated bladders. All had difficulty with micturition and urinary-tract infection; 4 of the 5 patients had significant residual urine. One male patient was admitted in renal failure due to prostatic hypertrophy and another patient was admitted with retention due to a prostatic abscess.

Table I.—Details of 7 Patients (Group A) presenting 3–28 Years after Abdominoperineal Excision of the Rectum for Carcinoma

Case	Age and Sex	Survival (yr.)	Difficulty with Micturition	Time of Onset after Operation	Urinary Infection	Additional Procedures	Residual Urine (ml.)	Cystometrogram
1. H. S.	83 M.	7	+	Immediate	+	Repeated bouginage	500	Denervated
2. L. P.	58 M.	28	+	Immediate	+	Bouginage; transvesical prostatectomy; cystotomy and removal of bladder stone	200	Denervated
3. E. C.	64 F.	4	+	2 yr.	+	Antibiotics	100	Denervated
4. E. W.	61 F.	6	+	Immediate	+	Antibiotics; pelvic floor repair	150	Denervated
5. E. McC.	49 F.	10	+	9 yr.	+	Antibiotics	Nil	Denervated
6. O. B.	71 M.	3	+	2½ yr.*	+	Dialysis; antibiotics	Anuric	Normal
7. H. C.	65 M.	4	+	4 yr.	+	Nil	500	Normal

* This patient had renal failure.

Group B.—Twenty-eight patients were studied prospectively. Denervation as demonstrated by a cystometrogram (*Fig.* 2) was present in 8 of the 28 patients (6 males and 2 females) after abdominoperineal resection.

The cystometrograms found to be abnormal were repeated at 2, 6, and 12 weeks and thereafter at 3-monthly intervals. No bladder showing denervation postoperatively has subsequently returned to normal.

All the patients with normal innervation voided spontaneously on the removal of the catheter.

Two male patients showed a significant residual urine 6 months after abdominoperineal resection and investigation by pyelography and cystoscopy demonstrated signs of prostatic obstruction. These patients were asymptomatic and had normal bladder innervation.

MANAGEMENT OF PATIENTS WITH A DENERVATED BLADDER

Patients in whom denervation was shown to have occurred were managed in the following way.

The catheter was removed after the cystometrogram had been performed and the patient was given carbachol (0·5–1 ml. 6-hourly) by injection. Residual urine estimation was carried out 12 hours later and parenteral carbachol was administered daily until the residual urine was shown to be less than 100 ml. The patient was then given oral cholinergic therapy (Myotinine, 5–10 mg. q.i.d.), the dose being reduced as a reduction in the residual urine occurred. Two male patients required transurethral resection as well as cholinergic therapy in order to obtain satisfactory voiding; no patient required further prolonged catheter drainage.

DISCUSSION

Retention of urine following combined excision of the rectum occurs in 17–50 per cent of patients (Watson and Williams, 1952; Buckwalter and others, 1955). This has in the past been attributed to bladder-neck obstruction and rarely to parasympathetic nerve injury. Rankin (1969) showed that nerve injury had occurred in 11 of the 45 patients in his series undergoing abdominoperineal excision of the rectum. Our own series shows that 5 of 7 patients with late vesical complications had a denervated bladder, and similar neurological damage was present in 8 of 28 patients in the prospective study.

The information obtained by investigation in the immediate postoperative period ensured that the correct treatment was instituted and avoided retention and its sequel of bladder overdistension. Long-term review of the patients to check for signs of urinary retention, especially in the male patients, will detect those developing significant prostatic obstruction.

Failure to recognize the primary neurological nature of the postoperative urinary difficulty may lead to these patients being subjected to unnecessary, repeated, and often major surgical procedures, as in *Cases*, 1, 2, and 3 (*Table I*). Urinary infection had been present in the patients in group A from the time of operation despite repeated courses of antibiotics.

The operative mortality and long-term survival following abdominoperineal excision of the rectum for carcinoma continues to improve (Morgan, 1965; Mann, 1969). Appreciation of the palliation achieved by the removal of a rectal tumour has led to more extensive procedures (Hughes, 1963; Moore, 1965). There are therefore an increasing number of patients who are liable in both the short and the long term to vesical complications, and it is incumbent upon surgeons carrying out such operations to remember the possibility of nerve damage and to minimize its consequences. In this way the patient will have an improved quality of life following operation.

Acknowledgements.—I am indebted to Mr. T. J. McNair, Mr. T. I. Wilson, Mr. P. Edmond, and Mr. J. W. W. Thomson for their help and encouragement in the preparation of this paper and to the surgical staff of the Royal Infirmary, Edinburgh, for permission to study their patients.

I am grateful to Miss Catherine Keil for undertaking the secretarial work involved.

SHORT NOTES OF RARE OR OBSCURE CASES

THE OCCURRENCE OF CARCINOID TUMOUR IN TERATOMA OF THE TESTIS

BY C. S. SINNATAMBY, A. B. GORDON, AND J. D. GRIFFITHS
ST. BARTHOLOMEW'S HOSPITAL, LONDON

SUMMARY

The third reported case of a carcinoid tumour arising in a teratoma of the testis is presented. The points of difference between the present case and the 2 previously reported ones are discussed.

Unusual locations of carcinoid tumours are considered in the light of theories explaining their origins. The features of ovarian carcinoid tumours are reviewed and parallels drawn between them and the rarer testicular carcinoid tumours.

THE occurrence of a carcinoid tumour in a teratoma of the testis is a rare phenomenon. Only 2 similar reports have been found in the literature (Simon, McDonald, and Culp, 1954; Berkheiser, 1959) and in both instances the carcinoid tumour had occurred in a cystic teratoma in a patient in the sixth decade. Dixon and Moore (1953) made no mention of carcinoid tumour in their review of 990 cases of testicular tumour. Among 995 cases of neoplastic lesions of the testis studied by the Testicular Tumour Panel and Registry 3 examples of carcinoid tumour were encountered, none of which showed evidence of teratoma formation in the affected testis (Collins and Pugh, 1964). Two further cases of testicular carcinoid, not associated with teratomatous growths, were described by Kemble (1968) and Kermarec and Duplay (1968). The occurrence of a carcinoid tumour in a mainly solid teratoma of the testis in a 31-year-old man is therefore considered worth reporting.

CASE REPORT

A 31-year-old man was referred because of an enlarged left testis which had been noted during a medical examination for a pension scheme. The patient stated that he had had this enlargement for as long as he could remember and had neither noticed any recent increase in size nor experienced any discomfort at the site. Five years previously he had been investigated for infertility at another hospital, where he had been told that no abnormality had been detected, and subsequently he had fathered 2 children. He had not undergone surgery previously.

Physical examination revealed a fit man of athletic build, the positive findings being restricted to the scrotum. The left testis was enlarged to 6 cm. in its longest axis. It was firm and non-tender, normal testicular sensation being present. It could not be transilluminated. The right testis was not enlarged. Lymphadenopathy, abdominal masses, and gynaecomastia were not present. The E.S.R. was 5 mm. in 1 hour, the haemoglobin 14·8 g. per cent, and the white-cell count 4100 per c.mm. with a normal differential. The plasma urea and electrolytes were normal. Urine examination and chest radiography revealed no abnormality.

A diagnosis of teratoma of the testis was considered likely. The left testis was delivered through a scrotal incision. There was no fluid in the tunica vaginalis. The testis was enlarged and its posterior aspect felt abnormally firm. A wedge of tissue was removed for frozen section and the cut surface was noted to be yellow in colour. The frozen section was reported as being from a teratoma. The left inguinal canal was then opened through a groin incision and the spermatic cord was isolated, ligated, and divided at the internal ring. The cord, epididymis, and testis were removed through the scrotal incision. The inguinal canal was repaired and both wounds were closed.

Macroscopically a pale yellow tumour, measuring 4 cm. in its greatest diameter, was found to occupy the lower pole and posterior surface of the removed testis, abutting on to but not invading the tunica (*Fig.* 1). The cut surface showed mainly firm homogeneous tissue, apart from a few small cystic spaces in the lower part of the mass. The tumour was not encapsulated and merged somewhat irregularly with the surrounding testicular tissue.

Microscopically the tumour comprised three intimately mingled types of tissue all supported by a connective-tissue stroma. The small cystic spaces had a pseudo-stratified ciliated columnar epithelial lining (*Fig.* 2) and, adjacent, there were small islands and strands of poorly outlined cells with eosinophilic cytoplasm and pale uniform nuclei which had an irregularly whorled arrangement (*Fig.* 3). Some of these groups of cells were related to partially calcified spherical structures similar to psammoma bodies. The overall arrangement was that of a

tissue intermediate in appearance between arachnoid and a meningioma. Lying next to these areas and extending to form the bulk of the tumour mass were varying sized and shaped clusters of regular cells, many with a distinctly acinar arrangement (*Fig.* 4). The pale eosinophilic cytoplasm contained abundant, basally situated, strongly eosinophilic granules. Specific staining by the Fontana-Masson method revealed them to be argentaffin granules which stained rust-red with the Diazo technique. The nuclei were oval, and mitotic figures were not seen. There was no capsular invasion but the carcinoid element extended in fine clusters into the surrounding testicular tissue. The spermatic cord, epididymis, and testicular tissue in the upper portion of the testis showed no significant abnormality.

Postoperatively the patient made an uneventful recovery. A lymphangiogram showed no filling defects in the abdominal nodes. The urinary 5-hydroxyindole-acetic acid was 5 4 mg. per 24 hours (normal 2–10 mg. per 24 hours) and the whole-blood 5-hydroxytryptamine was 174 mg. per ml. (normal 50–250 mg. per ml.). The patient denies having had any symptoms suggestive of either an abdominal carcinoid tumour or the carcinoid syndrome at any stage before or after his operation. He remains well 6 months after operation.

DISCUSSION

Carcinoid tumours in the appendix were first described by Obendorfer in 1907, and in 1914 Gosset and Masson showed that they originated from Kulchitsky cells. The ability of the cytoplasmic granules in these cells and in the tumours to reduce silver salts led to the use of the term 'argentaffin carcinoma'. While the terminal ileum and appendix are the commonest sites of tumour formation, they have also been found to arise in all parts of the alimentary canal from the oesophagus to the rectum (Cheek and Wilson, 1970). Similarly, they have been reported in appendages of the alimentary tract such as the gall-bladder (Porter and Whelan, 1939), the common bile-duct (Little, Gibson, and Kay, 1968), and the pancreas (Persand and Walrond, 1971). Their occurrence in alimentary areas is not unexpected in view of the presence of Kulchitsky cells at such situations (Morson, 1958). Carcinoid tumours have also been found in the nasopharynx (Jarvi, 1945), the larynx (Goldman, Hood, and Singleton, 1969), and the tracheobronchial tree (Logan, Sehdeva, Hatcher, and Abbott, 1970), which can be accounted for by the finding of normal argentaffin cells in the respiratory tract by De Muylder and Fayt (1954).

A significant number of carcinoid tumours have been reported in the ovary. Hoch, Lichtig, Peretz, Paldi, Pascal, Kuchs, and Brandes (1971) found 32 'primary' carcinoid tumours of the ovary in a recent review of the literature and in 27 of them the carcinoid tumour was part of a benign cystic teratoma. The multipotentiality of teratomas provides an explanation for the unusual location of these ovarian carcinoids and attempts have been made to determine whether they had arisen in relation to teratomatous gastro-intestinal or respiratory structures. In a review of 5 cases Peterson (1957) found that 2 had arisen in relation to the gastro-intestinal epithelium, while Climie and Heath (1968) noted that in 5 out of 9 other cases the carcinoid element was associated with respiratory structures. The ovary, of course, can be the seat of a metastasis from a primary carcinoid tumour in a conventional site such as the ileocaecal region, and 8 such cases have been reported by Shuster, Mendoza-Divino, and Joselson (1970). Brown and Richart (1969) were of the opinion that ovarian carcinoids which were neither associated with ovarian teratomas nor secondary to a primary carcinoid tumour elsewhere were examples of so-called 'simplified teratomas' in which one element outgrew all the others. Toker (1969), on the contrary, believed that they had originated *ab initio* from Kulchitsky cells in the ovary. Normal Kulchitsky cells, however, have not been found in the germinal organs.

Parallels can be drawn between ovarian carcinoid tumours and the few testicular carcinoid tumours that have been reported. In the 2 testicular cases recorded by Simon and others (1954) and Berkheiser (1959) the carcinoid tumour had arisen in a benign cystic teratoma and in each case the authors tried to determine whether it had originated from gastro-intestinal or respiratory teratomatous structures. A respiratory-tract derivation was decided upon by Simon and others and a gastro-intestinal tract origin by Berkheiser. No teratomatous component was seen in either of the cases described by Kemble (1968) and Kermarec and Duplay (1968). Kemble believed that the carcinoid tumour had arisen from argentaffin cells present *ab initio* in the testicle, while Kermarec and Duplay considered also the possibility of the tumour representing a simplified teratoma in which all the other teratomatous structures were absent. The further possibility of a testicular carcinoid tumour being a metastasis from a primary growth in the alimentary tract is illustrated by 1 of the 3 cases mentioned by Collins and Pugh (1964). This patient died a few months after orchidectomy with multiple carcinoid tumours in the peritoneum and mesentery; his appendix had been removed previously but had not been examined histologically. The importance of excluding an abdominal primary neoplasm whenever a carcinoid tumour is encountered within the scrotum is further emphasized by a case of metastatic involvement of the epididymis reported by Cope and Newcomb (1930) and another case described by Kemble (1968) in which a metastatic deposit was found on the serosal surface of the tunica vaginalis; in both instances the primary growth was situated in the small intestine.

The case described here is the third reported case of a carcinoid tumour arising in a teratoma of the testis. There are points of difference, however, between the present case and the 2 previously reported cases. The patient described by Simon and others (1954) was a 58-year-old man who had experienced 2 years of accelerated enlargement of a 14-year scrotal swelling. Berkheiser's (1959) patient was a 54-year-old man who complained of 1 year's painful enlargement of a testis that had been increased in size from birth. Our patient was a much younger man (31 years of age) without testicular symptoms, his lesion being detected at a routine medical examination. In both the previously reported cases the tumour was an essentially cystic teratoma in which the carcinoid component was relatively small—an 8-mm.-diameter nodule in a 5-cm.-diameter cyst in the former, and groups of carcinoid cells in the walls of the cysts in a multicystic tumour in the latter. In the case reported here the tumour was mainly solid and the major part of it comprised clusters of carcinoid cells. It was not possible to identify with certainty the tissue from which the carcinoid element had arisen. The epithelium in the teratomatous part of the tumour, however, was distinctly respiratory in type (*Fig.* 2). The tendency for a component tissue of a teratoma to proliferate has already been mentioned in connexion with the origin of carcinoid tumours. The small area of meningioma-like tissue (*Fig.* 3) represents a similar tendency towards cellular proliferation, which in this instance is overshadowed by that of the carcinoid component.

The carcinoid tissue and the other elements present in the testicular teratoma described here all appeared well differentiated on microscopic study. Collins and Pugh (1964), however, stated that even the most differentiated teratoma cannot be designated as benign. Similarly, Morson (1958) believed that there is no justification for the use of the term 'benign carcinoid'. In each instance the benign or malignant nature of the lesion is determined by its clinical behaviour. In the present case there was no clinical or radiological evidence of metastases from the testicular lesion, or of a primary neoplasm responsible for the latter.

None of the reported carcinoid tumours of the testicle has been a functioning tumour associated with the carcinoid syndrome or with biochemical evidence of endocrine secretion by the tumour cells. Of the ovarian carcinoid tumours reviewed by Kelley and Scully (1961), however, 37·5 per cent were considered to be functioning, and Brown and Richart (1969) stated that the carcinoid syndrome occurs relatively more frequently among patients with neoplasms of the ovary than in those with lesions of the gastro-intestinal tract, because the venous drainage from the ovary by-passes the liver where 5-hydroxytryptamine produced by the carcinoid cells is destroyed by monoamine oxidase. There was no evidence of flushing, diarrhoea, wheezing, or cardiac lesions in the case reported here. In the absence of such suggestive clinical features the preoperative diagnosis of a primary testicular carcinoid tumour is virtually impossible. Thus, in all the reported cases biochemical studies of endocrine activity have only been performed postoperatively. This was true of the present case as well, and the patient's postoperative whole-blood 5-hydroxytryptamine and urinary 5-hydroxyindole-acetic acid levels were within the normal range. Such postoperative estimations, however, may when abnormal indicate the persistence of further carcinoid tumour in the patient, as occurred in the case reported by Kemble (1968), where a carcinoid tumour nodule on the tunica vaginalis was secondary to an ileal carcinoid tumour and the postorchidectomy urinary 5-hydroxyindole-acetic acid level was high.

OMENTAL TRANSPOSITION IN THE TREATMENT OF RADIONECROSIS

BY DAVID F. CORT AND J. LEIGH COLLIS*
QUEEN ELIZABETH HOSPITAL, BIRMINGHAM

SUMMARY

A technique is described for the closure of chest-wall defects following radical excision for radionecrosis. Such defects are usually extensive with an avascular bed and often involve an opening into the pleural cavity; surgical closure poses significant problems. The method described here utilizes a transposed omental flap to provide a vascular bed for a skin-graft, whilst cephalad shifting of the origin of the diaphragm is used to close the pleural defect. This latter innovation has the dual advantages of simplicity and effectiveness, whilst greatly facilitating the passage of the omentum to the chest wall with minimal risk of omental strangulation.

THE ability of the greater omentum to adhere to inflamed and traumatized viscera, and thus to contribute to the resolution of intraperitoneal inflammation, is fundamental to the successful outcome of abdominal surgical procedures. The particular properties of mobility, vascularity, plentiful endowment with lymphatics, and powers of cellular proliferation bestow a unique status upon this structure. Surgical exploitation of these properties has been carried beyond the abdomen by transposition of the omentum for myocardial revascularization (Vineberg, 1969) and in the relief of lymphoedema (Goldsmith and De los Santos, 1966).

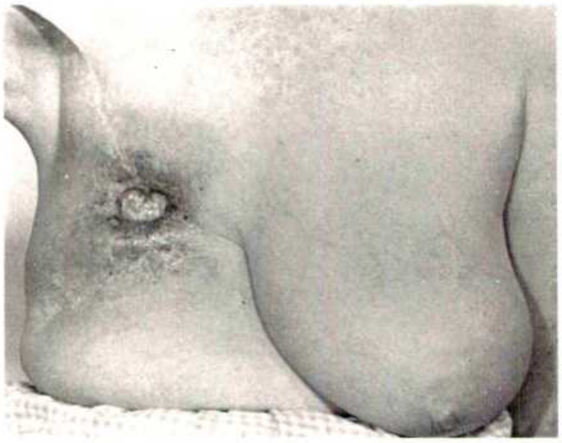

FIG. 1.—General tissue damage from irradiation with an ulcer to the right of the sternum.

The facility with which the omentum will support a split-skin graft was demonstrated by Kiricuta (1963), who used transposed omentum covered by a skin-graft in the treatment of a radionecrotic ulcer on the chest wall. Dupont and Menard (1972) reported 4 cases in which this principle had been used, with details of the operative techniques. Essentially, the omentum was transposed to an extra-abdominal site in the form of a flap pedicled upon the gastro-epiploic vessels, passing through a defect in the musculofascial layer of the abdominal wall and thence via a subcutaneous tunnel to the site of election.

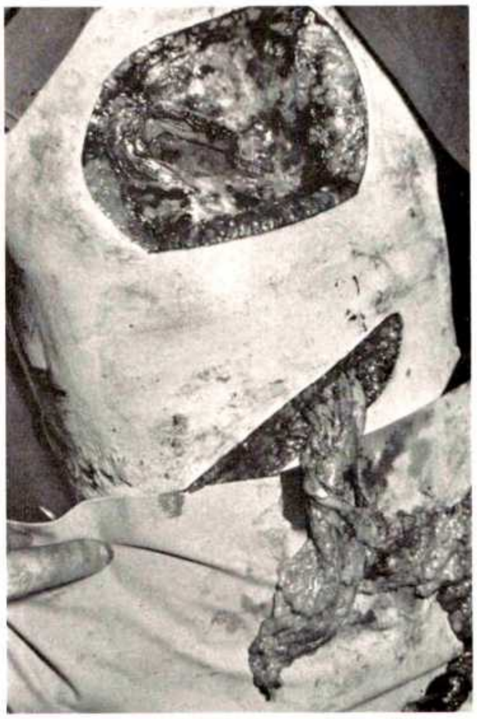

FIG. 2.—A wide excision of the tissue damaged by irradiation has been made. This has included excision of the fourth costal cartilage and a part of the adjacent fourth rib. A Kocher's incision has been made and the omentum delivered on to the surface before being taken up into the defect behind the costal margin.

We have recently applied this method in a similar clinical situation and report here certain further observations on the technique.

CASE REPORT

A 55-year-old Caucasian female presented with a radionecrotic ulcer on the right anterior chest wall (*Fig.* 1).

---

* Requests for reprints to Professor J. Leigh Collis, Queen Elizabeth Hospital, Edgbaston, Birmingham, B15 2TH.

Fourteen years previously she had undergone a classic right radical mastectomy for carcinoma of the breast, followed by postoperative irradiation (3000 r). Within 1 year of operation she had developed a local recurrence in the scar, which was treated successfully by further irradiation (5000 r). Thereafter, the area had remained quiescent, with no evidence of recurrence or metastasis, for 13 years. She had then suffered minor trauma to the irradiated scar, resulting in ulceration which failed to heal. Surgical exploration revealed radionecrotic costal cartilage, which was excised, and biopsy showed no evidence of recurrent tumour.

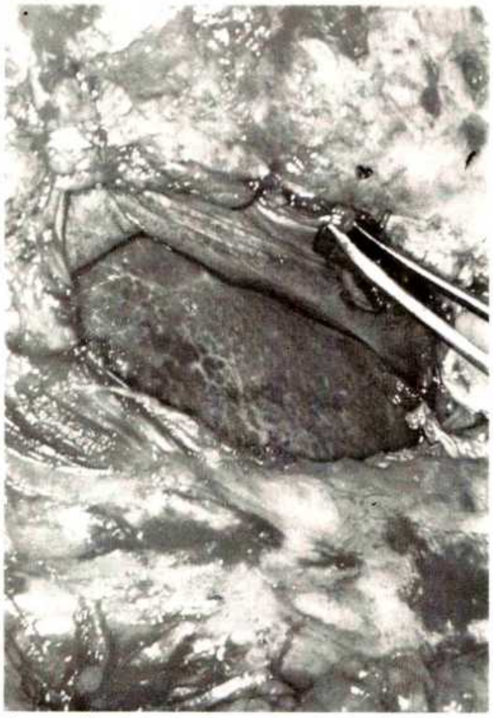

FIG. 3.—The defect in the anterior chest wall with the diaphragm sutured to its medial and lateral sides and the upper margin. The liver is seen in the base of the opening.

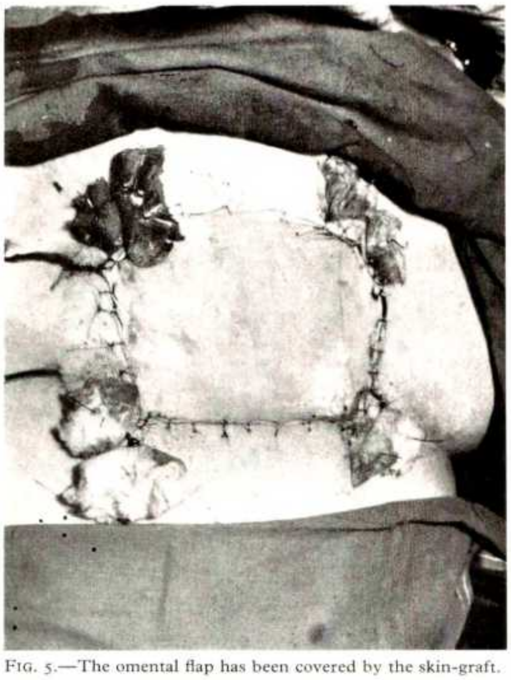

FIG. 5.—The omental flap has been covered by the skin-graft.

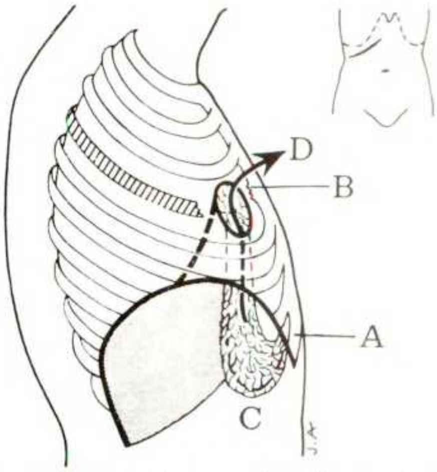

FIG. 4.—Diagrammatic representation of the procedure used. The diaphragm was freed from its anterior attachment (A) and raised to (B). This left the opening in the anterior chest wall excluded from the thorax and in free communication with the peritoneal cavity. The great omentum was brought up (C) behind the costal margin and delivered to the surface at D. The insert shows the Kocher's incision.

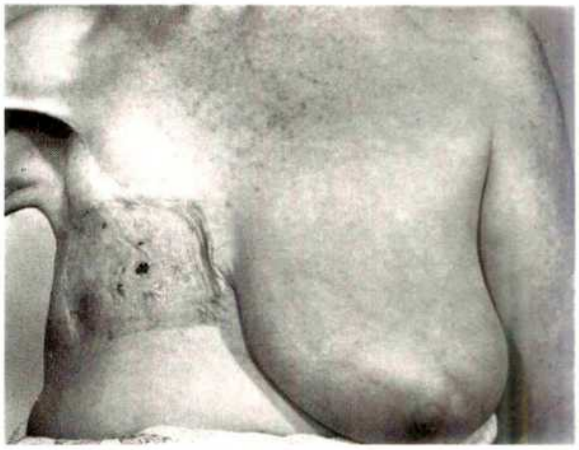

FIG. 6.—The wound soundly healed postoperatively.

The ulcer persisted, requiring daily dressings, and the patient requested definitive surgery to resolve this situation. Further biopsy was negative in respect of tumour, and a chest radiograph showed no gross change in the subjacent ribs. Wide excision of the ulcer and adjacent indurated tissues was clearly required, thus posing the problem of closure of an extensive defect in a heavily irradiated area.

A free graft of skin would not survive on the predicted wound bed, and a transposition flap from the upper abdomen was considered inadvisable in view of the size of the defect and the significant risk of partial loss of such a flap. Conventional repair by tubed pedicle or marsupial flap was rejected on account of the multiple stages involved.

The use of transposed omentum to provide a vascular bed for the reception of a free skin-graft was therefore selected as the only method which would permit excision of the ulcer and definitive closure of the defect at a single operative procedure.

OPERATIVE TECHNIQUE.—The ulcer was widely excised, down to the skeletal plane of the chest wall, revealing poorly vascularized tissues and a necrotic fourth costal cartilage. This was removed together with an adjoining portion of rib, thereby creating a defect in the parietal pleura (*Fig.* 2). The lung surface was free from intrapleural adhesion and was in consequence free to collapse down.

The abdomen was opened using a Kocher incision and the greater omentum was freed from old adhesions to a hysterectomy scar. Exteriorization of the omentum demonstrated an adequacy of tissue for the purpose intended, and further omental mobilization (in terms of creating a pedicle upon the right gastro-epiploic vessels) was not required in this case.

The diaphragm was detached from its insertion along the right anterior costal margin and the freed edge was moved cephalad and sutured to the muscle and periosteum along the superior border of the pleural defect (*Fig.* 3). (The pleural cavity was drained by means of a rubber tube and water seal.) In this manner the chest-wall wound was brought into communication with the peritoneal cavity via the orifice in the rib cage from where the piece of rib and costal cartilage had been removed, thus establishing a retrocostal route for the passage of the omentum from the abdomen to the site of repair (*Fig.* 4).

The margins of the chest-wall wound were then prepared for reception of the skin-graft. One of the problems of grafting a mobile surface on the trunk is the inevitable tendency for respiratory and postural movements to cause distortion of the wound edge, thereby transmitting a shearing force to the graft, and hence a high liability to haematoma formation and partial graft loss. This may in part be overcome by anchoring the wound margins to the deep fascia with a continuous pull-out nylon suture, passing between the subcutaneous tissue in the wound edge and the deep fascia, emerging at each end from the skin surface, and there locked by means of a bead and collar. One such suture was inserted along each of the four margins of the wound and secured in this manner.

The omentum was then drawn up into the chest wound and was seen to negotiate the route described without tension or torsion, and was fixed to the edges of the rib-cage orifice with fine catgut sutures; the abdominal wound was then closed. The transposed omentum was draped carefully over the base of the chest wound, and secured in position with multiple fine catgut sutures. Particular care was taken to avoid any impairment of the omental circulation during these manœuvres.

A split-skin graft was taken from the left iliac fossa, using a Padgett dermatome. This donor site was selected in preference to the conventional area on the thigh, because a large and relatively thick sheet of skin was required and under these circumstances there is considerable merit in using the trunk rather than a limb (Cort and Herbert, 1971). The graft was applied to the omental bed and sutured in place with a Redivac drain beneath the lower margin of the graft, emerging through a lateral stab wound (*Fig.* 5). Drainage was provided because there is reason to believe that omentum may produce a significant volume of transudate in the early postoperative phase, with a consequent risk of a serous effusion beneath the graft (McLean and Buncke, 1972). Gentle pressure and further fixation were established by tie-over sutures and a bolster dressing, care being taken to avoid excess tension on these sutures lest the delicate omental vessels be compressed.

The postoperative course was uneventful, with removal of the chest and abdominal drains at 48 hours. The graft-bed drain yielded 250 ml. of serous fluid in the first 72 hours and was removed at 96 hours. Graft inspection on the seventh day showed 100 per cent take, and the omental vessels were noted to be prominent beneath the graft. Healing of all areas was complete by the fourteenth day (*Fig.* 6), and histological examination of the resected tissue confirmed extensive radionecrosis with no evidence of recurrent tumour.

DISCUSSION

Previous authors have reported closure of defects in the rib cage and pleura using Marlex mesh overlaid by omentum and graft (Dupont and Menard, 1972). We suggest that the diaphragmatic manœuvre described here has considerable advantages when it is anatomically feasible. The need to implant foreign material is avoided and the method provides a retrocostal route for the omentum, thereby greatly reducing the risk of omental strangulation at the site of transgression of the abdominal wall or in a subcutaneous tunnel. In the present case the defect left by excision of the necrotic chest wall was not large and the incised diaphragm was brought to the upper margin of the defect with ease. It is considered that there would have been sufficient diaphragmatic tissue for the plan still to have been used if the third as well as the fourth costal cartilage had been affected. It is also felt that wider areas of chest wall could be excised and treated in the same way with careful planning for the individual case. The abdominal incision could be made lower and the posterior rectus sheath could be raised as a flap in continuity with the diaphragm.

We found no need to perform any specific omental mobilization in terms of a gastro-epiploic pedicle. This factor must be presumed to vary widely between individual patients, but it is worthy of note that a direct simple transposition may be practicable, thus simplifying the nature of the operation.

HAEMANGIOPERICYTOMA OF THE PRE-SACRAL SPACE

By STEWART HART and LORNA SISELY*

QUEEN VICTORIA HOSPITAL, MELBOURNE

SUMMARY

A slowly growing tumour in the pre-sacral space is described. On surgical excision this proved to be a haemangiopericytoma which has since recurred locally. The difficulty and necessity of adequate removal are discussed.

A HAEMANGIOPERICYTOMA was first described by Stout and Murray (1942) as a vascular tumour in which the proliferating cell is a pericyte of Zimmerman (1923), which is a modified smooth muscle-cell surrounding small blood-vessels and normally being responsible for their contractility.

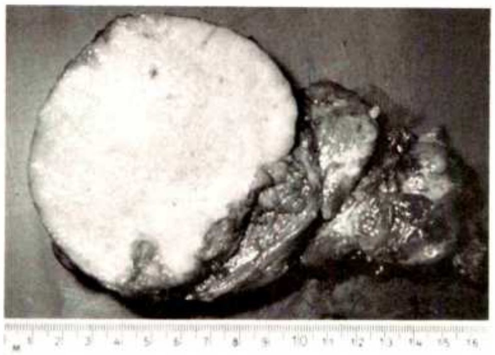

FIG. 1.—Cut surface of the specimen showing a white, whorled appearance.

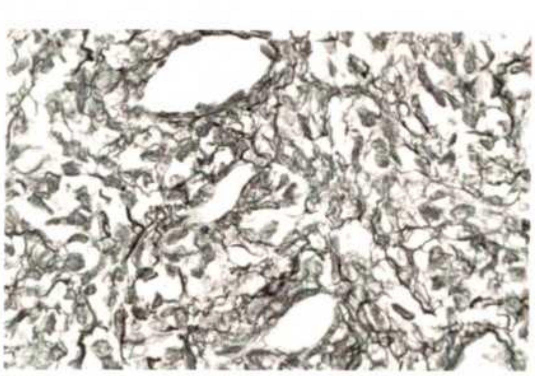

FIG. 3.—Section of the tumour stained with silver to show the reticulin-fibre supporting structure. (× 400.)

The essential characteristics of a haemangiopericytoma are that it consists of many capillaries, with or without lumina, lined by normal endothelial cells and surrounded by a delicate reticulin-fibre supporting structure. The space between these capillaries is filled with proliferating pericytes, which are spindle-shaped cells without myofibrils and having no organoid structure. This tumour is therefore distinguished histologically from haemangio-endothelioma, glomus tumour, vascular leiomyoma, vascular fibrosarcoma, and undifferentiated carcinoma (Harrison and Bulteau, 1972).

Haemangiopericytomas can occur anywhere in the body where there are capillaries, but approximately 45 per cent are found in the musculoskeletal system and 18 per cent in the intra- and retroperitoneal spaces (Backwinkel and Diddams, 1970).

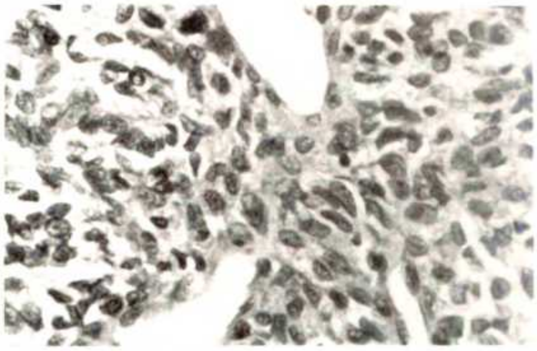

FIG. 2.—High-power view of a section of the tumour. H. and E. (× 400.)

Jackman, Le Mon Clark, and Smith (1951) described the pre-sacral space as a common site for masses of congenital, infective, or neoplastic origin, but of 64 neoplastic tumours from a total of 114 cases recorded at the Mayo Clinic from 1935 to 1948, no case of haemangiopericytoma was mentioned, accentuating the rarity of a pre-sacral haemangiopericytoma.

CASE REPORT

Mrs. C. T. was aged 23 in 1952 when she presented to the Queen Victoria Hospital, Melbourne, in her third pregnancy, on which occasion no abnormality was recorded. Subsequently she had three further normal pregnancies, but in 1959, when she was seen during her seventh pregnancy, she was found to have a pre-sacral mass of approximately 5 cm. in diameter attached to the sacrum. Plain radiographs showed a soft-tissue shadow only with no bony abnormalities. It was decided not to interfere at this time and the pregnancy resulted in a normal delivery. Her eighth and ninth pregnancies followed, the former being complicated by an unstable lie, but both ending in vaginal deliveries. Tubal ligation was performed in 1963 and she was followed by the Surgical Unit because of her pelvic tumour.

As the tumour was slowly growing, operation was undertaken in 1966. A full blood examination was normal, a Casoni test was negative, and a chest radiograph was clear. A barium-enema examination and intravenous pyelography confirmed that the tumour was displacing, but not involving, the rectum and ureters. Operation was performed by two surgeons using a synchronous combined approach. The tumour was fairly well encapsulated over most of its surface with no major feeding vessels found during dissection. However, there was a large amount of oozing from the surface of the tumour, as well as from the sacrum, and a blood transfusion of 17 pints was required during the procedure.

---

* Address for reprints: Miss Lorna Sisely, Queen Victoria Hospital, Lonsdale Street, Melbourne, Victoria, 3000, Australia.

Anteriorly the tumour 'capsule' was elongated downwards and intimately adherent to the posterior rectal wall. As complete removal was not possible without excision of the rectum, and the true nature of the tumour was not known, small firm remnants of the tumour capsule were left adherent to the rectal wall. Bleeding was eventually controlled with packs which were left in situ and removed 48 hours later.

The excised tumour was approximately 9 cm. in diameter (*Fig.* 1) with its cut surface exhibiting a white, whorled appearance, which can be explained by the absence of blood-filled capillaries due to compression of their lumina by the proliferating pericytes. The capsule was elongated in the direction of its rectal attachment just above the anal sphincter.

Microscopically, the tumour was seen to be a haemangiopericytoma (*Figs.* 2, 3) with numerous endothelial-lined vascular spaces separated by cords of fleshy pericyte cells.

Postoperatively the patient's convalescence was uneventful, but since that time there has been a gradual increase in size of the remnants, and in May, 1972, she had a semi-fixed nodular tumour of about 4 cm. in diameter lying in the retrorectal space. Otherwise the patient is well and remains symptomless.

DISCUSSION

At the time of surgery the true diagnosis was in doubt and therefore a frozen section was performed. This was of no assistance other than to confirm the presence of mitotic cells.

The extensive blood-loss during surgery indicated a vascular tumour of some type and indeed caused some concern in obtaining the amount of blood necessary for rapid replacement. When dealing with a possible haemangiopericytoma it is emphasized that adequate blood should be readily available to avoid this problem. Douglas, Mitchell, and Short (1966) described a case of retroperitoneal haemangiopericytoma in which the common and internal iliac arteries were controlled by tapes during surgery, both internal iliac arteries eventually being ligated. Despite this procedure there was still considerable bleeding from the pelvic floor.

Stout (1949) indicated that in a haemangiopericytoma, although the tumour appears well encapsulated, nests of dividing cells exist at the periphery of the 'capsule'. This is one reason why local recurrence occurs in 50 per cent of intra-abdominal cases and why wide excision is advocated by most authors (Slattery, Aronson, and Loman, 1956). Spiro, Brockunier, and Brumschwig (1964) have described a supraradical approach removing the anus, rectosigmoid, uterus, adnexae, and vagina for a recurrent tumour in a similar situation.

In the present case a clearance wide enough to prevent recurrence would involve excision of the anus and rectum, and it is the opinion of a consultative group of surgeons that this would not be justified in view of the absence of symptoms, the very slow progress of the tumour, and the low incidence of distant metastases.

The use of deep X-ray therapy alone or as an adjunct to surgery has not proved beneficial for large tumours of this kind, although Harrison and Bulteau (1972) reported a case of haemangiopericytoma of the nasal cavity which responded well to cobalt radiotherapy. The authors are not aware of any reported cases where cytotoxic therapy has been used.

Acknowledgements.—The authors wish to thank Dr. E. Abrahams and Mr. H. Berkshire for their assistance in the preparation of the illustrations.

REVIEWS AND NOTICES OF BOOKS

Practice of Surgery. Current Review. Volume 1. By WALTER F. BALLINGER, M.D., St. Louis, and THEODORE DRAPANAS, M.D., New Orleans. 10 × 7 in. Pp. 321 + x. Illustrated. 1972. London: Henry Kimpton. £10·55.

THIS book consists of a series of reviews on specific subjects by members of the departments of surgery at the Tulane University School of Medicine in New Orleans and at the Washington University School of Medicine in St. Louis. The subjects are those in which, in the opinion of the editors, important advances are being made. These cover a wide range of general, vascular, traumatic, thoracic, and plastic surgery, so that the book will interest most surgeons. The chapters on fluid replacement in trauma, polyhormonal syndromes, and ventilatory failure after operation or injury are particularly good, while there is much of interest in most chapters. Each chapter has an excellent bibliography related to its subject.

The chapter on emergency medical transportation is of interest in describing the relatively backward position of the U.S.A. compared with the excellent service in this country thanks to such organizations as the St. John Ambulance Association, the local authorities, and the National Health Service.

The book can be recommended to all surgeons as a convenient method of keeping well informed over a wide range of surgery and as a source of references for further reading.

Recent Progress in the Study of Disorders of the Colon and Rectum. Edited by S. DROBNI and M. FEHER. 9½ × 6¼ in. Pp. 538. Illustrated. 1972. Budapest: Akademiai Diado. L.8.50.

THIS book publishes papers delivered at the International Congress of Hendrologicum Collegium held in Budapest in July 1970, and it consists of ninety-six papers by authors from twenty-six countries, with many contributions from surgeons in Eastern Europe and Russia. It is divided into sections on congenital anomalies, diagnostic procedures, polyposis, malignant disease, colitis, proctology, etc., the largest section of thirty-seven papers being on malignant disease, while seventeen papers are on various aspects of colitis.

There are some surprising omissions; for example, there is no contribution on the problems of rectal prolapse and there are only two contributions that deal with diverticular disease of the colon. Most of the papers are published in English, with a few in German and one in French. The printing and production are excellent, with the figures and illustrations (mostly black and white but a few in colour) clear and lucid.

Surgeons in England will not find anything very new to them in these papers, but many of the problems discussed are also subjects of controversy and slow advance in this country, and it is interesting to learn how surgeons in other lands are trying to solve them. Large-bowel malignancy and its many problems seem to be as common in Eastern Europe as in the Western world, and there also seems to be considerable division of opinion about the value and place of sphincter-preserving operations, both in low rectal cancers and in cases of ulcerative colitis. There are some useful contributions on amoebic infection, reminding us that its diagnosis may be difficult even when it is considered, and that the sigmoidoscopic appearances may closely resemble those of non-specific ulcerative colitis.

Unfortunately, not all the contributions have summaries and none of the chapters has any references at the end, even when references are mentioned in the text, an omission which rather detracts from the value of this book as a work of reference.

The Upper Cervical Spine. By DETLEF VON TORKLUS and WALTER GEHLE, Hamburg. 10½ × 7½ in. Pp. 101. Illustrated. 1972. Stuttgart: Georg Thieme Verlag. DM.48.

THIS is a useful book. It is not easy to read, but it presents very full information about the anatomy, anomalies, and pathology of the upper cervical spine. It is clearly based on a great deal of painstaking work. The text is very well illustrated throughout by diagrams and reproductions of radiographs, which greatly ease the reader's task and assist the understanding of this sometimes difficult region. Paediatricians will in particular welcome the sections dealing with development and anomalies, while all clinicians who have to treat necks will be grateful for this collection of reliable basic information. The authors have—rightly—dealt only very briefly with the matter of treatment. To do so would to some extent have lessened the value of the book. They have, instead, concentrated on bringing order to the description of situations at and below the occiput; most readers will think that they have succeeded in this considerable task. The figures are sensibly numbered and well arranged so that references to them in the text can instantly be followed. Many references are given, and these are conveniently listed. The index is short, but is adequate and reliable. The arrangement and heading of the sections could perhaps be sharper and more definite, and it is hoped that some errors of proof reading will be corrected in the next edition. Dr. Michaelis's translation of what may have been a difficult text on what certainly is a complex subject is good and clear. Most English readers will have cause to thank him for opening up this mine of information. The slim volume costs £7, but it is an important book and it should be seen by all who are concerned with the diagnosis and treatment of disorders of the cervical spine.

Abdominale Angiographie. By W. WENZ, with the co-operation of G. VAN KAICK, D. BEDUHN, and F.-J. ROTH. Pp. 226. Illustrated. 1972. Berlin: Springer-Verlag. DM.96.

THIS book in German is based on the authors' experience of abdominal angiography in 2804 adult and child patients and is meant as a guide to the non-specialist radiologist working in a small hospital, to trainee radiologists, and to general surgeons who wish to know what help can be obtained from specialized radiology. Renal angiography (except for trauma) has been omitted.

The vascular anatomy of the abdomen is described. There are detailed sections on the various forms of arterial and venous angiography with descriptions of the equipment and techniques needed.

There is unfortunately no discussion or illustration of photographic subtraction which has recently become cheap, very quick, and reliable. The authors prefer electronic and colour subtraction, neither of which would appear to be suitable for a small department.

There are detailed sections on the angiography of abdominal syndromes followed by discussion of the angiography of individual organs. Throughout the book the authors maintain a good balance between the relative value of clinical examination combined with the routine radiographic investigations, scintigraphy, and angiography. For example, the value of angiography in pancreatic disease is very fairly and soberly assessed.

The section on the morbidity of angiography is very good and describes the treatment of complications in detail. It is a sobering thought that 21 per cent of their patients had changes in the blood-flow to their legs following angiography.

The illustrations of 183 cases are small but demonstrate their points. The 21 colour illustrations are harder to understand than the black and white ones and add no further information.

The most useful part of the book for its users will undoubtedly be the up-to-date and very full bibliography of 790 references.

A textbook will never replace practical experience in angiography. However, with this proviso in mind this book succeeds as a guide to the investigator of abdominal diseases who is inexperienced in specialized radiology. It tells him the indications for angiography of the abdomen in a given situation; the technique of the procedure with its inherent dangers; it also indicates his chances of obtaining worth-while information unobtainable by other means and how to assess the findings. It will be a useful reference book on the bench.

Orthopaedics in Infancy and Childhood. By G. C. LLOYD ROBERTS, M.Chir. (Cantab.), F.R.C.S., London. 8½ × 5½ in. Pp. 337 + x. Illustrated. 1971. London: The Butterworth Group. £6·75.

THIS book is intended to be of value to both orthopaedic surgeons and paediatricians and is written by an orthopaedic surgeon with a wide experience in the care of children of all ages.

In its systematic arrangement consideration of the generalized disorders of the skeleton is followed by that of the effects of vascular, lymphatic, and metabolic anomalies and diseases, and discussion of bone cysts, tumours, and various infections. There is a chapter on the disorders of the central nervous system which owes much to the influence of Paul Sandifer in the part on cerebral palsy; in the section on the disabilities associated with myelomeningocele a commendably moderate and realistic attitude is taken towards the whole problem. There follows a short description of a variety of rare conditions. The remaining two-thirds of the book deal with the disorders of the different regions. Nothing seems to have been missed out, but with such a vast range of items it is obvious that many get only a short mention.

The many queer combinations of disturbances of growth and form in childhood provide a delightful ambience for the eponymously minded and no opportunity is lost here and much good it does us all in enlarging our diagnostic capacity and enjoyment; sometimes it is almost as good as the best dermatology, but may one protest, however, at 'acromionectomy'!

The many illustrations are good, but it is unfortunate that the name of the patient appears in some of the radiographs, and this should be avoided in the next edition.

This book deserves to be read by all orthopaedic surgeons who have to treat children and should be of much value to paediatricians when faced with a baby with a rare deformity.

Synopsis of Surgery. Second edition. Edited by RICHARD D. LIECHTY, M.D., Iowa, and ROBERT T. SOPER, M.D., Iowa. 7¾ × 4¾ in. Pp. 1108 + xiv. Illustrated. 1972. London: Henry Kimpton. £7.

IN spite of its title this is really a general surgical textbook for students compacted by listing and tabling some of the material. The 26 contributors come predominantly from the University of Iowa. This second edition has been expanded with chapters on total parenteral feeding, transplantation, and gynaecology. The number of illustrations has been increased but the diagrams remain clearer than the photographs and radiographs, some of which are darkly reproduced. The text is well written and on the whole well balanced, but clinical descriptions are sometimes too brief and therefore too generalized; for instance, mesenteric vascular occlusion is described as causing the rapid onset of abdominal distension and tenderness, with no mention of the frequent absence of signs. In contrast, operative detail is occasionally too lavish; a short treatise is devoted to the various forms of colostomy.

Its high price will put this book out of the reach of most students.

Orthopaedics and Accidents. By MARGARET MILLER, R.G.N., S.C.M., and JAMES H. MILLER, M.B., Ch.B., F.R.C.S. (Glas.), F.R.C.S. (Edin.). 8¼ × 5½ in. Pp. 256 + xiv. Illustrated. 1972. London: The English Universities Press Ltd. £1·35.

THIS pleasant little book is well worth browsing through since it contains a great deal of interesting information which is well set out.

It will be useful to senior students and house officers as well as to the nursing staff. The section on orthopaedic nursing will allow the young house-surgeon to have a new insight into nursing problems.

It is the sort of book that will be found on sister's desk in the orthopaedic ward or in the casualty department.

A few antique heresies, such as the value of electric heat in tennis elbow and the antiquated methods of applying traction, have crept in but probably this is no great disadvantage because the young have to develop their own critical faculty.

A good little book to be recommended and the authors are to be congratulated.

Reconstruction Surgery and Traumatology, Volume 13. Edited by G. CHAPCHAL, Nijmegen. 9½ × 6¾ in. Pp. 209 + ix. Illustrated. 1972. Basle: S. Karger. £10·80.

THE first part of this book occupies half the pages and is devoted to surgical and related methods of dealing with the effects of cerebral palsy. It deals in turn with the methods that can be recommended for the nervous system and the different deformities that occur in the limbs. It presents a useful summary of present practices in these fields and provides a fairly large bibliography.

The second section occupies 72 pages and deals with the treatment of spinal injuries, with particular reference to the need for careful handling of the patient as the best means of promoting recovery by avoiding further damage; the application of rigid fixation to the mandible by the use of the tension-band principle, the fate of exposed bone, and the management of pressure sores.

The third section includes a statement that the aetiology of idiopathic infantile scoliosis is not known and then offers an explanation based on the effects of different countries' customs with regard to the postures in which children are placed. The final chapter is on metabolic aspects of scoliosis.

The English is not very good and there are many spelling mistakes in this otherwise well-produced but very expensive review.

Prolactin and Carcinogenesis. Edited by A. R. BOYNS and K. GRIFFITHS. 8½×6 in. Pp. 230+viii. Illustrated. 1972. Cardiff: Alpha Omega Alpha Publishing. Price not given.

THE report of the proceedings of the Fourth Tenovus Workshop lives up to the high standard of its predecessors and is published just 8 months after the meeting itself. Prolactin was identified as a distinct hormone in man only 2 years ago but since then a large amount of work has been done on its chemistry, estimation, physiology, and pathology. Its special importance lies in the part it plays in the development and function of the breast, its undoubted role in supporting the growth of mammary carcinoma in experimental animals, and its possible similar function in human breast cancer. It appears also to influence the prostate in animals and may be involved in prostatic disease in man.

Much of the work on prolactin from both sides of the Atlantic is reported here, together with verbatim records of the critical and informed discussions. The emphasis, as the title indicates, is on its relation to cancer. The book should be in every large medical library and all endocrinologists, pathologists, and surgeons working in this field will find it indispensable reading and a useful source of references to earlier works.

Developments in Biomedical Engineering. Edited by MARTIN M. BLACK, School of Applied Sciences, University of Sussex. 9×6 in. Pp. 192+x. Illustrated. 1972. London: Sussex University Press, distributed by Chatto & Windus, London. £6.

THIS excellent book, which is perhaps highly priced for the general reader, contains much information about the rapidly developing field of biomedical engineering. The topics dealt with are divided into three groups: prosthetics and biological valves; membranes and pumps; biological simulation and measurements. Each section is subdivided into parts dealing with specific problems. The subsections include much detail but seem to the general reader to demand a considerable background of experience for full appreciation. Nevertheless, the book is so well written that it has a somewhat wider appeal than just to the specialist.

Plastics Materials in Surgery. Second edition. By BERNARD BLOCH, M.B., Ch.B., F.R.C.S., Sydney, and GARTH W. HASTINGS, Ph.D., B.Sc., Th.L., F.R.I.C., M.R.S.H., North Staffordshire Polytechnic, Stoke-on-Trent. 9×6 in. Pp. 273+ix. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $18.75.

WE badly need a book on the use of plastics in surgery, whether as implants or otherwise. In 1967 Bloch and Hastings produced the first edition of their book which was a catalogue of what had been used, where and how. It read like a railway timetable, but on the whole was less useful because it was uncritical. The second edition brings one up to date with source references, but times have changed. We have all used plastics and are bewildered by their variety. We now need an authoritative and critical account, with facts and figures, on which plastic to use and why. When a patient says, 'How long will it last, doctor?' we mumble something, but we still do not know. When a new plastic is produced everyone finds it ideal and discards the old one. As the authors state: 'Clinical use is in advance of experimental evidence of suitability.' It always has been, yet there is little guidance to be found in this book, even though the first chapter purports to discuss methods of assessment, and in chapter 5 toxicity and biological and mechanical evaluation are dealt with, but the treatment is too vague and non-specific.

For the tiro some of the information can be misleading, and much of it will lead to disaster; on p. 146 it is stated: 'Cartilage powder is found to accelerate wound healing.' If this is so, then we should all be using it; like detergents for washing up the dirty dishes, it saves time and effort. But is it true? All the ten publications about cartilage powder have come from one centre, even though only two are listed. Anyone picking up this book might expect guidance on which plastic to use; he will be disappointed, and perhaps overwhelmed by the 760 references in chapter 4.

For the practical surgeon this book has little to offer and is rather expensive.

Environmental Health Perspectives. Experimental Issue No. 2, October, 1972. 10×7¾ in. Pp. 128+iii. Illustrated. 1972. North Carolina: U.S. Department of Health, Education, and Welfare, National Institute of Environmental Health Sciences. Price not given.

THIS is a journal with prepared articles from a variety of sources, dealing specifically with the problems of environmental health. This issue includes such diverse subjects as the effects of noise and ototoxic drugs, aspects of microwave radiation, and susceptibility to lead toxicity. It is unlikely to appeal to the general reader and is a journal for the specialist.

Fundamentals of Anesthesia Care. By BETTY J. SMITH, C.R.N.A., New York. 9×6 in. Pp. 120+vii. Illustrated. 1972. London: Henry Kimpton (St. Louis: C. V. Mosby). $2.

IN her preface Miss Smith explains that her book has been written for student-nurse anaesthetists and that it is not intended as a single introduction to every part of anaesthesia. She provides a well-written and excellent account of many largely, but not entirely, technical aspects of anaesthesia, and some of surgery. She takes great care to emphasize those most important but often small points which collectively, and occasionally individually, make such a difference to the comfort and safety of the patient. There is splendid advice on behaviour in the presence of conscious and semiconscious patients in the induction and postoperative care rooms, and practical comment upon such matters as the care of the patient's lips and the insertion of a needle into a vein. Miss Smith's obvious dislike of conveyor-belt systems and her dedication to the patient as an individual deserve special commendation in this age of 'turnover' and 'cost effectiveness'. The limitations of the book for the physician anaesthetist are entirely outweighed by its obvious advantages as a carefully prepared account of routine technical procedures that every junior doctor in anaesthesia should know about. Too many anaesthetists take these for granted nowadays and they are rarely described in scientific texts.

Head and Neck Surgery. By P. M. STELL, F.R.C.S., Liverpool, and A. G. D. MARAN, M.D., F.R.C.S., Dundee. 8½×6 in. Pp. 454+x. Illustrated. 1972. London: William Heinemann. £7·75.

ONE of the privileges of increasing age is that it provides an opportunity for writing textbooks and criticizing the young! Although the value of the former is doubtful, there may well be grounds for suspecting that many younger surgeons are more concerned with surgical expertise than case selection or patient care.

This particular book is in many ways exceptional. The authors are certainly youthful, although vastly experienced in the problems of head and neck surgery. In addition, they have avoided the all-too-common pitfall of producing just another 'Atlas of Surgical Techniques'.

For several years they have been jointly responsible for a highly successful surgical course and this book is largely based on the course syllabus. The first half is devoted to basic principles and the remainder to a fairly detailed and didactic account of the various operative procedures necessary for the eradication of disease in the various sites which make up the head and neck.

No claim is made that this is anything but an introduction to this particular surgical specialty, and as such it succeeds admirably. Naturally, experienced surgeons will disagree with some of the more detailed sections, for uniformity of opinion is not a characteristic of practising surgeons. However, it is all good sense, clearly written and tolerably well illustrated, considering the small pages provided by the publishers.

Buy it, read it, and read it again.

Surgical Emergencies. Diagnosis and Management. Edited by T. SCHRIRE, M.A., M.B., F.R.C.S., F.R.S.S.Afr., Cape Town. 8½ × 5½ in. Pp. 286. Illustrated. 1972. London: William Heinemann. £4·15.

THIS book is intended to give guidance to those who organize casualty departments and to give instruction to casualty officers. There are helpful suggestions concerning lay-out, equipment, and management of the casualty department. The clinical chapters are variable in their potential value to the junior casualty officers, but those on hand infections, on the repair of superficial wounds, and on the emergency care of chest and head injuries are practical. As a reference book on the casualty department shelf it merits purchase, but it has less value as a medium of basic instruction for the junior casualty officer.

Abdominal and Vaginal Hysterectomy. By S. JOEL COHEN, M.B., B.Ch., F.R.C.S., F.R.C.O.G., Johannesburg. 9¾ × 7½ in. Pp. 170 + xii, with 153 illustrations. 1972. London: William Heinemann. £3·50.

As indicated in the foreword by Sir Norman Jeffcoate, Mr. Joel Cohen is an acknowledged surgical master. In this monograph he describes his techniques of hysterectomy in considerable detail. The text is well and liberally illustrated to emphasize the relevant operative steps. Both abdominal and vaginal hysterectomies are described, with the latter being given the most space. The author makes the case for vaginal hysterectomy as the best means of removing the uterus even when there is no prolapse present. An interesting and useful 'appendix' section is housed separately inside the back cover and describes the role of the operating nursing sister. Here again the author describes in detail the 'routine' as it affects the theatre sister taking the case.

This book should be of interest both to the experienced and to the trainee in gynaecological surgery.

Bile Salts in Health and Disease. By K. W. HEATON, M.D., M.R.C.P., Bristol. 8½ × 5½ in. Pp. 252 + x. Illustrated. 1972. Edinburgh: Churchill Livingstone. £3·50.

IN 1937 Baillière, Tindall & Cox published the *Physiological Chemistry of the Bile* by H. Sobotka. This book was to become a kind of bile bible for the next 30 years, wherein could be found much information on the bile-salts in the human and in many animal species. In the past 20 years research into the physicochemical properties of the bile-salts has explained their role and that of lipoproteins in the carriage of cholesterol in the aqueous bile, thus providing a basis for the understanding of the formation of gall-stones. More recently, gas/liquid chromatography has provided the technological advances necessary for studying the enterohepatic circulation of bile-salts and hepatic bile-acid pools in health and disease, and there has been a supernoval explosion of research.

Dr. Heaton's book is about all of these developments, and includes chapters referring to his own special contribution in the role of the diseases of the intestine affecting the enterohepatic circulation of bile-acids with reference to gall-stone formation.

It is a very useful, smallish book with over 700 references, and is ideal for the specialist surgeon interested in gastro-enterology.

Functional Anatomy and Histology of the Lung. By CHUZO NAGAISHI, M.D., Kyoto. 11¾ × 8½ in. Pp. 295 + xxviii. Illustrated. 1972. Baltimore: University Park Press. $49·50.

IN this book nine eminent men in nine forewords have chosen to extol the high qualities of the author as a surgeon, scholar, and anatomist.

To break into the book one may think of an anatomical subject and then look it up. For instance, under the heading of 'The Relationship between Pulmonary and Bronchial Vascular Systems' will be found a history of investigations since 1937 to the present time. The findings are grouped and described. Controversial points are highlighted. The bearing of an anatomical or histological point upon pathology is often observed. This same thoroughness applies throughout the book. The references are full and there is a good proportion of Japanese studies fitting in with, and elaborating, those of the West. The reproduction and diagrams are excellent and there are many instructive electron-microscopy photographs. The English is good, although in a few places one may have to read the text several times to get the feel of a sentence. This is a unique and outstanding book. The reviewer is minded to repeat the words of a tourist to his wife after leaving a Botticelli room in the Uffizi: 'That room is full of very good paintings.'

Acute Inflammation. By J. V. HURLEY, M.D., Ph.D. (Melb.), F.R.C.Path., Melbourne. 8½ × 5½ in. Pp. 144 + vii. Illustrated. 1972. Edinburgh: Churchill Livingstone. £2·50.

THIS short monograph aims at describing current views on the morphology and mechanism of acute inflammation and its sequelae. It gives an admirably succinct account of these subjects including basic ultrastructural changes and recent work on the chemical control of the phenomena of inflammation. In these respects the monograph provides a most convenient summary of recent research and will be valuable to those working for examinations or merely wishing to bring their knowledge up to date. It is to be noted, however, that the book does not deal with immunological mechanisms, which are now known to be intimately concerned with the initiation and persistence of many previously unexplained phenomena in the field of inflammation.

Praktische Anatomie, Volume 1, Part 4. **Bein und Statik.** By J. LANG and W. WACHSMUTH, Würzburg. 12 × 9½ in. Pp. 473 + xii. Illustrated. 1972. Berlin: Springer-Verlag. DM.640.

IN this book the descriptive and applied anatomy of the lower limb is celebrated—perhaps that is one of the few words suitable for describing this immaculately produced volume. Even those with no knowledge of German will be impressed by the range of material covered but above all by the illustrations, many of which are among the most outstanding of all contemporary representations of the human body. There is only one snag to this beautiful example of book production—at about £80 for this one volume (or about £70 as a subscription price, for there must be several more to come to complete the whole body) even libraries will require rich uncles.

Post-prostatectomy EPSIKAPRON® is better than post-prostatectomy bleeding*

**This observation has a high degree of clinical significance.*

Post-prostatectomy blood loss may be a litre or more[1,2]. Use of EPSIKAPRON can reduce this loss by 80-90%[3,4]. "The control of blood loss has proved to be not only statistically but also clinically significant"[2]. Blood transfusion, which is costly and not without risk, ". . . can be avoided and draining catheters kept patent without difficulty and removed earlier, which makes the post-operative course smoother and shorter"[3].

EYE SURGERY

H. B. Stallard, M.B.E., T.D., M.A., M.D. (CANTAB.), M.CHIR., F.R.C.S. (ENG.), HON.LL.D. (ST. ANDREWS), *Surgeon, Moorfields Eye Hospital; Eye Surgeon, St. Bartholomew's Hospital.*

This new edition covers the whole field of eye surgery including orbital and reconstructive (plastic) surgery. The complete updating of material makes this the authoritative work for all eye surgeons.

946 pages 779 illustrations **£13·25**

TRAUMA SURGERY: EXCEPTING BONES AND JOINTS

P. Powley, M.B., B.S., F.R.C.S., *Consultant Surgeon, Swindon and District Hospital Group.*

This book is designed for hospital staff involved with the reception and initial treatment of the victims of accidents—either road or industrial. It explains in detail the various injuries to the parts of the body other than the main bones and stresses which injuries require specialist treatment from the onset.

136 pages 14 illustrations Paper Covers **£1·50**

THORACIC SURGICAL MANAGEMENT BELCHER&STURRIDGE

J. R. BELCHER, MS, FRCS
Surgeon, London Chest Hospital, Thoracic Surgeon, Middlesex Hospital and

M. F. STURRIDGE, MS, FRCS
Surgeon, London Chest Hospital, Thoracic Surgeon, Middlesex Hospital

This newly revised edition is a clearly written, simply illustrated and thoroughly practical guide for those engaged in the day-to-day management of thoracic surgical patients. With the enormous increase in the scope of cardiac surgery has come a better understanding of the principles of resuscitation and supportive management. All members of the intensive care team, as well as surgeons, will find this book of considerable value.
The authors are both well-known London chest surgeons. Mr Belcher is particularly interested in the growth of medical care in the developing countries in his own field, and has travelled widely in India, Malaysia and Indonesia on lecture and study tours.

Our head of table is unique.

The Matburn MS is a dramatic addition to our M table series, which are used in more countries throughout the world than any other operating tables.

The MS controls are grouped on a moveable selector arm at the head end to enable all major table movements to be made without disturbing the surgical team or the sterile area.

It's the most advanced table of its kind.

For further details and demonstration, please use the coupon.

INJURY

Volume 4/Number 4

The British Journal of Accident Surgery

INJURY provides a focal point of information for all those engaged in the many fields of medicine which accident surgery involves—casualty officers, surgeons concerned with all parts and systems of the body, specialists in orthopaedic and plastic surgery, anaesthetists, nursing staff in accident units, etc.
Original articles take up a large section of the journal, and contributions from all over the world are published. Book reviews, abstracts from other publications, and summaries and reports of meetings add to the wide and well-organized coverage which INJURY offers its readers.

Contents

S. Sevitt 281 Fatal road accidents in Birmingham: Times to death and their causes
O. Székely, G. Szánto, and A. Takats 294 Hyperbaric oxygen therapy in injured subjects
K. Solheim 301 Closed diaphragmatic rupture
E. O. Karaharju 307 Blunt abdominal trauma in patients with multiple injuries
R. G. Pringle 311 Missed fractures
Squadron Leader M. L. Ayres 317 Survival after suction into jet engine intake
B. M. Wroblewski 319 Trauma and the cystic meniscus: review of 500 cases
A. Uemichi, H. Iwami, E. Kakinoki, S. Ri, and S. Kohno 322 Re-implantation of severed limbs: report of two cases
V. Kumar 327 The syndrome of the fracture of the lesser trochanter in adults: a neglected aspect of the trochanteric fracture
B. N. Bailey and S. N. Desai 335 An approach to the treatment of hand burns
S. N. Deliyannis 341 Avulsion of the tibial tuberosity: report of two cases
R. J. Dinley and E. Michelinakis 345 Local anaesthesia in the reduction of Colles' fracture
P. J. Sykes 347 An unusual penetrating injury of the cheek: a case report
W. G. J. Hampson 351 A simple instrument designed to simplify measurement of required nail length during fixation of a fractured neck of femur
J. R. Schetrumpf 352 A combined retractor and sucker with built-in clearing device for spinal surgery
W. G. Everett 354 Traumatic lumbar hernia
Mark Flynn 357 Disruption of symphysis pubis while horse riding: a report of two cases

THIRD EDITION RECENTLY PUBLISHED

A Short Textbook of Surgery

Selwyn Taylor, DM, MCh, FRCS, Dean, Royal Postgraduate Medical School, and Surgeon, Hammersmith Hospital.
L. T. Cotton, MCh, FRCS, Surgeon, King's College Hospital.

The contents of this book represent a broad conspectus of surgery as it is practised today, based on physiological and pathological principles. Surgery in all its aspects is a rapidly changing subject, and although it is only four years since publication of the last edition, extensive rewriting has been required to bring the book up to date. Subjects such as the treatment of shock have been completely rethought and new theories and methods of management are fully dealt with in this new edition. The newcomer to surgery will find it a splendid introduction to the subject.

Dexon* alone can replace 75% of the various sutures used in most procedures.

When a Dexon* suture replaces a suture combination (catgut, silk, nylon) the overall cost is less.

Using Dexon* sutures can eliminate most post-operative care obligatory with other suture materials with obvious cost savings.

You can prove these savings for yourself.
Ask your Theatre Superintendent to get full details from your Dexon* representative, or write to Mr. D.G.Codrai.

Dexon*-the everyday suture.

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX. Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·83	£3·70	£4·27	£5·70	£5·69	£6·32	£7·74	£8·99
4	3·58	5·19	6·09	7·12	8·07	9·09	10·97	12·97

10/12	9·32	12·72	15·09	17·72	20·34	22·97	28·40	33·05
14/16	10·37	14·34	17·47	20·59	23·72	27·03	33·18	39·55
18/20	14·62	19·47	23·47	27·47	31·78	35·93	44·05	50·89
COVERS	1·94	2·75	3·57	4·38	5·19	6·00	7·63	9·25

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX*. Remittances should be made payable to *The British Journal of Surgery*.

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House,* 159 *Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

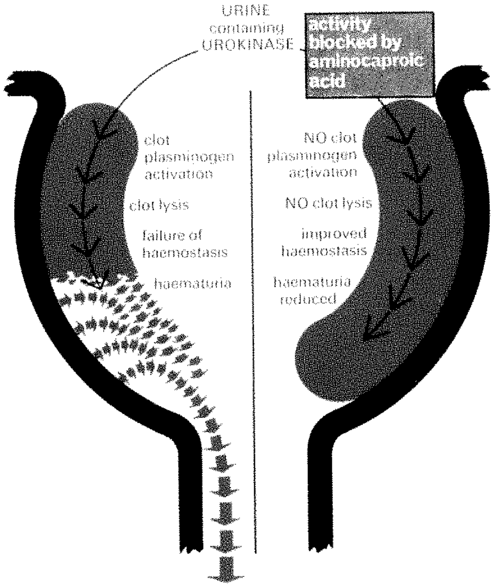
TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

The mechanism of post-prostatectomy bleeding and EPSIKAPRON® control



URINE containing UROKINASE
activity blocked by aminocaproic acid
clot plasminogen activation
clot lysis
failure of haemostasis
haematuria
NO clot plasminogen activation
NO clot lysis
improved haemostasis
haematuria reduced

Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing:

the need for post-operative blood transfusion
clot retention
catheterization
the risk of infection
the period of hospitalization

Presentation

Epsikapron Solution for Injection 0.4 g/ml Box of 6 ampoules of 10 ml, each containing 4.0g aminocaproic acid (0022/5003) Epsikapron Effervescent Powder 50% Box of 30 sachets, each containing 3.0g aminocaproic acid (0022/5004) Epsikapron Syrup 0.3g/ml Bottle of 250ml (0022/5005)

INTRA-UTERINE [illegible]

Enables uterine contents to be removed by suction applied through a wide aperture, swivelling curette which can be rotated freely through 360°, without kinking the flexible suction tubing, to facilitate sweeping of the whole of the intra-uterine surface. A perforated basket within the suction bottle retains the aspirated tissues clear of blood to be immediately visible for identification. F171–03 Down's Intra-Uterine Suction device with pump for abortion by Intra-Uterine suction, as illustrated. F171–08 to F171–14 suction curette, 8 mm, 10 mm, 12 mm and 14 mm for use with above apparatus.

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND

1974 MOYNIHAN PRIZE

The Association of Surgeons of Great Britain and Ireland is offering a Moynihan Prize of £100, together with a Medal, for the best short paper (12 minutes) on new work delivered at the Annual Meeting in Aberdeen from April 3rd–5th, 1974. All authors should have been qualified for less than fifteen years. In the case of multiple-author papers, the Medal will be presented to the person reading the paper, and the award may be divided between the authors.

Any Fellow or Associate Fellow wishing to submit or to sponsor a short paper for this Prize is asked to send the title, together with ten copies of an abstract, to the Honorary Secretary, Association of Surgeons of Great Britain and Ireland, at The Royal College of Surgeons, 35/43 Lincoln's Inn Fields, London, WC2A 3PN, *by* 30 *October*, 1973. He should also give the date of qualification of the author or authors.

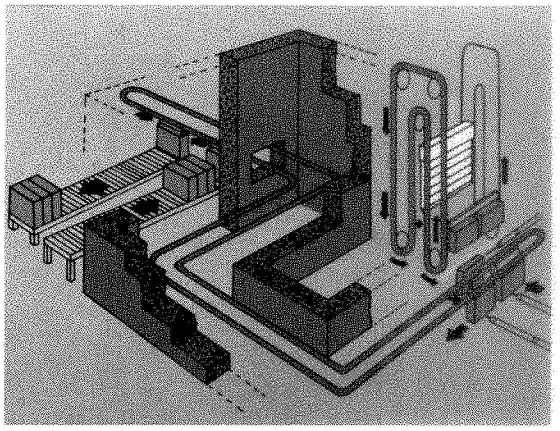
If selected, competitors will be required to submit a manuscript suitable for publication four weeks before the Meeting. All papers which are delivered at the Meeting will be published in the *British Journal of Surgery* in the following October.

August, 1973.

GUY BLACKBURN,
Honorary Secretary.

Jean Miller is a calculating killer

Jean sends ETHICON products on a journey from which no living thing can return. It is a 12-hour tour of our irradiation area where the gamma rays from a Cobalt 60 source penetrate every suture and its packaging.



The dosage, meticulously controlled at 2·5 megarads, means certain death to every known form of microbic life.

Since the sutures are already sealed inside their packaging before irradiation, they cannot possibly be recontaminated when they emerge from the treatment.

ETHICON were the first to use Cobalt 60 for the sterilization of surgical sutures. It gives the most certain approach to perfection in sterilization.

And nothing less is good enough for ETHICON or the surgeons whom they serve.

ETHICON

ETHICON LIMITED, SCOTLAND

Tissue approximation needs ETHICON precision

Tolerances for ETHICON sutures range from 0·0002″ (for gauge conformity in natural catgut) to 0·0001″ (for 6 mm micro-surgical needles). For every ETHICON suture is shaped by the needs of the surgeon. It is our concern to meet these needs with precision.

ETHICON
Surgical Gut

Dependable strength and absorption properties. Chromic and plain gut presented for every field of surgery.

ETHICON
MERSILK.*

BRAIDED SILK

Silk made to exacting surgical specifications. In many sterile presentations, including 80 MERSUTURES* Eyeless Needled Sutures.

ETHICON
Surgical Linen Suture

Specially prepared for maximum strength and knot security.

ETHICON

Important New Editions

EYE SURGERY. 5th Edition

H. B. Stallard, M.B.E., T.D., M.A., M.D. (CANTAB.), M.CHIR., F.R.C.S. (ENG.), HON.LL.D. (ST. ANDREWS), *Surgeon, Moorfields Eye Hospital; Eye Surgeon, St. Bartholomew's Hospital.*

This new and completely re-designed edition covers the whole field of eye surgery including orbital and reconstructive (plastic) surgery. Complete updating of material with an individual selective approach to operative procedures rather than a general survey of the possible techniques makes this the authoritative work for all eye surgeons. Postgraduates will find it fully covers their needs. As a reference book it should be in every library.

A MANUAL OF ANAESTHETIC TECHNIQUES. 4th Edition

W. J. Pryor, M.B., CH.B. (N.Z.), F.F.A. R.C.S. (ENG.), D.A. (ENG.), F.F.A. R.A.C.S., *Anaesthetist, Christchurch Hospital, New Zealand,* and D. C. T. Bush, V.R.C., M.B., CH.B. (N.Z.), D.A. (ENG.), F.F.A. R.A.C.S., *Anaesthetist, Christchurch Hospital, New Zealand.*

Amongst the new sections added to this completely revised edition are neurolept-analgesia and dissociative anaesthesia. This should be of great interest to house surgeons, anaesthetic registrars, and those in need of specialized information.

424 pages 123 illustrations **approx. £7·00**

Important New Book

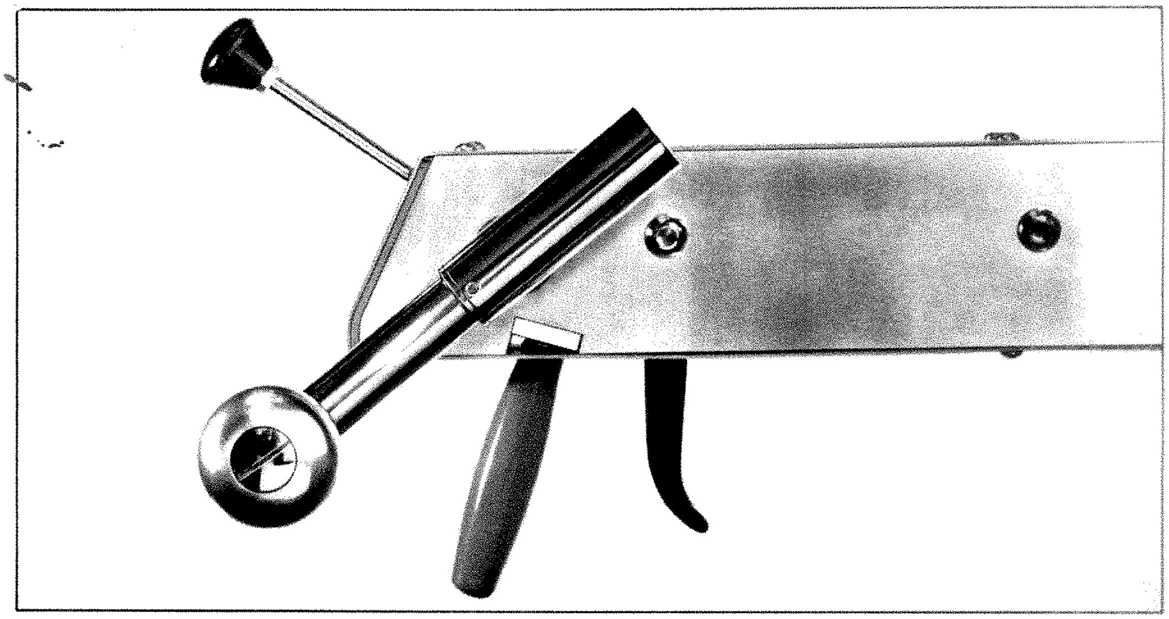
COMMON SURGICAL EMERGENCIES

C. B. Williams, M.D., F.R.C.S., *Senior Registrar in General Surgery, United Bristol Hospitals.*

This book is designed to provide the information needed for the 'on the spot' management of surgical emergencies. It also includes a list of drugs in common use under these conditions.

156 pages Illustrated **£1·50**

JOHN WRIGHT & SONS LTD., BRISTOL, ENGLAND BS8 1EX



Our head of table is unique.

The Matburn MS is a dramatic addition to our M table series, which are used in more countries throughout the world than any other operating tables.

The MS controls are grouped on a moveable selector arm at the head end to enable all major table movements to be made without disturbing the surgical team or the sterile area.

It's the most advanced table of its kind.

For further details and demonstration, please use the coupon.

Fight cancer with a will

When testators ask your advice, please remind them of the urgent work of the Imperial Cancer Research Fund. In the Fund's up-to-date laboratories trained minds are using every weapon of modern science to fight all forms of cancer, including leukaemia.

Now one of the world's great research centres, the I.C.R.F. relies entirely on public support. The cancer problem *must* be solved. Please help now.

Patron:
H.M. THE QUEEN
President:
The Honourable Angus Ogilvy

Form of Bequest

I hereby bequeath the sum of.................pounds free of duty to the Imperial Cancer Research Fund, Lincoln's Inn Fields, London, WC2A 3PX for the purpose of scientific research, and I direct that the receipt of the Honorary Treasurer or Secretary shall be a good discharge for such legacy.

Please write for further information to: The Secretary, I.C.R.F. (Dept 164),
PO Box 123, Lincoln's Inn Fields, London WC2A 3PX

ORIGINAL PAPERS

THE EFFECTS OF INTRAVENOUS AND INTRADUODENAL FEEDING ON NITROGEN BALANCE AFTER SURGERY

By J. T. HINDMARSH* and R. G. CLARK

UNIVERSITY DEPARTMENTS OF CHEMICAL PATHOLOGY AND SURGERY, ROYAL INFIRMARY, SHEFFIELD

SUMMARY

To assess the value of nutrition in the first week after surgery, total nitrogen balance was determined in three groups of patients (two experimental, one control) undergoing vagotomy and pyloroplasty from 1 day before to 8 days after operation. In the experimental groups nutrition was maintained postoperatively by the intravenous route in one and intraduodenally in the other at a level adequate for normal non-postoperative subjects. Water and electrolyte intakes were similar in the three groups, but patients in the control group received no calories or nitrogen in the immediate postoperative period.

With respect to nitrogen economy, the group fed largely by the intraduodenal route fared best. Nevertheless, nitrogen balance did not reach equilibrium until day 5 in any group, probably indicating a relative increase in protein catabolism in the early postoperative period.

MANY investigators have shown that the administration of calories and protein derivatives to patients in the immediate postoperative period can reduce the negative nitrogen balance consequent upon the operative procedure, although the extent of the reduction has varied considerably. There is also controversy whether the intravenous (i.v.) or the intraduodenal (i.d.) route is the better way to feed the postoperative patient. Thus, Koop, Riegel, Grigger, and Barnes (1947) reported that nitrogen is more readily spared postoperatively when nutrients are given i.d., whereas Abbott and Albertsen (1963b) took the opposite view. Many factors, including age (Walker, Watt, Morgan, and Parker, 1971), sex (Abbott and Albertsen, 1936a), body-weight, debilitating disease, postoperative complications, degree of surgical trauma (Moore and Ball, 1952), and environmental temperature (Campbell and Cuthbertson, 1967), are known to affect the metabolic response to trauma.

In the present study of nitrogen balance postoperatively we compared results of feeding by the i.v. and i.d. routes, eliminating as far as possible any intergroup differences possibly attributable to factors known to affect the metabolic response. Thus only healthy male subjects undergoing one particular operation were studied, they were matched by age and weight, and the same surgeon performed all the operations. Any subject in whom postoperative complications developed was excluded from the study.

PATIENTS AND METHODS

The subjects of our study, who were undergoing total perabdominal vagotomy and Heineke-Mikulicz pyloroplasty for chronic duodenal ulceration, were nursed at an ambient temperature of 23 ± 2° C. and a relative humidity of 40–60 per cent. They were divided into three groups (two experimental and one control) which were closely matched by such factors as age ($P > 0{\cdot}2$, Kruskal-Wallis test) and weight ($P > 0{\cdot}2$, t-test). The study consisted of nine balance periods, each of 24 hours' duration, starting at 8 a.m. on the day before operation (day -1) and ending at 8 a.m. on day 8.

Group 1 (8 patients).—Nutrition was given i.v. only during the first 3 days postoperatively (days 1–3), then partly i.d. and partly by mouth during days 4–6, the amount of the i.d. infusion being reduced and of the oral diet increased so that by day 7 feeding was wholly oral with a diet similar to that taken on the day before operation (day -1). The parenteral nutrients used were Aminosol 10 per cent (a casein hydrolysate), Intralipid 10 per cent, and fructose and

glucose solutions. The amino-acid solution and fat emulsion were infused simultaneously into a T-piece attached to an i.v. cannula; heparin (1000 U. per 500 ml.) was added to the former solution immediately before infusion in order to hasten fat clearance. Intraduodenal infusions were given via a gastrostomy tube (Kay, 1964) inserted at operation.

* Including energy potentially derived from protein and its derivatives.

Group 2 (7 patients).—The diet was given entirely by i.d. infusion during days 1–3, employing a jejunostomy feed of our own composition (Hindmarsh, 1971). Feeding was as in group 1 during days −1 and 4–7.

Group 3 (11 patients).—The patients in the control group had a water and electrolyte intake similar to that in the experimental groups throughout the study. They received no calories or nitrogen during days 1–3 but increasing amounts of these on days 4–6. On day 7 solely oral feeding was re-established with a diet similar to that taken by all the patients on day −1.

The water, Na, and K intake of all three groups and the calorie and nitrogen intake of the two experimental groups differed only in relation to the difficulty in arranging dietary régimes containing the desired amount of each substance; for example, the large Na content of Aminosol meant that group 1 received more of this ion than did the other groups on days 1–3. The calorie, water, nitrogen, Na, and K intake of patients in the experimental groups were maintained postoperatively at levels sufficient to produce equilibrium or a positive balance when given by mouth to resting, non-traumatized patients (*Table I*). For ease of management all the patients in any one group received the same feeding régime without any attempt to relate intake to individual body-weight. Mean energy and nitrogen intakes per kg. of body-weight were 30·6 Cal. and 180 mg. respectively in group 1 and 30·2 Cal. and 163 mg. in group 2.

Total nitrogen losses were determined in the urine, faeces, and gastric aspirates. We measured Na and K in the faeces and gastric aspirates and faecal fat to determine the proportion of feed given i.d. lost by these routes. The gastric aspirates of all the patients who were fed i.d. were inspected for cloudiness as an extra check that the feed had not refluxed. Urine carbohydrate losses also were measured throughout the study.

Total nitrogen was measured by the micro-Kjeldahl method (Varley, 1967a), Na and K by flame photometry (Varley, 1967b), and faecal fat by the method of van de Kamer, Huinink, and Weyers (1949). The daily nitrogen balance was calculated by subtracting from the intake the nitrogen losses in the urine, faeces, and gastric aspirate, and the cumulative nitrogen balance of each patient was calculated by totalling his daily nitrogen balances. Group mean daily and cumulative nitrogen balances were calculated.

RESULTS

The negative nitrogen balance was smaller in the groups fed postoperatively than in the control group in the early postoperative period (*Table II*). However, neither group 1 (i.v.) nor group 2 (i.d.) achieved nitrogen equilibrium at this time despite their receiving nitrogen and calorie intakes that were adequate in all three groups the day before operation. Group 2 fared somewhat better than group 1 with respect to nitrogen economy, the mean daily negative nitrogen balances of the former being somewhat less than those of the latter during days 1–3; the difference was highly significant ($P < 0·001$) on day 2. The differences between the nitrogen balances of the three groups are clearly apparent in their mean daily cumulative nitrogen balances (*Fig.* 1); with respect to nitrogen economy, group 2 fared best, group 1 achieving an intermediate position between group 2 and group 3 (control).

In all three groups only small amounts of carbohydrate (mean $\leqslant 3·2$ g. per day) were recovered from the urine, and Na and K losses in the gastric aspirates and Na, K, and fat losses in the faeces were slight. These findings have been reported in detail (Hindmarsh, 1971).

DISCUSSION

The studies of Cuthbertson (1930, 1932, 1936) in the United Kingdom and Howard, Winternitz, Parson, Bigham, and Eisenberg (1944) and Howard, Bigham, Eisenberg, Wagner, and Bailey (1946) in the United States showed that after such major trauma as fracture of the long bones the administration of normally sufficient amounts of nitrogen and calories did not prevent a negative nitrogen balance at the height of the catabolic phase. Furthermore, even increasing the daily intake of calories to 5400 and of nitrogen to 34 g. did not invariably produce nitrogen equilibrium. At the other extreme Krieger, Abbott, Levey, and Holden (1958) and Abbott, Levey, and Krieger (1959) reported that in some of their female patients nitrogen equilibrium was maintained after relatively minor trauma, such as cholecystectomy, on as little as 170 mg. of nitrogen per kg. of body-weight and about 23 Cal. per kg. per day. After partial gastrectomy, nitrogen equilibrium was achieved over a 5-day period with the i.v. administration of about 270 mg. of nitrogen and 35 Cal. per kg. per day (Abbott and Albertsen, 1936a, b).

Data from 23 published studies of the effect of calorie and nitrogen administration on nitrogen balance in the immediate postoperative period are summarized in *Fig.* 2, which relates daily nitrogen intake to nitrogen balance at three levels of calorie intake. In most cases the charted nitrogen balance is the cumulative balance of days 0–3. When calorie and nitrogen intakes were not related to body-weight and the weight was not stated, we assumed a weight of 70 kg. for men and 60 kg. for women. Most of these patients were fed i.v. and a few intrajejunally or orally. Data from patients undergoing such minor operations as inguinal herniorrhaphy or very traumatic surgery were excluded; therefore, the results shown relate to surgery levels 3–6 in the trauma scale (Moore and Ball, 1952), mostly level 3 or 4. The regression lines cover only reported values, i.e., they were not extrapolated. All of the correlation coefficients showed a highly significant relationship ($P < 0·001$) between daily nitrogen intake and nitrogen balance.

Analysis of the data from which *Fig.* 2 was constructed shows that an intake of less than 20 Cal. per kg. of body-weight per day never provided equilibrium in males or females. With an energy intake of 20–40 Cal. per kg. per day, nitrogen equilibrium could be achieved with a nitrogen intake

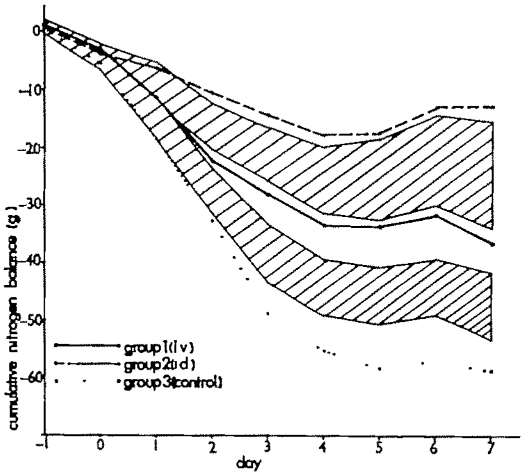

FIG. 1.—Mean daily cumulative nitrogen balances in the three groups. Shaded areas indicate the range of 2 S.D. of the mean differences. (Where the lines that join the means are outside these areas, the means are significantly different ($P < 0·05$).)

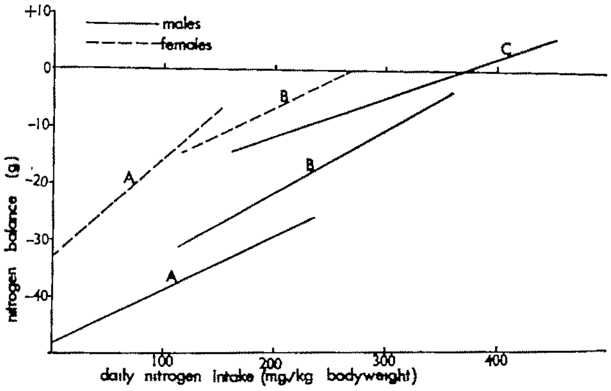

FIG. 2.—The relationship between the reported daily nitrogen intake and nitrogen balance after surgery at three energy intakes: A, <20; B, 20–40; and C, >40 Cal. per kg. of body-weight per day.

Data from the following studies were employed to construct the figure: Brunschwig, Clark, and Corbin, 1942; Gardner and Trent, 1942; Mulholland, Co Tui, Wright, and Vinci, 1943; Co Tui, Wright, Mulholland, Carabba, Barcham, and Vinci, 1944; Werner, 1947; Riegel, Koop, Drew, Stevens, and Rhoads, 1947; Wilkinson, Billing, Nagy, and Stewart, 1950; Beal, Cornell, and Gilder, 1954; Van Itallie, Moore, Geyer, and Stare, 1954; Abbott, Davis, Benson, Krieger, and Levey, 1955; Abbott and others, 1957; Beal, Payne, Gilder, Johnson, and Craver, 1957; Holden, Krieger, Levey, and Abbott, 1957; Krieger, Abbott, Levey, and Holden, 1957; Levey, Krieger, Benson, Davis, and Abbott, 1957, Krieger and others, 1958; Abbott and others, 1959; Gilder, Moody, Cornell, and Beal, 1961; Abbott and Albertsen, 1963a, b; Brøckner, Larsen, and Amris, 1964; Larsen and Brøckner, 1965; Johnston, Marino, and Stevens, 1966.

of about 280 mg. in females and probably about 400 mg. per kg. per day in males. It would be unwise, however, to assume from these data that nitrogen equilibrium postoperatively can be achieved with a lower nitrogen intake in females than in males; most of the females had undergone cholecystectomy, whereas most of the males had had partial gastrectomy or a similar operation, and it is possible (although unlikely) that the former operation is less traumatic than the latter. With an energy intake greater than 40 Cal. per kg. per day, nitrogen equilibrium could be achieved in males given 370 mg. of nitrogen per kg. daily; no female subjects reached this energy intake.

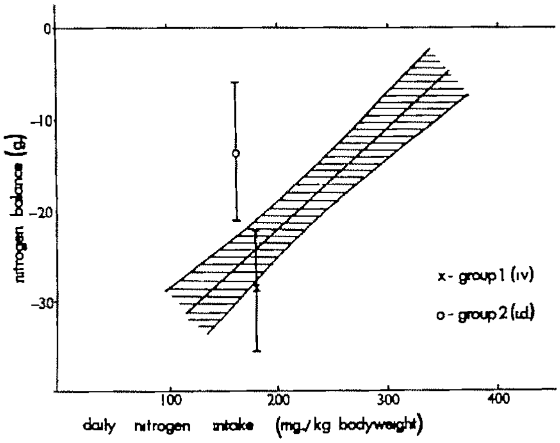

FIG. 3.—Cumulative nitrogen balance in groups 1 and 2 during days 1–4 compared with the regression line (from *Fig.* 2) of the relationship between daily nitrogen intake and postoperative cumulative nitrogen balance of male patients with an energy intake of 20–40 Cal. per kg. of body-weight per day. Bars indicate the range of ±2 S.E.M., shaded area encloses the 95 per cent confidence limits of the regression line.

We compared the results obtained in our groups 1 and 2 with the reported results for male subjects in the early postoperative period (*Fig.* 3). Because nutrition was not given to patients in the present groups 1 and 2 on day 0, the cumulative nitrogen balances shown are those of days 1–4 only. Only group 1 (Aminosol i.v.) values are close to the regression line constructed from the other authors' reports, group 2 (i.d.) values evidencing significantly more nitrogen sparing ($P < 0{\cdot}05$).

Although Krieger and others (1958) and Abbott and others (1959) showed that nitrogen equilibrium could be maintained in some subjects, particularly females after cholecystectomy, on as little as 170 mg. of nitrogen and 23 Cal. per kg. of body-weight per day, and Spivey and Johnston (1972) and Johnston (1972) reported this state postoperatively on 240 mg. of nitrogen and 40 Cal. per kg. per day, in most previous studies (*Fig.* 2) equilibrium could not be achieved on an intake adequate for normal non-postoperative circumstances. As the results of our group 1 were close to the regression line constructed from the results of previous studies, this group is used as an example of the 'typical' patient in the subsequent discussion.

A possible explanation for our failure to achieve postoperative nitrogen equilibrium in group 1 could be that trauma increases energy requirements temporarily; if so, a normally adequate calorie intake would result in an energy deficit and impaired nitrogen utilization. Cuthbertson (1932) and Cope, Nardi, Quijano, Rovit, Stanbury, and Wight (1953) stated that basal metabolism increases after trauma, including surgery. However, Kinney, Zarem, and Rogers (1959), Kinney (1960), and Levey, Czarnecki, Krieger, and Abbott (1960) have shown that, although basal energy expenditure increases by about 10 per cent after operations similar to those undergone by our patients, total energy expenditure differs little from the 'normal' amount of healthy males at rest (about 2000 ± 200 Cal. per day) because of reduced activity in the early postoperative period. Therefore, the daily intake of 2100 Cal. by our group 1 patients should have been sufficient to meet their postoperative energy requirements.

It could be argued that the infused fat emulsion or carbohydrate may not have been properly utilized. This is unlikely to be the case since infused Intralipid is well utilized by man (Reid, 1967a, b); further, there can be no question about the metabolism of fructose and glucose, and there were no excessive losses of these carbohydrates in urine. However, nitrogen equilibrium was not achieved, which leads us to question whether these patients' nitrogen intake was adequate.

To have reasonable certainty of nitrogen equilibrium from an oral diet a healthy adult male should receive not less than 850 mg. of good-quality protein (136 mg. of protein nitrogen) per kg. of body-weight per day, the protein calories providing between 7 and 15 per cent of the total energy intake (Davidson and Passmore, 1969). Our group 1 patients (i.v. feeding) had a daily nitrogen intake of about 180 mg. per kg. (nitrogen calories = 15 per cent of the total energy intake) postoperatively. *Fig.* 3 indicates that, assuming proportionally increased utilization, approximately twice this intake would have been required to achieve equilibrium.

Four possible explanations for the apparently greater nitrogen requirements of these postoperative patients than of normal subjects are:—

1. The protein derivative Aminosol might not be of high biological value. If this were the case it would be utilized inefficiently.
2. Aminosol infusion might be associated with high urinary losses of amino-acids and/or peptides.
3. Nutrients given parenterally might be less efficiently utilized than their counterparts given orally.
4. Nitrogen catabolism might be increased relative to anabolism postoperatively.

1. Biological Value of the Infused Protein.—Aminosol and most of the amino-acid preparations employed in the studies cited in *Fig.* 2 are casein hydrolysates whose composition differs little from the reference pattern adopted by the F.A.O./W.H.O. (1965) as ideal for human nutrition. Therefore, it is unlikely that the amino-acid composition of Aminosol was responsible for the negative nitrogen balance in group 1.

2. Urinary Loss of Amino-acids and Peptides.—The greater loss of α-amino-nitrogen by group 1 than by group 2 patients amounted to only about 2·5 per cent of the nitrogen infused (Hindmarsh, 1971).

Urinary peptide losses were not specifically measured, but in other studies in which Aminosol was infused at a similar rate urinary peptide-amino-nitrogen losses amounted to less than 7 per cent of the total amino-nitrogen infused (Lidström and Wretlind, 1952; Póka, Csóka, Czirbusz, Foldi, and Tőrők, 1967). Therefore, these losses can be discounted as a major cause of the negative nitrogen balance in group 1. This applies also to the studies analysed in *Fig.* 2, most of these patients having received nitrogen in the form of Aminosol or Amigen. Abbott, Krieger, Holden, Bradshaw, and Levey (1957) reported that patients given 12·5 g. of nitrogen i.v. daily as Amigen excreted only 6–12 per cent unchanged in the urine.

3. Comparative Utilization of Nitrogen given Orally and i.v.—Normal daily calorie and nitrogen requirements of healthy resting subjects fed orally and those fed i.v. may be different. Few studies have been made of normal subjects fed wholly parenterally, but Artz and Williams (1957) showed that their resting normal subjects were easily maintained in nitrogen equilibrium by the daily i.v. administration of 1600 Cal. and 13·6 g. of nitrogen. Results obtained in the present group 2 provide further evidence that poor utilization of nutrients given parenterally is not the only factor responsible for the lack of nitrogen equilibrium; these patients failed to achieve nitrogen equilibrium while being fed i.d. in the early postoperative period (although this was achieved with an identical diet given i.d. some 6 weeks later (Hindmarsh, 1971)).

It is not certain whether the calorie : nitrogen ratios of the diets contributed to the different nitrogen excretion rates of the group 1 and group 2 patients. The diet ratio (Cal. per g.) of the former group on days 1–3 was 168 : 1 and of the latter was 185 : 1. Calloway and Spector (1954) showed that optimal nitrogen utilization could be achieved when the diet ratio exceeded about 170 : 1, and Dudrick and Ruberg (1971) considered a ratio of 150 : 1 sufficient for optimal assimilation of nitrogen given i.v.; therefore our different diet ratios should not have had this effect. It may be, however, that the postoperative patient requires a greater calorie : nitrogen ratio, and that a minimum of 200 : 1, as used by Spivey and Johnston (1972), might have reduced the difference in nitrogen excretion by our two experimental groups. Alternatively, nitrogen may be better utilized when given as whole protein than as individual amino-acids and small peptides (Rose, Coon, and Lambert, 1954), or the calorie : nitrogen ratio may need to be greater for i.v. than for oral feeding to produce equivalent nitrogen assimilation. Part of the difference in nitrogen losses in groups 1 and 2 could be attributed to the Aminosol-induced urinary excretion of amino-acids and peptides. However, the subtraction of 10 per cent of the total nitrogen excretion of group 1 to allow for this loss (Lidström and Wretlind, 1952; Póka and others, 1967) still gave figures greatly in excess of those in group 2 patients during days 1 and 2.

4. Comparative Nitrogen Catabolism and Anabolism in the Immediate Postoperative Period.—Normal subjects on an energy-sufficient but nitrogen-free diet lose about 7 g. of nitrogen per day, largely in the urine (Calloway and Spector, 1954). This 'endogenous nitrogen loss', which results from the irreversible breakdown of some proteins during cellular metabolism, must be countered in the diet if nitrogen equilibrium is to be maintained. If the breakdown rate of tissue protein is increased, endogenous nitrogen losses and, therefore, the minimal daily nitrogen requirement will increase. There is much evidence to suggest that this is the case after trauma. Thus, in their experiments with ^{15}N-labelled glycine, Levenson, Braasch, Mueller, and Crowley (1959) showed that the rate of catabolism of plasma protein was increased after burning in the rat, and others have reported similar findings in man (Owen, 1967; Davies, Liljedahl, and Birke, 1969; Davies and Liljedahl, 1970). Further, an increased loss of isotopically labelled nitrogen from muscle protein containing the label in dogs and rats after burns and surgical operations has been reported (Levenson, Pulaski, and Del Guerico, 1964; Muto, Koyama, Kagamihuchi, Hara, Sekiya, and Sakai, 1967).

An increase in protein catabolism relative to anabolism seems, therefore, the most likely explanation for our failure to achieve nitrogen equilibrium postoperatively in the experimental groups, although the somewhat less efficient utilization of nutrients given intravenously than intraduodenally no doubt contributed to the greater negative nitrogen balance in group 1 (Aminosol i.v.).

Acknowledgements.—We are grateful to Paines & Byrne, Ltd., Greenford, Middlesex, for supplies of Aminosol and Intralipid; to Mr. R. A. Dixon, Sheffield University, and Dr. K. L. Weldon, Dalhousie University, for help with the statistics; to Miss Norma Lauder, departmental dietitian, for help with the diets; and to Miss U. F. Matthews, Director of the Editorial Service to the Faculty of Medicine, Dalhousie University, for assistance with the manuscript. The Endowment Fund of the United Sheffield Hospitals kindly gave us financial help.

THE USE OF THE ARTERIAL SLING TOURNIQUET IN SURGICAL PRACTICE

By D. C. DUNN

DEPARTMENT OF SURGERY, UNIVERSITY OF CAMBRIDGE

SUMMARY

An inflatable sling tourniquet has been developed to control arteries during surgical procedures and has been assessed clinically and experimentally. It has been found to give precise and reliable control over normal and arteriosclerotic arteries and to be extremely atraumatic in practice. It is particularly useful when catheters or shunts are to be passed up the occluded artery.

THE danger of applying a conventional clamp across an atheromatous artery is well recognized by arterial surgeons. Unless a satisfactory 'soft' portion of the artery can be found there is a danger of cracking an intimal plaque with a risk of subsequent thrombosis or dissection.

The design of present metal clamps allows a high pressure to be exerted on a narrow area of artery and only permits deformation of the artery in one direction. It is flattened from side to side between the clamp blades.

Clamps designed specifically to be atraumatic to diseased arteries have been described previously by Brown (1961) and Fogarty, Raible, and Krippaehne (1966). These authors discussed the specifications for the ideal arterial clamp and suggested designs which fulfil these.

The idea of using an inflatable sling to control arteries during clinical surgery has already been published (Dunn, 1971). A number of prototype slings have now been manufactured and used clinically over the past 2 years. They consist of an elongated balloon with a stiff backing which is threaded around the artery and secured by passing a ring around the two ends. The balloon is inflated through a tube attached to one end using a medical syringe. The stiff backing results in the inflated balloon compressing the artery in the line of least resistance (*Fig.* 1).

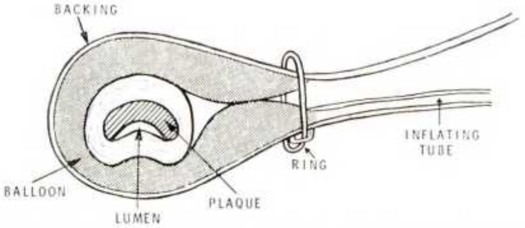

FIG. 1.—Tourniquet applied to an arteriosclerotic artery. Inflation occludes the lumen without cracking the intimal plaque.

The tourniquet has significant advantages over other clamps in that it is cheap and easy to manufacture and has no fixed 'side-to-side' occlusion plane and no handles protruding in the wound.

MATERIALS AND METHODS

Experimental Assessment.—In one experiment in a dog the sling was applied to the upper aorta and a conventional Atraugrip clamp (Down Bros., London) below it, and an arteriotomy was made between them, Both clamps were then applied at maximum pressure and the aorta was then removed and examined.

In a rabbit a miniature tourniquet and a clamp were applied to the aorta with sufficient pressure just to control the blood-flow in the isolated segment as assessed by making an arteriotomy between them. The clamps were left in place for 30 minutes, during which time the animal was heparinized to prevent distal thrombosis. The arteriotomy was then closed and the heparin reversed with protamine. Twenty-four hours later the segment of aorta was removed and examined microscopically for signs of damage and thrombus formation.

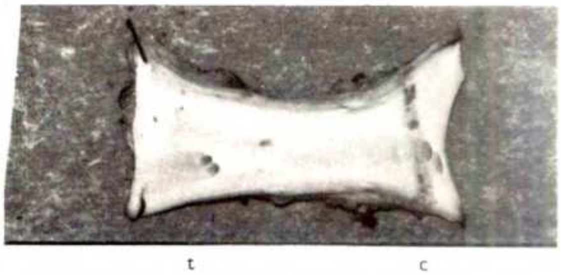

FIG. 2.—Dog's aorta removed after occlusion by both a clamp (c) and a tourniquet (t). The metal clamp has bruised the artery lining. The tourniquet has left no mark.

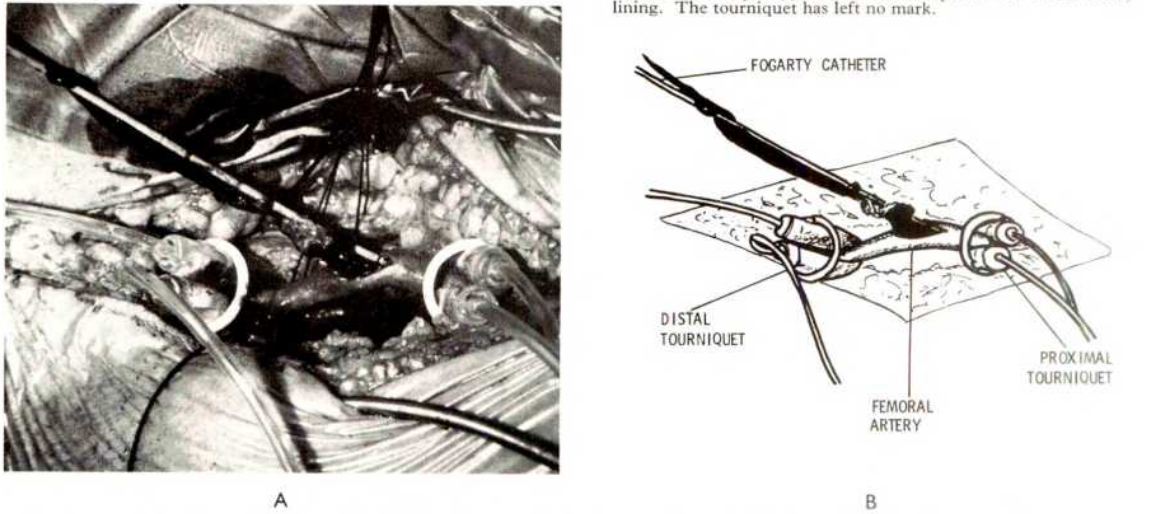

FIG. 3.—Femoral artery embolectomy. The assistant deflates the proximal tourniquet to allow the passage of the thrombus. Control is complete throughout the procedure.

Clinical Assessment.—The sling has been used in place of conventional clamps in five kidney transplant operations (where it was applied to the external iliac artery above the arterial anastomosis), in two femoral artery embolectomies, and in three operations for arterial insufficiency due to atheromatous disease. One of the renal transplant patients had severe atheromatous disease of the external iliac artery at the site of occlusion.

The sling was also assessed by applying it to an atheromatous artery removed from a limb after amputation for distal gangrene. The way in which it compressed the artery was observed and the degree of control was assessed by forcing saline under pressure through the artery.

RESULTS

Experimental.—The aorta of the dog is shown in *Fig.* 2. The injury due to the clamp is clearly seen. Histology was non-contributory as pathological changes did not have time to develop.

In the rabbit experiment the aorta was removed 24 hours after clamping. The mark of the conventional clamp was clearly seen with fresh red mural thrombus attached to it. There was no mark or thrombus at the tourniquet site. Histology showed an area of complete necrosis of the whole arterial wall at the site of the conventional clamp. There was neutrophil polymorph infiltration at this point and haemorrhage into the adventitia. At the tourniquet site there were occasional dead cells visible in the media with a few polymorphs between the medial fibres. No other evidence of necrosis of the arterial wall was seen. Some adventitial haemorrhage was noted.

Clinical.—Satisfactory and reliable control of the vessels was achieved in all the cases, even in the presence of atheroma.

The renal transplant patient with atheromatous disease of the external iliac vessel died 23 days postoperatively from myocardial infarction. Post-mortem examination of the iliac artery confirmed the presence of brittle plaques of atheroma in the iliac vessel at the clamp site. These were undamaged. Other arteries which had been occluded showed no signs of damage either at operation or postoperatively.

The sling had marked advantages over conventional clamps in femoral artery embolectomy (*Fig.* 3). The Fogarty catheter could be passed through the occluded artery and haemostasis maintained during embolectomy by inflating the sling and compressing the arterial walls on to the catheter. The degree of control and 'grip' on the catheter could be precisely controlled by the assistant with the inflating syringe.

Four different surgeons found the sling easy to apply. Slightly more arterial length had to be mobilized than for a conventional clamp. The absence of protruding clamp handles which could catch on arterial sutures was appreciated. The tourniquet was rather bulky but this did not present serious difficulties. Early models tended to slide along the artery in the direction of the blood-flow, but the addition of roughening to the surface of the balloon has largely overcome this difficulty. In the experimental situation loss of control due to accidental deflation of the balloon proved easy to overcome by pulling on the sling until a conventional clamp could be applied. The deflated sling gives the same degree of control as the conventional rubber sling has done in the past. The balloon is tough and not easy to penetrate with a suture needle. Once the anastomosis was completed the blood-flow through the artery could be precisely controlled by an assistant applying pressure to the inflating syringe. This made any leaks in the suture line easy to identify and close by suture without excessive blood-loss.

Application of the clamp to an excised atheromatous artery confirmed that the artery was satisfactorily occluded and compression did not split the intimal plaque.

DISCUSSION

The clinical and experimental work described in this paper confirms that the arterial sling tourniquet can satisfactorily control blood-vessels and is much less traumatic than conventional arterial clamps. It has been shown that the sling can occlude atheromatous arteries both gently and securely without damaging them.

The disadvantages of the instrument, namely that it is more bulky than a normal clamp, requires more mobilized length of artery for its application, and has a less fierce grip on the arterial wall, are much outweighed by its advantages. It is extremely atraumatic, has no handles to catch on sutures, and the control of the blood-flow within the artery is precise and can be carried out by an assistant at a distance. It is the author's instrument of choice in femoral artery embolectomy, kidney transplantation, and for occluding arteries with atheromatous plaques on their walls.

Since publication of the first paper about this sling (Dunn, 1971), there have been reports (Kountz, 1972) on similar balloon occlusion devices which have been used in experimental situations, mainly in the United States. The clinical potential of such devices has not previously been realized or reported on.

The tourniquet will soon be in production by A. Franklin and Sons, England.

Acknowledgement.—I am grateful to Professor R. Y. Calne and the staff of the Department of Surgery, University of Cambridge, and also Mr. W. A. B. Smellie and Professor G. W. Taylor, St. Bartholomew's Hospital, London, for help in the assessment of this device.

A patent has been granted.

SURGICAL TREATMENT OF ANEURYSM OF THE THORACIC AORTA UNDER A TEMPORARY EXTERNAL BY-PASS SHUNT

By TADASHI INOUE, AKIRA SHOHTSU, KOZO KAWADA, IZUMI NAGAI, SUSUMU TANAKA, SHIGEYUKI TAKEUCHI, AND YASUHIRO SOHMA

DEPARTMENT OF THORACIC AND CARDIOVASCULAR SURGERY, KEIO UNIVERSITY SCHOOL OF MEDICINE, TOKYO, JAPAN

SUMMARY

Twenty-eight patients were operated upon for aneurysm of the thoracic aorta using a temporary external by-pass shunt. Four early deaths occurred, the cause of which could not be related to the by-pass procedure itself. The temporary long external by-pass from the left subclavian artery or from the ascending aorta to the femoral artery was preferable for resection of an aneurysm of the descending aorta or the distal aortic arch which required cross-clamping of the aorta.

DURING resection and replacement with a graft in the treatment of an aneurysm of the thoracic aorta the blood-supply to the distal organs has to be maintained in order to prevent ischaemic damage and heart failure. A temporary external by-pass shunt or a mechanical by-pass such as a cardiopulmonary by-pass (Cooley, DeBakey, and Morris, 1957; Austen and Shaw, 1960), a left heart by-pass (Cooley and others, 1957; Gerbode, Bainbridge, Osborn, Hood, and French, 1957), and a femorofemoral by-pass (Neville, Thomason, Peacock, and Colby, 1966; Dillon, Young, and Sealy, 1967; Bloodwell, Hallman, and Cooley, 1968) is usually applied for this purpose.

In the present series of 45 patients with thoracic aneurysms who have been treated surgically a cardiopulmonary by-pass was used in 13 patients, whereas various external by-pass shunts were employed in 28 patients. In the remaining 4 patients resection of the aneurysm was performed without any supportive measure. This paper presents the results of resection of aneurysm of the thoracic aorta using a temporary external by-pass shunt.

Table I.—SUMMARY OF THE DATA FOR LEFT SUBCLAVIAN TO DESCENDING AORTA, COMMON ILIAC, AND FEMORAL ARTERY BY-PASSES

TYPE OF BY-PASS	NO. OF PATIENTS	BY-PASS GRAFT		BY-PASS TIME (RANGE AND MEAN) (min.)	COMPLICATION	EARLY DEATH	LATE DEATH

* Rupture of concomitant abdominal aneurysm.
† Acute renal failure.
‡ Rupture of aneurysm during dissection.
§ Sudden death from unknown origin.

MATERIAL AND METHODS

Twenty-eight patients underwent operation for an aneurysm of the thoracic aorta under a temporary external by-pass shunt during the period from June, 1966, to December, 1971, at the Keio University Hospital, Tokyo. There were 24 males and 4 females, ranging in age from 20 to 73 years.

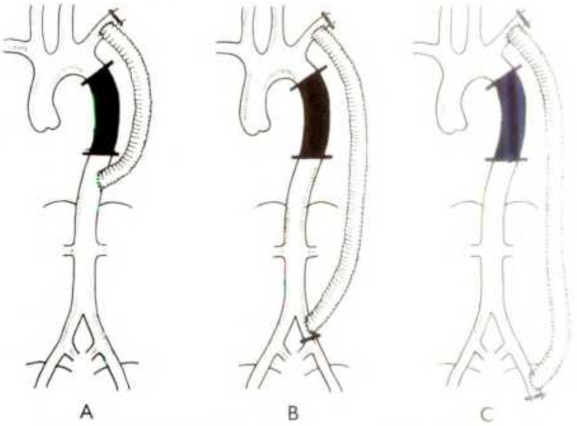

FIG. 1.—Diagrams showing temporary external by-pass shunts from the left subclavian artery to the descending aorta (A), to the left common iliac artery (B), and to the left femoral artery (C).

Twenty-four patients had an aneurysm of the descending thoracic aorta, 3 patients had an aneurysm of the aortic arch, and 1 patient had an innominate artery aneurysm. A dissecting aneurysm was found in 10 patients, a chronic fusiform enlargement in 9, and a saccular aneurysm in 9. The aneurysm was related to atherosclerosis in 13 patients, to cystic medial necrosis in 10, to syphilis in 4, and to trauma in 1.

A woven Teflon graft was used as a temporary external by-pass shunt without heparinization in all the patients during cross-clamping of the aorta.

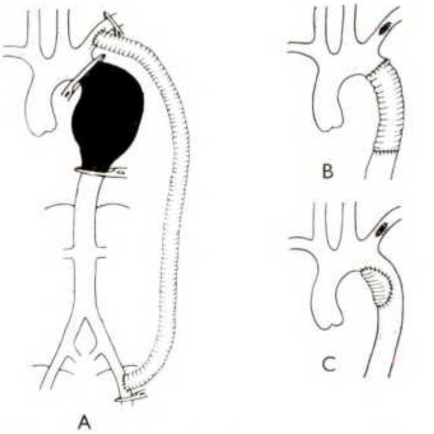

FIG. 2.—Diagrams showing the techniques of operation for an aneurysm of the descending thoracic aorta. A, Temporary long external by-pass from the left subclavian artery to the left femoral artery during occlusion of the aorta. B, After removal of the aneurysm the aorta was replaced with a Teflon tube graft. C, The defect of the aorta was covered with a Teflon patch after aneurysmectomy.

Various by-passes were used, including descending aorta to aorta, descending aorta to femoral, left subclavian to descending aorta, left subclavian to common iliac or femoral, and ascending aorta to femoral by-pass shunt.

RESULTS

1. Left Subclavian to Descending Aorta, Common Iliac, or Femoral By-pass Shunt (22 cases).—Twenty-two patients with an aneurysm of the descending thoracic aorta distal to the origin of the left subclavian artery were operated upon with the aid of an external by-pass shunt from the left subclavian artery to the descending thoracic aorta (3 cases), to the left common iliac artery (3 cases), and to the left femoral artery (16 cases) (*Fig.* 1). The by-pass graft ranged between 10 and 16 mm. in diameter and from 25 to 50 cm. in length. The by-pass time ranged from 30 to 110 minutes, with an average of 66 minutes (*Table I*).

After resection of the aneurysm the aorta was replaced with a woven Teflon graft in 21 of the 22 patients, while a Teflon patch was used to cover the defect of the aorta in the remaining 1 (*Fig.* 2).

Table II.—SUMMARY OF THE DATA FOR DESCENDING AORTA TO AORTA AND FEMORAL BY-PASSES

TYPE OF BY-PASS	NO. OF PATIENTS	BY-PASS GRAFT		BY-PASS TIME (min.)	COMPLICATION	EARLY DEATH	LATE DEATH
		Diameter (mm.)	Length (cm.)				
Descending aorta to aorta	1	14	20	90	Cerebral thrombosis	0	0
Descending aorta to femoral	1	12	50	99	0	0	0

Two of the 22 patients died in the early postoperative period. The causes were massive haemorrhage due to rupture of the aneurysm during dissection and rupture of a concomitant abdominal aneurysm on the second postoperative day. Late death occurred in 2 patients with a dissecting aneurysm, the cause of which remains unknown.

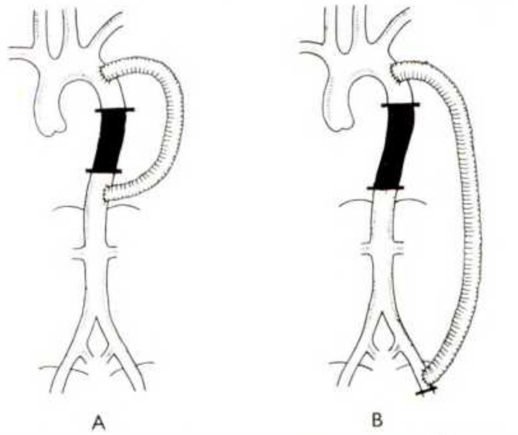

FIG. 3.—Diagrams illustrating temporary external by-pass shunts from the descending aorta to the distal thoracic aorta (A) and to the left femoral artery (B).

In spite of the by-pass time of 110 minutes, the length of the shunt of 50 cm., and no heparinization, no thrombus was recognized in any by-pass graft. Postoperative acute renal failure occurred in 1 patient with a dissecting aneurysm which was associated with complete obstruction of the left renal artery preoperatively.

2. Descending Aorta to Aorta or Femoral By-pass Shunt (2 cases).—The left subclavian artery was too small for the proximal anastomosis of the by-pass graft in 2 patients. In each case the descending aorta proximal to the aneurysm was used as an alternative. The distal anastomosis was with the descending aorta distal to the aneurysm in one patient and with the femoral artery in the other; the position of this anastomosis depended on the site and extent of the aneurysm (*Fig.* 3).

Aneurysmectomy and replacement with a graft were successfully performed in these 2 patients. Both of the by-pass grafts were 14 mm. in diameter with a length of 20 and 50 cm., respectively (*Table II*).

3. Ascending Aorta to Carotid or Femoral By-pass Shunt (4 cases).—For the 1 patient with an aneurysm of the innominate artery a by-pass shunt (10 mm. in diameter, 25 cm. in length) from the ascending aorta to the right common carotid artery was utilized to provide distal perfusion while the blood-flow in the innominate artery was interrupted (*Fig.* 4 A). Following resection of the aneurysm the by-pass graft was left in place as a permanent conduit after being shortened.

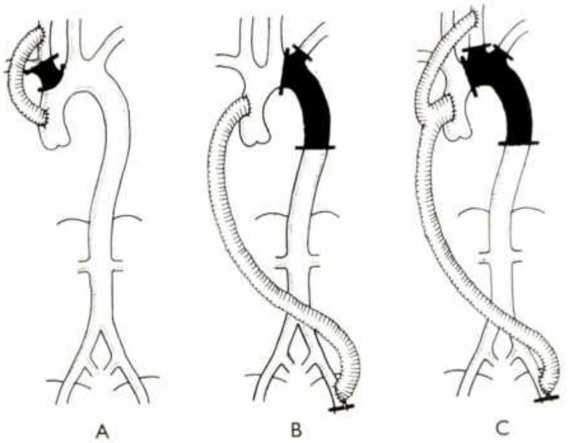

FIG. 4.—Diagrams indicating temporary external by-pass shunts from the ascending aorta to the right common carotid artery (A), to the left femoral artery (B), and to both the femoral and the left common carotid arteries (C).

An ascending aorta to femoral by-pass (14 mm. × 50 cm.) was applied in 2 patients with an aneurysm of the distal aortic arch which required clamping of the aorta proximal to the origin of the left subclavian artery (*Fig.* 4 B). In the remaining patient with an aneurysm of the aortic arch distal to the origin of the innominate artery an ascending aorta to femoral by-pass (20 mm. × 50 cm.) with a branch to the left carotid artery (10 mm. × 25 cm.) was utilized (*Fig.* 4 C). After resection of the aneurysm the aorta was replaced with a graft in 1 patient and was repaired with a Teflon patch in the other 2 patients (*Fig.* 5).

Table III.—SUMMARY OF THE DATA FOR ASCENDING AORTA TO FEMORAL AND COMMON CAROTID BY-PASSES

TYPE OF BY-PASS	NO. OF PATIENTS	BY-PASS GRAFT		BY-PASS TIME (min.)	COMPLICATION	EARLY DEATH	LATE DEATH
		Diameter (mm.)	Length (cm.)				
Ascending aorta to right common carotid	1	10	25	50	0	0	0
Ascending aorta to femoral	2	14	50	30, 70	1*	1†	1*
Ascending aorta to femoral and left common carotid	1	20 10	50 25	60		1‡	

* Infection.
† Rupture of aneurysm during dissection.
‡ Acute obstruction of superior mesenteric artery.

By-pass time ranged between 30 and 70 minutes. Early postoperative death occurred in 2 patients, and was related to acute obstruction of the superior mesenteric artery and to massive haemorrhage due to rupture of the aneurysm during dissection, respectively (*Table III*).

DISCUSSION

Since Cooley and DeBakey successfully removed an aneurysm of the ascending aorta by utilizing a cardiopulmonary by-pass in 1956 a total cardiopulmonary by-pass has been widely employed in the resection of an aneurysm of the ascending aorta or the aortic arch.

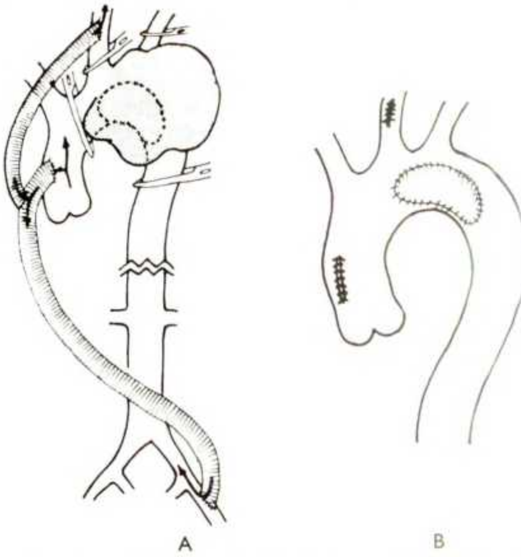

FIG. 5.—Diagrams showing the techniques of operation for an aneurysm of the distal aortic arch. A, Temporary long external by-pass with a carotid branch during clamping of the aortic arch. B, After excision of the aneurysm the aortic defect was covered with a Teflon patch.

On the other hand, a left-heart by-pass with a pump (Cooley and others, 1957; Gerbode and others, 1957) or a femoral vein to femoral artery partial by-pass with a pump oxygenator (Neville and others, 1966; Dillon and others, 1967; Bloodwell and others, 1968) is usually used during the resection of an aneurysm of the descending thoracic aorta. A mechanical by-pass, however, requires systemic heparinization, which may cause excessive bleeding from the prosthetic graft and the dissected surrounding tissues. An additional disadvantage of the left-heart by-pass is the difficulty in the control of blood-flow from the left atrium, which may result in atrial hypertension (Kahn, Vathayanon, and Sloane, 1968; Hug and Taber, 1969).

Clinical application of a temporary external by-pass between the left subclavian artery and the descending thoracic aorta has been reported (Adams, 1955; Stranahan, Alley, Sewell, and Kausel, 1955; Storey, Nardi, and Sewell, 1956; DeBakey and Cooley, 1961). Nagel and Williams (1966) utilized a temporary external by-pass from the left subclavian artery to the descending thoracic aorta with a Dacron graft 12 mm. in diameter. Kahn and others (1968) and Kirsh, Kahn, Crane, and others (1970) reported the use of an external shunt employing two metal cannulae connected by Tygon tubing placed on the aorta proximal and distal to the aneurysm, with an excellent result. Valiathan, Weldon, Bender, Topaz, and Gott (1968) described the use of a left subclavian to femoral by-pass with a GBH-coated polyvinyl catheter for the resection of an aneurysm of the descending thoracic aorta in 2 cases.

Since 1966 the present authors have applied a temporary external by-pass shunt without heparinization during cross-clamping of the descending thoracic aorta. A woven Teflon prosthetic graft was chosen as the by-pass material in order to avoid thrombus formation in the shunt. After using several short by-pass shunts, such as a left subclavian to descending aorta or a descending aorta to aorta by-pass, shunts from the left subclavian to the common iliac or to the femoral artery have been employed. This method has previously been reported as the 'temporary long external by-pass method' (Inoue, Kawada, Tanaka, Sohma, Fukuda, and Koyanagi, 1972). Thus, using the diseased aorta as the anastomosis site to the by-pass graft is avoided and the operating field is left free. Moreover, the by-pass flow rate is controlled by the cardiac output of the patient, and therefore artificial regulation of the by-pass flow is unnecessary. Neither thrombosis nor heart failure occurred during by-pass in our series of 24 patients with a descending thoracic aortic aneurysm. Furthermore, postoperative paraplegia due to spinal cord ischaemia or renal failure did not occur except in 1 patient who had a dissecting aneurysm with obstruction of the left renal artery.

Mahorner and Spencer (1954) reported a temporary external by-pass with a homograft for the resection of an aneurysm of the innominate artery. In 1971 Murray, Brawley, and Gott described a temporary by-pass with a GBH-coated cannula from the ascending aorta to the right carotid artery during reconstruction of the innominate artery.

In 1955 Cooley and DeBakey (1955) performed a complete reconstruction of the aortic arch during bridging with a homograft from the ascending to the descending aorta. In Japan Kimoto, Wada, Ueno, Suzuki, Harada, and Maruyama (1960) and Wada, Tashiro, Ueda, and Suda (1960) successfully resected an aneurysm of the aortic arch using the method described by Cooley and DeBakey (1955). However, it may not always be easy to expose the descending aorta as the site for distal anastomosis in this short by-pass. Moreover, the by-pass itself may disturb the operating field. Therefore, we prefer to employ a long by-pass from the ascending aorta to the femoral artery with or without a carotid branch. However, a sufficient distance of normal aortic wall from the aortic annulus to the aneurysm is absolutely necessary for the attachment of the by-pass graft. A pump oxygenator should be prepared for immediate use when this procedure is found to be inadequate.

SELECTION OF OPERATION FOR DUODENAL ULCER BASED ON ACID SECRETORY STUDIES—A REAPPRAISAL

By J. V. ROBBS, S. BANK, I. N. MARKS, and J. H. LOUW

THE GASTROINTESTINAL CLINIC, GROOTE SCHUUR HOSPITAL, CAPE TOWN, AND THE DEPARTMENTS OF SURGERY AND MEDICINE, UNIVERSITY OF CAPE TOWN, SOUTH AFRICA

SUMMARY

The incidence of recurrent duodenal or jejunal ulceration was assessed 5–10 years after selective surgery for duodenal ulceration in 253 patients after vagotomy and drainage and in 55 patients after vagotomy and antrectomy.

In the vagotomy and drainage group 8·6 per cent of the patients developed proven or highly suspected recurrent duodenal or jejunal ulcer. None of these patients had preoperative maximal acid output (M.A.O.) values less than 25 mEq. per hour. No recurrent jejunal ulcers occurred in the vagotomy and antrectomy group despite the fact that they had the same incidence of incomplete vagotomy by Hollander's criteria as the vagotomy and drainage group.

It is suggested that a policy of selection of patients for vagotomy and drainage based on a preoperative M.A.O. of 25 mEq. per hour seems more justified and realistic than the previously used level of 40–50 mEq. per hour. Vagotomy and antrectomy should probably be employed if the M.A.O. is greater than 25 mEq. per hour.

THE ideal operation for patients with duodenal ulceration remains elusive. Partial gastrectomy (Visick, 1948; Goligher, Moir, and Wrigley, 1956; Goligher and Franz, 1964; Goligher, Pulvertaft, and Watkinson, 1964), vagotomy without drainage (Dragstedt, Camp, and Fritz, 1949; Tanner, 1950, 1964), gastro-enterostomy alone (Lewisohn, 1925; Leiff, 1929; Tanner, 1964), vagotomy and gastrectomy with either Billroth-I or -II anastomosis (Herrington, 1963; Goligher and others, 1964; Bryant, Klein, and Griffin, 1967; Goligher, Pulvertaft, de Dombal, and others, 1968a, b; Jordan and Condon, 1970), a variety of vagotomy and drainage procedures (Weinberg, Stempien, Movius, and Degradi, 1956; Edwards, Classen, and Sawyers, 1960; Goligher and others, 1964, 1968a, b) and, more recently, parietal cell vagotomy without drainage (Amdrup and Jensen, 1970; Johnston and Wilkinson, 1970; Interone, 1971) have been employed in an attempt to reduce mortality and morbidity, but the long-term morbidity remains of the order of 10–15 per cent.

One of the most serious complications is the inability to cure the ulceration or to prevent recurrent ulceration after surgery. The finding that most patients with recurrent ulceration after gastrectomy had high levels of postoperative acid secretion led various groups of workers to advocate a policy of 'tailoring the operation' to the preoperative basal (Orr, 1962) or histamine-stimulated acid secretory status (Bruce, Card, Marks, and Sircus, 1959; Louw, 1964; Small, Bruce, Falconer, Sircus, and Smith, 1967). Systematic trials of the 'tailoring procedures' and, in effect, the role of gastric acid secretion in operative selection were interrupted, however, by the advent of vagotomy and drainage. Indeed, the relative simplicity and lower mortality of vagotomy and drainage resulted in the almost universal adoption of this procedure for almost a decade.

It soon became apparent that vagotomy and drainage applied to all patients was associated with a high recurrent ulcer rate (Goligher and others, 1964, 1968a, b; Bryant and others, 1967), and Bank, Marks, and Louw (1967) confirmed that the procedure was associated with an inadequate or 'safe' reduction in acid secretion in the majority of patients.

The purpose of the present paper is to reassess the value of preoperative acid secretory studies with regard to recurrent ulceration and to suggest a policy of 'tailored surgery' to the currently popular operations.

MATERIAL AND METHODS

Three hundred and eight patients submitted to elective surgery for chronic duodenal ulceration at the Groote Schuur Hospital were reassessed 5–10 years later with regard to the incidence of recurrent ulceration. A loosely applied policy of selection for surgery was practised in these patients, vagotomy and antrectomy being used for many patients with M.A.O. values greater than 40 mEq. per hour and vagotomy and drainage for the remainder. Thus, 253 patients had vagotomy and drainage, the vagotomy being either truncal or selective. Selective vagotomy was aimed at preserving both the hepatic and coeliac branches and the routine drainage procedure employed was a pyloroplasty of the Heineke-Mikulicz type. Gastro-enterostomy was reserved for the cases in which pyloroplasty proved technically hazardous. A few patients had gastroduodenostomies of the Jaboulay or Finney type. The remaining 55 patients were submitted to truncal vagotomy and antrectomy with a Billroth-II type reconstruction in all cases.

A preoperative augmented histamine or pentagastrin test (A.H.T.) (Bank and others, 1967) was performed in all the patients and 262 patients were available for postoperative studies. Postoperative insulin tests were performed on 138 patients (Bank and others, 1967); 127 after vagotomy and drainage and 11 after vagotomy and antrectomy.

CLINICAL ASSESSMENT

Recurrent Ulceration.—Recurrent ulceration has been grouped into duodenal (or jejunal) and gastric, and in view of the difficulty experienced in some instances in confirming the diagnosis of recurrent duodenal ulceration these patients have been further subdivided into 'proven' and 'highly suspected' groups. (Recurrent gastric uleration was less of a diagnostic problem with routine fibre-optic gastroscopy.) The 'proven' group comprised those patients in whom an ulcer was found at subsequent surgery. The 'highly suspected' group consisted of 11 patients with a clinical history associated with radiological, gastroscopic, or acid secretory data which were strongly suggestive of recurrent ulceration but in whom further surgery was not carried out because of a satisfactory response to medical therapy and reluctance to reoperate at that stage. Of these 11 patients, 10 gave a classic history of ulcer-type dyspepsia (2 having gastro-intestinal bleeding as well) and 1 was admitted with a gastro-intestinal haemorrhage. The reinstitution of ulcer therapy resulted in an abatement of the symptoms in all the patients. Two of the 11 patients had an ulcer crater demonstrated on barium-meal examination and 8 had acid secretory studies after histamine and insulin which indicated a 'high risk to recurrent ulceration'. The study was undertaken before duodenoscopy became a routine practice in the clinic.

Interpretation of the Insulin Test.—Insulin test results were interpreted by Hollander's criterion, i.e., an increase of 20 mEq./l. over basal levels (10 mEq./l. if the basal level was anacid) following the administration of insulin was taken as a positive response and indicative of incomplete vagotomy (Hollander, 1946, 1948).

Table I.—RECURRENT ULCERATION AFTER VAGOTOMY AND DRAINAGE AND AFTER VAGOTOMY AND ANTRECTOMY FO DUODENAL ULCER

OPERATION	DUODENAL/JEJUNAL ULCERATION						GASTRIC ULCERATION		TOTAL ULCERATION	
	Proven		*Suspected*		*Total*					
	No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent
Vagotomy and drainage (253 cases)	11	4·3	11	4·3	22	8·6	8	3·2	30	11·8
Vagotomy and antrectomy (55 cases)	0	0	0	0	0	0	1	1·8	1	1·8

Table II.—EFFECT OF VAGOTOMY AND DRAINAGE AND OF VAGOTOMY AND ANTRECTOMY ON THE GASTRIC ACID SECRETORY RESPONSE TO HISTAMINE (PENTAGASTRIN) AND INSULIN

OPERATION	A.H.T.							INSULIN				
	No. of Tests	*Mean Preoperative Value* (mEq. per hr.)		*Mean Postoperative Value* (mEq per hr.)		*Mean Percentage Reduction*		*No. of Tests*	*Multiple Criteria Positive*		*Hollander Positive*	
		B.A.O.	M.A.O.	B.A.O.	M A O.	B.A.O.	M A.O.		No.	Per cent	No.	Per cen
Vagotomy and drainage	253	5·1	27·3	1·8	9·0	64·7	67·0	127	28	22	52	40·9
Vagotomy and antrectomy	55	10·3	41·6	0·7	2·3	93·2	94·5	11	0	0	4	36·4

In addition, the multiple criteria suggested by Bank and others (1967) were employed. These criteria are: (*a*) an increase of free acid of 20 mEq./l. or more over basal values (10 mEq./l. if the basal level was anacid) (Hollander, 1948); (*b*) a basal level in excess of 2 mEq. per hour (Bachrach, 1962); (*c*) an increasing volume after insulin (Waddell, 1957); (*d*) whether the Hollander response occurs within 60 minutes or not, i.e., whether the vagotomy is 'adequate' or not (Ross and Kay, 1964; Johnston, Thomas, Checkells, and Duthie, 1967); (*e*) an increas of 1·5 mEq. per hour of free acid or 2 mEq. pe hour of total acid over the basal hour secretion occurring during any hour after insulin (Bank and other 1967). Three or more of these criteria occurrin together were assessed as signifying a high risk t recurrent ulceration.

RESULTS

Incidence of Recurrent Ulceration.—*Table* shows that 8·6 per cent of patients after vagotom and drainage had proven (4·3 per cent) or highl suspected (4·3 per cent) duodenal or jejunal ulce recurrence while *none* of the small number of patient in the vagotomy and antrectomy group develope jejunal ulceration.

Eight of the 253 patients subjected to vagotom and drainage developed gastric ulceration, an incidence of 3·2 per cent. One case of recurrent gastri ulceration (1·8 per cent) was encountered in th vagotomy and antrectomy group. The differenc between the two groups was not statistically significant ($P > 0·05$).

Pre- and Postoperative Acid Secretory Studie (*Table II*).—

Augmented Histamine (Pentagastrin) Test.—Th mean preoperative maximal acid output (M.A.O. in the vagotomy and drainage group was 27·3 mE per hour. Patients submitted to vagotomy an antrectomy had a very much higher mean preoperative M.A.O. (41·6 mEq. per hour). Basal aci output (B.A.O.) was 5·1 and 10·3 mEq. per hou respectively.

Vagotomy and antrectomy resulted in a reductio of the preoperative B.A.O. and M.A.O. levels o over 90 per cent. This reduction was significantl greater than the 64·7 per cent for basal and 67·0 pe cent for maximal acid output after vagotomy an drainage.

Insulin Test.—Of the 127 patients in the vagotomy and drainage group who had insulin tests done, 52 (40·9 per cent) had a positive response using Hollander's criterion, and of 11 patients who had a vagotomy and antrectomy, 4 (36·4 per cent) had a positive Hollander test.

Table III.—Comparison of Recurrent Ulceration Rates in Patients with a Preoperative M.A.O. greater than 25 mEq. per Hour and in those with a Preoperative M.A.O. less than 25 mEq. per Hour who were submitted to Vagotomy and Drainage

M.A.O. Group	Total No. of Patients	Duodenal/Jejunal Ulceration						Proven Gastric Ulceration		Total Ulceration	
		Proven		*Suspected*		*Total*					
		No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent
>25 (mEq. per hr.)	143	11	7·7	7	4·9	18	12·6	2	1·4	20	14·0
<25 (mEq. per hr.)	110	0	0	4	3·6	4	3·6	6	5·5	10	9·1

Table IV.—Comparison of the Gastric Acid Secretory Response to Histamine/Pentagastrin and Insulin in Patients with a Preoperative M.A.O. greater than 25 mEq. per Hour and in Those with a Preoperative M.A.O. of less than 25 mEq. per Hour who were submitted to Vagotomy and Drainage

M.A.O. Group	Total No. of Patients	A.H.T.						Insulin				
		Mean Preoperative Level (mEq. per hr.)		*Mean Postoperative Level* (mEq. per hr.)		*Percentage Reduction*		*Total No. of Tests*	*Multiple Criteria Positive*		*Hollander Positive*	
		B.A.O.	M.A.O.	B.A.O.	M.A.O.	B.A.O.	M.A.O.		No.	Per cent	No.	Per cent
>25 mEq. per hr.	143	6·8	35·8	2·2	11·3	67·6	68·4	60	17	28·3	26	43·3
<25 mEq. per hr.	111	3·4	17·9	1·4	5·8	58·8	67·6	42	4	9·5	13	30·9

When multiple criteria were used as an index of positivity, the proportion of incomplete vagotomies was much lower than when Hollander's criterion alone was used. Twenty-two per cent of the vagotomy and drainage group and none of the vagotomy and antrectomy group had three or more positive criteria.

Relationship of Preoperative M.A.O. to Recurrent Ulceration after Vagotomy and Drainage.—In examining the augmented histamine test (A.H.T.) data in the vagotomy and drainage group it was found that no patient with a preoperative M.A.O. less than 25 mEq. per hour had a proven duodenal ulcer recurrence (*Table III*). There was a tendency for 'suspected ulcer' to occur in patients who secreted less than 25 mEq. per hour, but there was no significant difference in this respect between the patients who secreted more and those who secreted less than 25 mEq. per hour.

On the other hand, gastric ulcer recurrence occurred more frequently in the patients who secreted less than 25 mEq. per hour, but the difference was not significant ($P > 0{\cdot}05$).

Comparison of Acid Secretory Data in Patients subjected to Vagotomy and Drainage with Preoperative Acid Secretory Values greater or less than 25 mEq. per Hour.—*Table IV* shows that the percentage reduction in acid output in the two groups of patients was similar after operation, but that the B.A.O. and M.A.O. values were very much lower in the patients who secreted less than 25 mEq. per hour.

Insulin Tests.—Twenty-six (43·3 per cent) of the 60 patients in the over-25 mEq. per hour group who had insulin tests had a positive result using Hollander's criterion as compared with 13 (30·9 per cent) of 42 insulin tests in the under-25 mEq. per hour group. The difference was not statistically significant ($P > 0{\cdot}05$). When multiple criteria were used as the method of interpretation the over-25 mEq. per hour group had a significantly higher proportion of positive results (28·3 per cent) than the under-25 mEq. per hour group (9·5 per cent; $P < 0{\cdot}05$).

Comparison of Ulcer Recurrence Rates in Patients with Preoperative M.A.O. of greater than 25 mEq. per Hour after Vagotomy Operations (*Table V*).—

Vagotomy and Drainage.—One hundred and forty-three patients (56·5 per cent) had a preoperative M.A.O. of greater than 25 mEq. per hour and among these, 18 proven and suspected recurrent duodenal ulcers were found and 2 gastric ulcers (1·4 per cent).

Vagotomy and Antrectomy.—Forty-seven (84·5 per cent) of these patients secreted more than 25 mEq. per hour and none of them had either proven or suspected recurrent duodenal ulceration. One patient presented with recurrent gastric ulceration. There is an obviously significant difference between these patients and the vagotomy and drainage group with regard to recurrent duodenal ulceration but not gastric ulceration.

DISCUSSION

Recurrent 'proven' or 'suspected' duodenal or jejunal ulceration is the single most important complication after vagotomy and drainage and most authors cite an incidence ranging from 10 to 15 per cent (Weinberg and others, 1956; Edwards and others, 1960; Goligher and others, 1964, 1968a, b; Bryant and others, 1967; Bank, Marks, Louw, and Cobb, 1970; Jordan and Condon, 1970). Based on this high recurrence rate Small and others (1967) embarked on a programme of selective surgery for duodenal ulceration aimed at eradicating jejunal ulcer.

Their policy of selection entailed submitting patients with an M.A.O. greater than 50 mEq. per hour to vagotomy and antrectomy, while those with values below this were subjected to either standard two-thirds gastrectomy or vagotomy and gastro-enterostomy. The results in this group of patients, who were followed up prospectively over 5 years, were compared with a group of patients who had been subjected to partial gastrectomy. Although the results were inconclusive the authors felt that perseverance with the policy was justified. Orr (1962) and Louw (1964) had previously reported favourable results following a policy of selection based on similar preoperative A.H.T. levels, whereas other authors (Holt and Lythgoe, 1961; Clark, Murray, Slessor, and Wyllie, 1964) were of the opinion that preoperative acid testing had little prognostic significance. All these reported series, however, used an arbitrarily selected M.A.O. value of 40 or 50 mEq. per hour as the indication for the more extensive operation. The fact that proven recurrent duodenal ulceration was still occurring in 4·3 per cent of our vagotomy and drainage patients and that a further 4·3 per cent had suspected recurrence in spite of these selective criteria indicated that a lower preoperative M.A.O. value than 40 mEq. per hour might be a better discriminatory 'hypersecretor level' above which recurrent ulceration was more likely to occur. None of the 11 unequivocally proven recurrent duodenal or jejunal ulcers in the present series occurred in patients with a preoperative M.A.O. value of less than 25 mEq. per hour and the lowest M.A.O. value among these patients was 26·9 mEq. per hour. A similar trend was found in patients with 'highly suspected' evidence of ulcer recurrence. It is of interest to note that re-examination of the data of Clark and others (1964) reveals that of their 6 recurrent ulcers only 1 had a preoperative acid secretion of less than 25 mEq. per hour.

Vagotomy and drainage can be expected to reduce preoperative acid values (both basal and maximal) by 65–70 per cent irrespective of their magnitude. Thus, the postoperative acid output of patients with a low preoperative output will obviously be lower than that of patients with a high preoperative value. In the present series patients with a preoperative M.A.O. value of less than 25 mEq. per hour had a mean postoperative value of 5·8 mEq. per hour compared with 11·3 mEq. per hour in the group with a preoperative M.A.O. of more than 25 mEq. per hour. To date no recurrent jejunal ulcers (proven or suspected) have been found among patients undergoing vagotomy and antrectomy, the majority of whom (85 per cent) had an M.A.O. value in excess of 25 mEq. per hour, whereas 12·6 per cent of patients with an M.A.O. greater than 25 mEq. per hour subjected to vagotomy and drainage developed proven or suspected recurrent duodenal ulceration. The significantly better results after vagotomy and gastric resection are hardly surprising in view of the greater percentage reduction of the preoperative acid output. It would appear that an M.A.O. in the region of 5–6 mEq. per hour after vagotomy and drainage is desirable to protect against ulcer recurrence. It should be noted that the insulin test is suspect at these low levels. Insulin tests performed on a group of hyposecretors who had not been subjected to gastric surgery or vagotomy, with pentagastrin-stimulated M.A.O. values of less than 6 mEq. per hour, yielded variable results, particularly in the form of false negatives when Hollander's or multiple criteria were used for interpretation. Previously published results of the insulin test in patients with intact vagi have usually been of patients with duodenal ulcer who tend to be high acid secretors (Ross and Kay, 1964; Gillespie, Gillespie, and Kay, 1969). Nevertheless, the overall incidence of positive insulin tests (by Hollander's criteria) among the vagotomy and drainage patients of 40·9 per cent lies at the upper limit of the range presented by many authors (Ross and Kay, 1964; Kay, 1969). All the tests in the present series were done at least 3 months, and in the vast majority over 6 months, after surgery. In fact, the time interval was more than 4 years in 60 per cent of the cases. The negative-to-positive insulin test conversion which is known to occur in the first 3 months after vagotomy (Gillespie and others, 1969; Bank and others, 1970) can therefore be disregarded in the present series.

Interpretation of the insulin test results in the two groups of vagotomy and drainage patients with a preoperative M.A.O. value of greater or less than 25 mEq. per hour revealed an insignificant difference in the incidence of incomplete vagotomy when Hollander's criterion alone was used. However, the group with a preoperative M.A.O. of less than 25 mEq. per hour had a significantly lower incidence of positive results when the multiple criteria were employed. The use of the latter was therefore regarded as a more accurate index of liability to recurrent ulceration than Hollander's method, albeit empirically. Hollander's criterion would seem to be far more accurate with regard to whether the vagi are in fact intact or not. It is also of interest to

Table V.—Comparison of Recurrent Ulceration Rates in Patients with a Preoperative M.A.O. greater than 25 mEq. per Hour after Vagotomy and Drainage and after Vagotomy and Antrectomy for Duodenal Ulcer

Operation	Total No. of Patients	No. of Patients with M.A.O. >25 mEq. per hr.		A.H.T. Mean Preoperative Value (mEq. per hr.)		Recurrent Ulceration: Duodenal/Jejunal, Proven		Duodenal/Jejunal, Suspected		Gastric, Proven	
		No.	Per cent	B.A.O.	M.A.O.	No.	Per cent	No.	Per cent	No.	Per cent
Vagotomy and drainage	253	143	56·5	6·8	35·8	11	7·7	7	4·9	2	1·4
Vagotomy and antrectomy	55	47	84·5	12·5	47·8	0	0	0	0	1	2·1

compare the incidence of incomplete nerve section in the patients undergoing vagotomy and antrectomy and in the vagotomy and drainage group. Admittedly very few (11) tests were done in the former group, but the 36·4 per cent incidence of incomplete vagotomy by Hollander's criterion is similar to that in the vagotomy and drainage group; however, none of the tests was positive by the multiple criteria in the patients submitted to vagotomy and antrectomy.

If a positive Hollander test is taken as being indicative of a significant degree of residual vagal innervation after vagotomy it seems that in the presence of a preoperative M.A.O. of less than 25 mEq. per hour residual vagal fibres are relatively unimportant when vagotomy and drainage are performed. On the other hand, with a preoperative M.A.O. value greater than 25 mEq. per hour the persistence of vagal innervation assumes far greater importance. Insulin tests done on the vagotomy and antrectomy patients suggest a similar incidence of incomplete vagotomy. The absence of recurrent jejunal ulceration in this group indicates that the addition of antrectomy when vagal denervation is incomplete can sufficiently reduce gastric acid output to provide adequate protection against recurrent jejunal ulceration. The report by Small and others (1967) that no recurrent jejunal ulcers occurred in their patients who had been treated by gastro-enterostomy without vagotomy and who had had a preoperative M.A.O. of less than 30 mEq. per hour tends to corroborate the findings in this study. However, this favourable outcome has not been our experience using this level of secretion (Bank and Marks, 1971) and it is well known that recurrent ulceration after gastro-enterostomy alone may be delayed for many years.

Gastric ulceration after the vagotomy operations occurred independently of the level of acid secretion or completeness of vagotomy and no single aetiological factor could be incriminated as the mechanism of gastric ulceration in all the patients. It is likely that one or more of the 'risk factors', e.g., gastric retention, inadequate pyloroplasty, gastritis, antral hyperfunction, and poor acid reduction, singly or in combination, are operational in any individual case. We have now encountered 31 gastric ulcers after vagotomy and drainage for duodenal ulcer, many of which were at the proximal end of the pyloroplasty, and such ulcers have possibly been previously erroneously diagnosed in other series as recurrent duodenal ulcer on the basis of radiological studies alone (Bank, 1971).

Intra-operative testing for completeness of vagisection using the Burge technique (Burge and Vane, 1958; Burge, 1970a, b; Inberg, 1970) has not been found to be universally applicable and it would appear to be impossible to achieve complete vagotomy in all patients even in the hands of surgeons experienced in its use. The results of this study imply that a policy of selection of patients for vagotomy and drainage based on a preoperative M.A.O. of 25 mEq. per hour seems more justified and far more realistic than the previously used level of 40–50 mEq. per hour. Vagotomy and antrectomy is thus suggested for patients with a preoperative M.A.O. in excess of 25 mEq. per hour, and vagotomy and drainage should be reserved for those with a lower M.A.O. value.

Acknowledgement.—This study was supported by the Medical Research Council of South Africa.

THE BUERGER SYNDROME IN JAVA

A DESCRIPTION OF THE CLINICAL SYNDROME AND SOME ASPECTS OF ITS AETIOLOGY

By G. L. HILL,* J. MOELIONO, F. TUMEWU, D. BRATAAMADJA, and A. TOHARDI
MARANATHA UNIVERSITY, BANDUNG, WEST JAVA, INDONESIA, AND OTAGO UNIVERSITY, DUNEDIN, NEW ZEALAND

SUMMARY

A case control field survey was carried out on 106 Indonesian patients with spontaneous peripheral gangrene. In 101 patients the disease was a four-limb youthful type of peripheral vascular disease occurring in young male smokers. Migratory superficial thrombophlebitis was present in 38 patients. This constellation of signs and symptoms was similar to that described for the Buerger syndrome.

Of the aetiological factors studied, tobacco, cold injury, familial aggregation, and a past history of mycotic infection may be of significance.

ALTHOUGH patients with spontaneous gangrene of the extremities were described in the Indonesian literature 50 years ago (Aalsmeer, 1922; Van Dijk and Oudendal, 1923) they were not recognized as forming a distinct clinical entity. At that time patients presenting with peripheral gangrene in Indonesian hospitals and clinics were variously diagnosed as suffering from Raynaud's disease, leprosy, diabetes, or syphilis.

In the early 1930's Professor E. P. Snijders from Amsterdam toured through Sumatra and Java, inquiring from hospitals about the incidence of patients presenting with gangrenous extremities. His report (Snijders, 1933) described in detail the case histories of 11 Indonesian young male smokers presenting with spontaneous gangrene of the extremities, and he recognized this group as forming a distinct clinical entity. He called this Von Winiwarter–Buerger's disease. Six of this group of patients were from Java.

Other papers describing 'Buerger's disease' in Indonesia have appeared but they are few and those that are available are mainly concerned with the treatment of the condition (Lodder and Müller, 1937; Van Leeuwen, 1938; Van Ouwerkerk, 1946; Kiagoes Agoess, Husni Hasbullah, and Djamaloeddin, 1971).

At the present time the vast majority of patients presenting with peripheral spontaneous gangrene in hospitals throughout Indonesia are diagnosed as 'Buerger's disease'. The clinical syndrome in these patients has not been described, its clinical course has not been documented, and no systematic study has been made into its pathogenesis or aetiology.

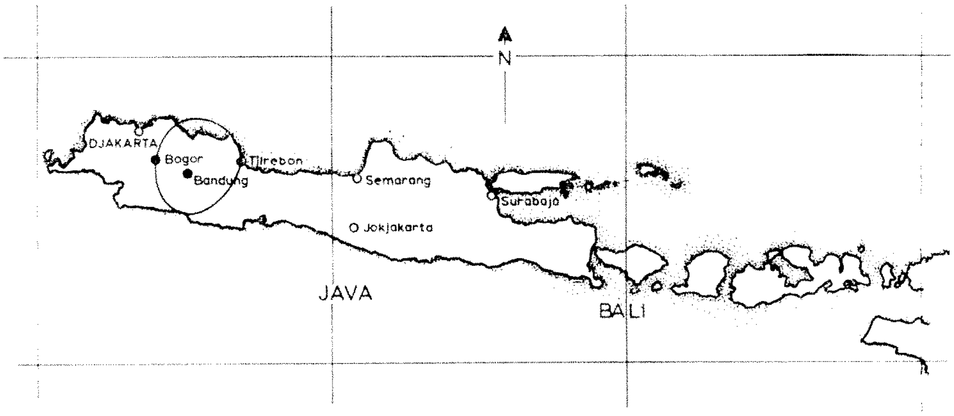

FIG. 1.—Map of the island of Java, Indonesia. The survey area is enclosed by the circle.

In this paper the results of a field survey of 106 Indonesian patients presenting with gangrene of the extremities is presented.

MATERIAL AND METHODS

Geographical and Sociological Setting.—The field survey was conducted in the eastern half of the province of West Java, Indonesia (*Fig.* 1). The area included the Bandung Plateau (2000 feet above sea-level) which is surrounded by hills and mountains ranging up to 8000 feet above sea-level. Also included were the cities of Bogor, which is noted for its excessive rainfall, and Tjirebon, which is an extremely hot city on the northern coast. Climatic limits within the area studied are shown in *Table I.*

The population and geographical centre of the area is the city of Bandung (1·5 million), but the area studied included the cities of Bogor, Tjirebon, Garut, and Tasikmalaja, as well as numerous small villages and towns. The population within the study area is not accurately known but is between 8 and 12 millions.

---

* Present address: Department of Surgery, General Infirmary, Great George Street, Leeds.

Most of the patients and the control subjects were living a rural type of life and even those living geographically in the cities were sociologically rural. The predominant ethnic group in West Java is the Sundanese, although Chinese, Javanese, and smaller numbers of other Indonesian ethnic groups are found.

Sampling.—It was intended to study the patients within the survey area who had been diagnosed as suffering from Buerger's disease. A quota sampling technique was used in which the survey area was stratified into regions each based on a population centre. Quotas of patients were drawn from every region.

For each patient in the study a closely matched control subject was obtained, who was matched for place of residence, age, sex, race, and socio-economic status. The closeness of this matching is shown in *Table II*. In practice the controls were the young men who fulfilled the above criteria and lived in close proximity to the patient. The validation of this sampling technique is discussed more fully elsewhere (Hill, 1972).

Table I.—THE CLIMATE IN THE SURVEY AREA

AREA	HEIGHT ABOVE SEA-LEVEL (m.)	AVERAGE YEARLY TEMPERATURE (°C.)	MEAN DAILY RANGE OF TEMPERATURE (°C.)	ABSOLUTE MINIMUM TEMPERATURE WHICH OCCURRED IN THE SAME YEAR AS MAXIMUM RANGE RECORDED	YEARLY RAINFALL (cm.)	NO. OF MONTHS PER YEAR WITH RAINFALL GREATER THAN 100 mm.

Chinese	6	4
Other	4	2
Total	106	100

The Field Survey.—The survey team travelled from village to village looking for patients within the quota regions. The patients and their controls were examined and interviewed in their homes by the survey team. The survey team consisted of a final-year medical student, a senior social science student, and a medically trained field supervisor. After gaining the confidence of the respondent and his family the medical student carried out a complete interrogation and physical examination on the respondent and followed this with a complete non-directive interview covering the clinical manifestations of the disease as well as the following large list of possible aetiologies: age, sex, race, heredity, occupation, socio-economic status, diet, tobacco, geography, past illness, cold and climate, immersion foot, mycotic infection, ergot, allergy, syphilis, trauma, and alcoholism.

This interview was followed by a separate directive interview carried out by the social science student who filled out a comprehensive precoded interview schedule concerned with possible environmental and sociological aetiological factors.

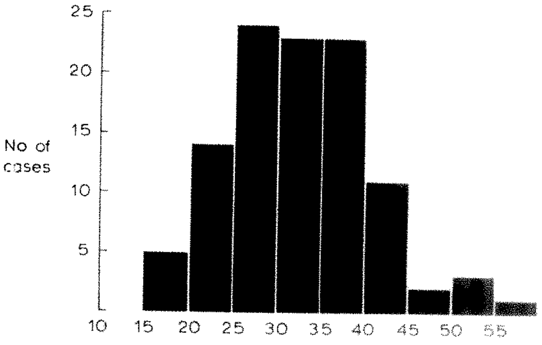

FIG. 2.—The age of onset of the disease in 106 patients.

The non-directive interview was used as an internal control for the directive interview and the field co-ordinator sought out and reinvestigated inconsistencies.

The information gained from both interviews was coded by one of the field supervisors (G. L. H.) and the results were analysed by the computer at the University of Otago, Dunedin, New Zealand.

RESULTS

The Clinical Syndrome.—The age distribution of the 106 patients at the time of the onset of their disease is shown in *Fig. 2*. The mean age of the group was 32 years and only 6 patients developed the disease after the age of 45 years.

Of the 106 patients studied, only 1 was a woman and she developed the disease at the age of 46 years. All the patients were cigarette smokers who had begun smoking before the onset of their disease and have continued to smoke.

Thirty-five patients had four-limb involvement (involvement was recorded when there was a missing distal pulse other than the dorsalis pedis + signs of ischaemia such as amputation, cyanosis, or pulp atrophy). A further 25 patients had three-limb involvement. In only 9 patients was the disease confined to one limb (*Table III*). In 22 patients one or both femoral pulses were impalpable, but 48 patients had normal femoral and popliteal pulses with absent posterior tibial pulses. Thirty patients had one or both radial pulses impalpable but all the patients had normal brachial pulses.

In 82 patients the disease commenced in the lower limbs. The initial symptoms are shown in *Table IV*.

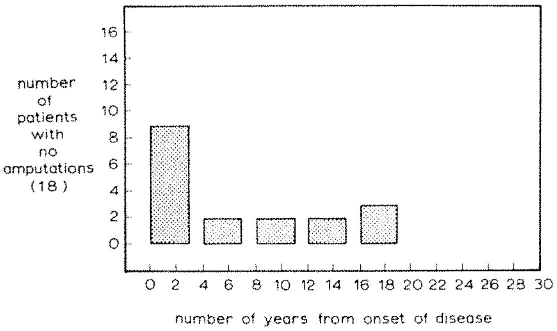

FIG. 3.—Patients without an amputation compared with the length of history.

Table III.—NUMBER OF LIMBS INVOLVED

No. of Limbs	*No. of Patients*
2 legs and 2 arms	35
2 legs and 1 arm	25
2 arms and 1 leg	2
2 legs	29
1 leg and 1 arm	6
1 leg	9
Total	106

Table IV.—INITIAL SYMPTOMS

Symptoms	*No. of Patients*
Numbness in feet	35
Tiredness and weakness in legs	33
Calf claudication	30
Foot claudication	27
Burning pain in foot	22
Cold feet	22
Ulceration and infection of digits	15
Thrombophlebitis	8
Cold hands	8
Hand claudication	6
Pain in fingers	6
Raynaud's phenomenon	2

The disease commenced peripherally and extended proximally. In 18 patients who had severe symptoms and clinical limb involvement, amputation had not been performed. The proportion of patients without amputation was higher among those with shorter histories (*Fig.* 3).

If the patients who had had an amputation are taken as a group the proportion with a major amputation as compared with those with only a digital amputation is higher among the patients with a longer history of the disease (*Fig.* 4). The patients with a longer history also tended to have more limbs with an amputation (*Fig.* 5).

Thirty-eight patients gave a history of superficial migratory thrombophlebitis and in the majority this was confined to the superficial tributaries of the long saphenous vein in the leg. Eight patients had superficial migratory thrombophlebitis as their initial symptom.

Twenty-eight patients complained of Raynaud's phenomena and in 24 this was confined to the hands.

Twenty-eight patients complained of hyperhidrosis of the hands and feet.

Other Physical Findings.—No xanthelasmata or other xanthomata were discovered in either the patient or control groups. No subject in either group was found to have any heart disease or any other incidental medical illness. One patient had developed a stroke at the age of 21 years. He had awoken one morning with paralysis of the right arm and his speech had been slurred. After 2 months' hospitalization he had improved and on physical examination at the time of the survey he had no residual signs (now aged 41 years).

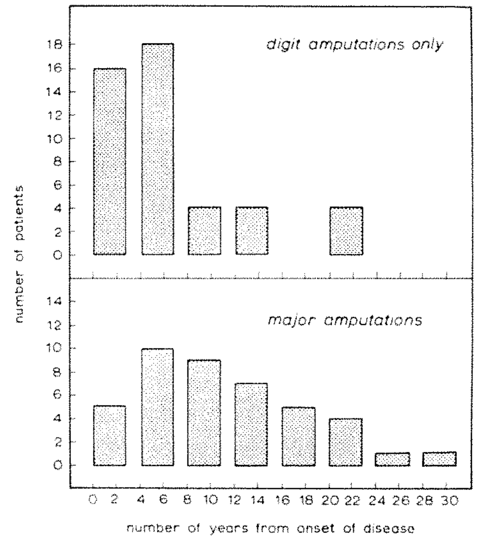

FIG. 4.—Patients with digital and major amputations compared with the length of history.

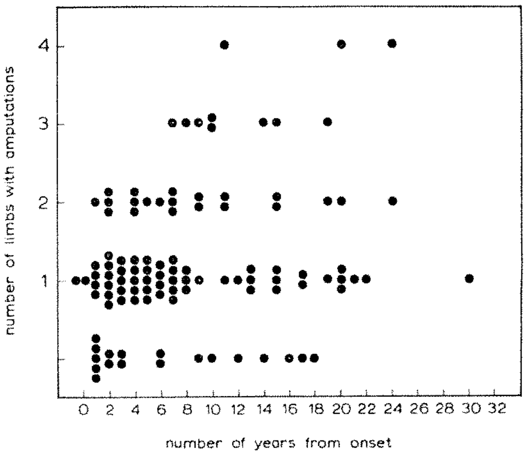

FIG. 5.—Number of limbs with an amputation compared with the length of history.

The Clinical Types.—Sixty patients presented a clinical picture of a slowly progressive peripheral arterial disease. In 59 patients the disease was periodic in nature, the slowly progressive pattern being interrupted by 'attacks' which in 16 patients were subacute in nature, resulting only in minor tissue loss such as ulceration or digital pulp atrophy. In the remaining 43 patients the 'attacks' were 'fulminant', commencing as an excruciatingly painful vesicle and progressing over a period of weeks to amputation. The degree of amputation was variable, most fulminant attacks resulting in the loss of several digits only, but in a minority of cases major amputation was the end-result of a single fulminant attack. When the intervals between attacks are averaged for the group as a whole attacks occurred every 29 months, but the range was wide, extending from 6 months to 10 years. Not only was this variation great from patient to patient, but for any individual there was no fixed pattern in the frequency or number of attacks.

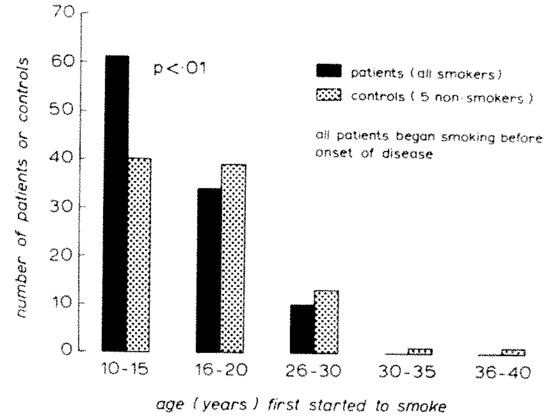

FIG. 6.—The age of commencement of smoking in the patients and their controls.

Fifteen patients developed an acute fulminant attack early in the course of their illness and after recovery from their amputation the disease has failed to progress. Six patients in this group have failed to show any progression of their disease for periods greater than 12 years.

Four patients, after commencing with an acute fulminant attack, developed circulatory compensation and have lost their symptoms.

Five patients presented a clinical picture which was not typical. Each of these patients developed their arterial disease after the age of 45 years, the eldest being 56 at the time of his first symptoms. All have their vascular disease confined to the lower limbs and 3 patients have one or both femoral pulses impalpable. One of this group is the only female patient in the series.

A summary of the 'clinical types' is shown in *Table V*. Only 84 patients could accurately be classified into clinical type as the remaining 22 had histories which were too short to judge the pattern of their disease adequately.

Aetiological Factors.—

1. *Tobacco.*—All of the 106 patients were smokers and all were smoking at the time of the survey. Ninety-five out of the 100 matched controls were smokers. Various types of cigarette were smoked, the commonest being Kawung, which is home-grown tobacco rolled in a tissue made from the leaves of a sugar palm. Another frequently smoked type was Kretek, which is a coarse form of tobacco mixed with cloves and spices and wrapped in normal tissue.

The type of cigarette smoked at the time of onset, and for the 3 years preceding the onset of the disease was evenly distributed between these two types and almost as large a group smoked the usual Western-type cigarette. Generally the type of cigarette smoked was the same in the patients and the controls.

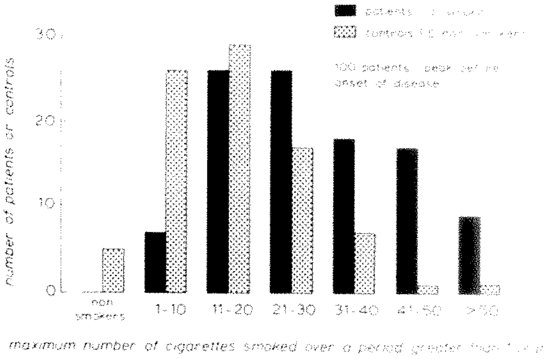

FIG. 7.—Peak smoking levels in the patients and their controls.

Table V.—SUMMARY OF CLINICAL TYPES

Clinical Type	*No. of Patients*
Slow progression with fulminant attacks	43
Slow progress with subacute attacks	16
Slow progress without attacks	1
Acute fulminant attack with failure of progression	15
Acute fulminant attack with circulatory compensation	4
Atypical	5
Unclassified	22
Total	106

All the patients had begun smoking before the onset of the disease.

If the patients are compared with the control group it is found that a significantly larger number of patients began smoking between the ages of 10 and 15 years ($P < 0{\cdot}01$) (*Fig.* 6).

Each respondent was asked about his peak smoking level, that is, the maximum daily number of cigarettes smoked consistently for a period of at least 1 year, and at what age was this peak smoking performed. One hundred patients smoked their peak before the onset of the disease, and at high levels of smoking (greater than 20 cigarettes per day) the patients consistently consumed more tobacco ($P < 0{\cdot}01$) than the controls (*Fig.* 7).

Thus, before the disease occurred the patients generally had begun smoking at an earlier age and were smoking more heavily than the controls. Nineteen patients had stopped smoking for periods of greater than 1 year, and 13 of these patients had noted an improvement in their condition, particularly in decreased rest pain and an increase in claudication distance. One patient related his attacks of migratory thrombophlebitis to commencing smoking after periods of cessation.

Sixteen patients had cut their smoking habits drastically (to less than 5 per day for a period greater than 3 years) and all but 1 claimed an improvement in the symptoms of rest pain and claudication. However, when compared with the patients who continued to smoke heavily there was no significant difference ($P > 0{\cdot}1$) in the mean period of time between attacks.

In the commonest clinical type of the disease, 25 patients related the periodicity of their attacks to times of increased smoking and the 2 patients whose disease did not progress over a long period of time had both cut their smoking over this period to less than 5 cigarettes per day.

◫ Reported to have Buerger's Syndrome (dead)

FIG. 8.—Familial aggregation of the Buerger syndrome in two families.

2. *Racial Distribution.—Table II* shows the racial distribution in both the patient and control groups. This distribution does not show a predominance of any one grouping and closely parallels the ethnic structure of the population of West Java.

3. *Socio-economic Status.*—This was assessed by both interviewers, who took into account not only salary but also housing, family structure, mode of living, and food.

In general all the patients were from the poorer section of the community and there were no patients who could be judged middle class even by Indonesian standards. The wealthiest patient in the series earned about £15 per month and lived in a two-roomed concrete-floored cottage at the back of his market shop.

As further evidence that the disease predominates in the lowest socio-economic groups the four local Bandung hospitals were surveyed. The three public hospitals which catered almost exclusively for the poor had between 15 and 22 new patients admitted with a diagnosis of Buerger's disease per year. The remaining hospital, of comparable size, which was for rich patients had had no admissions with a diagnosis of Buerger's disease in the past 5 years.

4. *Occupation.*—The immediate 3-year period prior to the onset of the illness was considered. Twenty-nine patients were rice farmers who had spent up to 3 months of each year working with their feet immersed in water. Sixty-three patients were outdoor workers with various labouring jobs which involved working in bare feet or using only a primitive type of sandal. These people were vendors, market workers, outdoor labourers, and Betjak drivers. Only 14 patients in the group had indoor jobs during this period. When compared with their matched controls at the same stage of their lives the employment distribution was not significantly different.

At the time of the survey 56 patients have continued in the same employment but the remainder have been forced to stop work because of their illness.

5. *Diet.*—The usual diet of the respondents was made up of polished rice, vegetables (carrot, spinach, cabbage, potatoes in season, maize, roots such as yam, and cassava), dried or fermented fish, and soya-bean cake, all spiced with peppers, ginger, cinnamon, or onions and various local leaves and shoots.

Small portions of beef, mutton, or frog, plus lung, liver, kidney, or intestine were eaten once or twice weekly. This diet applies to times of plenty. In hard times it might contract to maize, cassava, and potatoes.

In 58 patients and 42 controls the diet was very poor in protein of any type (i.e., less than 2 oz. per week) and in more than half of these people the only source of protein was from soya bean.

There was no clear vitamin-deficiency syndrome seen in any of the respondents.

6. *Familial Aggregation.—Fig.* 8 shows familial aggregation of the disease in two families.

Two other families whose family history is incomplete had histories suggestive of other members having peripheral vascular disease. One patient had a brother who was 3 years younger and who was handicapped at work with hand claudication. He was not examined by the team. The remaining patient claimed that his grandfather died of gangrene of his feet whilst still quite young.

One patient had an identical twin brother who was also a smoker. This man was found and on physical examination was entirely normal.

7. *Geographical and Climatic Distribution.—Fig.* 9 shows the place where each patient lived in the 3-year period prior to the onset of his illness. This shows no particular clustering when it is remembered that an area sampling technique was not used. The grouping around Bandung is a reflection of the dense population in that region. Thus there are patients presenting from all climatic extremes in the area surveyed and no region or particular climatic factor appears to predominate. When compared with their matched controls, at the same stage of their lives, this geographical distribution is not significantly different.

8. *Past History of Illness.*—The patients had a scattered collection of past histories of trauma and infectious disease but the distribution was almost identical to that of the control group. Both the patients and the controls had a similar incidence of food and drug allergy and this was less than 10 per cent. Alcoholism was not seen in either the patient or the control group. There was no suggestion of ergot poisoning in any of these patients or their families.

9. *Cold Injury.*—Each respondent was read a story of an Indonesian farmer who had suffered from a classic episode of trench foot. The reaction of each respondent was noted. Twenty-three of the patients recognized the condition immediately and claimed that they had suffered a similar episode before the onset of their illness. In most of these 23 patients the first episode had been followed by temperature instability, inappropriate sweating, and sometimes repeated episodes of lesser severity. None of the controls had had trench foot.

Eight patients complained voluntarily of cold urticaria and in 4 this was of the immediate acquired type. The other 4 patients complained more of systemic symptoms, with a history suggestive of the familial form of cold sensitivity. Only 1 of this group of 8 patients had also suffered from trench foot. Two control subjects complained of the acquired form of cold sensitivity.

Thus, of the group of 106 patients, 30 patients had had some form of cold injury and this was in general associated with working with feet immersed in water over long periods of time.

10. *Mycotic Infection.*—Each respondent was shown a series of coloured photographs of various forms of dermatomycoses. Their response was noted. Forty-two patients claimed that they had had tinea pedis before the onset of their disease. Only 16 of the controls, when compared with the onset age of their matched patient, had had tinea pedis. The difference is highly significant ($\chi^2 = 13{\cdot}05$, $P < 0{\cdot}001$).

At the time of the survey 10 of the patients and 4 of the controls had clinical fungal infection.

11. *Laboratory Tests.*—In 28 patients the fasting blood-glucose, serum cholesterol, and serum-protein electrophoresis were measured, and a Wassermann reaction and Kahn test for syphilis were carried out.

No instance of hyperglycaemia was discovered. No patient had hypercholesterolaemia. In all the patients the electrophoretic pattern of the serum proteins was within normal limits.

In 2 patients the Wassermann reaction and Kahn test were positive.

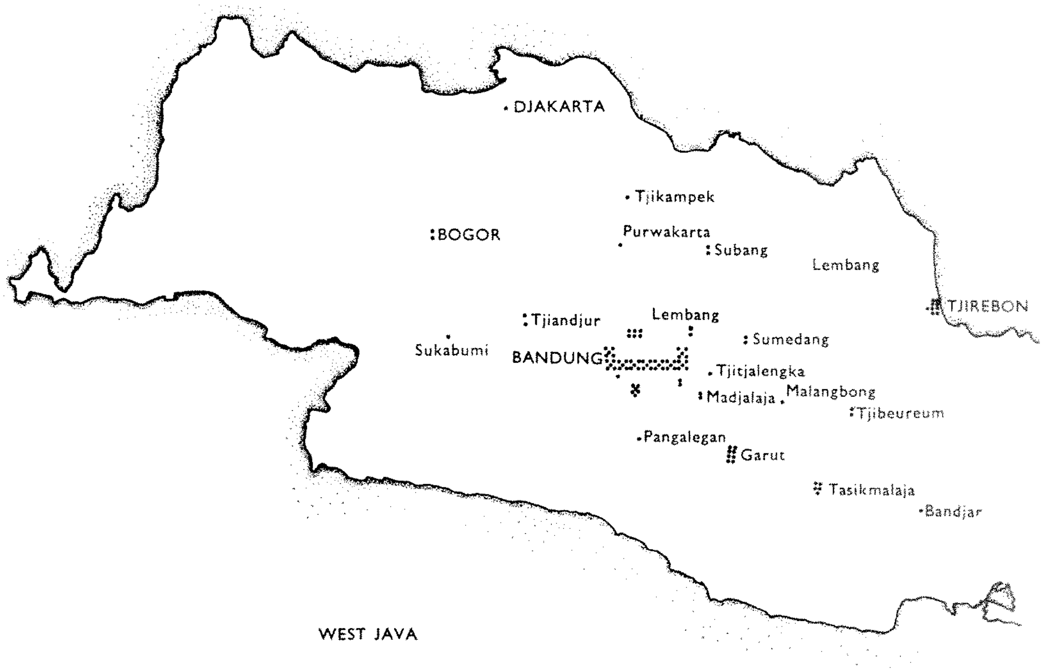

FIG. 9.—The province of West Java showing the place where each patient lived in the 3-year period prior to the onset of the disease.

DISCUSSION

The syndrome in the group of patients studied is a peripheral four-limb youthful type of arterial disease occurring in Indonesian males. Of the 106 patients who were studied by the survey team and who had been previously diagnosed as having 'Buerger's disease', 101 of them presented a picture consistent with the Buerger syndrome which has been described elsewhere (McKusick and Harris, 1961).

These 101 young Indonesian males had all developed their arterial disease before the age of 45 years and, of these, only 12 were over the age of 40 years at the time of onset of their disease. Thirty-five patients had four limbs involved and all the patients had one or both legs involved. Sixty-eight patients had one or both arms involved. The peripheral nature of the disease is suggested both by the amputation status of the group (*Figs.* 3–5) and also by the fact that nearly half the patients had normal femoral and popliteal pulses with distal pulses absent. Thirty-eight patients gave a history of migratory thrombophlebitis, and the conspicuous relationship of the disease to tobacco smoking has been established.

It may be wondered why 3 of the 22 patients with one or both femoral pulses impalpable are included in the group of 5 patients whose clinical picture is indistinguishable from juvenile atherosclerosis. The remaining 19 patients with one or both femoral pulses absent are evenly distributed throughout the series as regards the age of onset, length of history, number of limbs involved, and migratory thrombophlebitis, and no particular pattern emerges from a study of this group. A femoral arteriograph was available for 1 of these patients (*Fig.* 10). This shows a complete block of the superficial femoral artery and profunda system. There are abundant collaterals around the block. This patient developed his disease at the age of 27 years. He had a history of migratory thrombophlebitis and diminished pulsations in both radial arteries. The clinical picture and arteriographic appearances do not suggest juvenile atheroma in this patient.

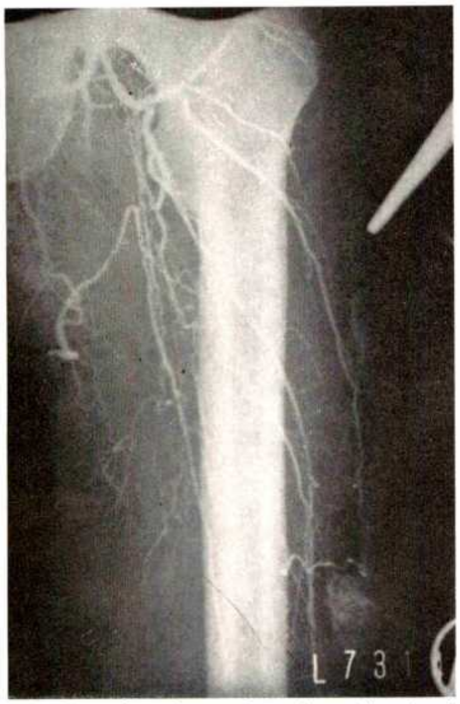

FIG. 10.—Femoral arteriogram of a patient with an impalpable femoral pulse.

The slowly progressive nature of the disease in this series, together with exacerbations producing increased arterial insufficiency resulting usually in digital amputation only, is similar to that described previously for Buerger's disease (Brown, Allen, and Mahorner, 1928; Juergens, 1972). This slowly progressive type of disease is different to the pattern seen in atherosclerosis, for although serious worsening nearly always occurs as a sudden event in patients with atherosclerosis this is usually a major deterioration, and spontaneous recovery from such an episode to a degree sufficient to provide a useful limb is most uncommon (Humphries, de Wolfe, Young, and Le Fevre, 1963).

It is interesting that the clinical types noted in the present series parallel the clinical types described in a large series from the Mayo Clinic over 40 years ago (Brown and others, 1928).

Being a field survey, histology was not available for any of the patients in the present series. Thorough documentation of the histological picture of 7 young Indonesian male smokers with spontaneous peripheral gangrene has been described previously (Lodder and Müller, 1937). Both acute and chronic lesions were described and the disease was identical to that described originally by Buerger (1908). It seems reasonable to conclude that the disease described by Lodder and Müller (1937) is the same as the one described in the present report.

Of the aetiological factors considered, age, sex, socio-economic status, occupation, familial aggregation, tobacco, cold injury, and past mycotic infection seem to be of some importance.

Other descriptions of the Buerger syndrome occurring in Asian countries (Whyte, 1917; McKusick and Harris, 1961; Yong, 1971) have all shown the disease occurring almost exclusively in the lower socio-economic groups although this is not a feature of the disease in Western countries (Goodman, Elian, Mozes, and Deutsch, 1965; Juergens, 1972).

Familial aggregation has been noted previously by other workers (Samuels, 1932; Weber, 1937; Martorell, 1952; Goodman and others, 1965), but of particular interest is the woman (*Fig.* 8) who has had 2 husbands and in both her sets of children the Buerger syndrome has appeared. A patient with a normal identical twin has not been described before.

Occupation probably reflects socio-economic status and both of these may be important only in so far as the increased susceptibility of the individual to cold injury which occurs in outdoor workers during the wet season. Patients with sensitivity to cold have been reported sporadically in the literature (Duke, 1925; Horton and Brown, 1929; Spittell, 1972), but not previously in association with vascular disease. Although minor degrees of feelings of abnormal coldness in an affected limb are well recognized in circulatory disease (Juergens, 1972) the cold urticaria described in the present series is a more specific entity.

Some investigators have reported a frequent history of frost-bite occurring prior to the onset of the Buerger syndrome (McKusick and Harris, 1961; Goodman and others, 1965), but others have not observed this (Juergens, 1972). Other studies have not noted the high incidence of trench foot. There is argument as to whether trench foot is basically the same process as frost-bite (Spittell, 1972), but it is interesting that the late vasospastic phase of trench-foot sensitivity to cold can be a marked feature (White, 1944). It may be that the patients with sensitivity to cold have actually suffered a minor degree of trench foot which they have since forgotten. It would be interesting to know the long-term follow-up of a large series of patients with previous trench foot. We have been unable to find any information about this in the literature.

Fungal infections are frequently present between the toes of patients with the Buerger syndrome (Eastcott, 1969), and some workers have suggested mycotic infection as an aetiological agent (Naide, 1941; Craven and Cotton, 1967). The problem that has never been clarified is whether the fungal infection occurs before or after the onset of the disease. The present study suggests that the fungal infection precedes the onset of the disease.

It is concluded that the clinical syndrome presented in this study is the same constellation of clinical symptoms and signs described as the Buerger syndrome in other studies. The environmental factors of significance in this syndrome as it presents in Java appear to be tobacco, cold injury, and a past history of mycotic infection.

Acknowledgements.—We wish to thank Professor P. A. Surjadi and Dr. J. E. Siregar and other members of the Board of Maranatha University for their financial help and also their support in all the phases of this study. We are grateful to Sdr. Adiwedjaja, Paryana, Hadiman, Soebiantoro, Surjadi, Budi, Tancar, and Bastion who all helped in various stages of the study. The Reverend D. E. Duncan and other members of the Overseas Missions Committee of the Presbyterian Church of New Zealand, Professor A. M. Clarke, Mr. G. F. S. Spears, Mrs. R. Molloy, Dr. Alan Smith of the University of Otago have all willingly and generously given their time at different periods during the project.

METABOLIC CHANGES FOLLOWING VARYING DEGREES OF PARTIAL HEPATECTOMY IN THE RAT

BY C. B. WOOD, S. J. KARRAN, AND L. H. BLUMGART*
UNIVERSITY DEPARTMENT OF SURGERY, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

SUMMARY

1. The metabolic and functional changes that follow hepatectomy in the rat are related to the extent of liver resection.

2. Regenerating liver cells show an impaired ability to excrete bilirubin, bromsulphophthalein, and ^{125}I Rose Bengal during the early postoperative period.

THE liver remnant undergoes a rapid proliferative response after partial hepatectomy. The process has been extensively studied and in the experimental animal the rate and degree of this response have been related to the extent of hepatic resection (Bucher and Swaffield, 1964). Removal of large quantities of liver tissue in animals and in man results in alterations in liver function (Harkness, 1957; Aronsen, Ericsson, and Pihl, 1969; Blumgart and Vajrabukka, 1972). Attempts have been made to relate the metabolic changes following partial hepatectomy in man to the amount of tissue removed (Lin and Chen, 1965). However, it is difficult to interpret the results of such studies since partial hepatectomy in man involves the removal of liver tissue already damaged by the disease process and leaves a remnant often affected by prior compensatory hyperplastic change. In addition, liver resection in man is often accompanied by pre- or peroperative hypovolaemic hypotension. As a result the function of the liver remnant after operation may be compromised by the effects of tissue hypoperfusion.

In order to overcome these difficulties, different degrees of resection were performed in the previously normal rat liver and the changes that occurred in liver function after resection were studied.

MATERIALS AND METHODS

Animals.—Male Sprague-Dawley rats weighing between 250 and 320 g. were used. They received food and water *ad libitum* throughout the experiments.

---

* Present address: Professor of Surgery, University Department of Surgery, Glasgow Royal Infirmary.

Operative Procedures.—Ether anaesthesia was used throughout.

1. Partial hepatectomy was performed using the method described by Higgins and Anderson (1931). This involved removal of the median and left lateral lobes of the liver. Studies on 30 animals in our laboratory have shown that this procedure removes 69 ± 2 per cent of liver tissue.

group II. Eight control animals, 4 having ether anaesthetic alone and 4 subjected to laparotomy and liver mobilization but without removal of any liver tissue, were added to each subgroup.

Blood samples were taken from all the animals before operation and then from alternate paired subgroups at 12 and 24 hours and 2, 3, 4, 7, 10, 13, 16, 19, 22, 25, and 28 days after operation.

2. Subtotal hepatectomy (Weinbren and Woodward, 1964). This involved resection of the median and left lateral lobes plus the caudate lobes and inferior division of the right lobe. Studies in our laboratory on 30 animals have shown that this procedure removes 80 ± 1·75 per cent of liver tissue.

All blood samples were taken from the jugular veins.

Arrangement of Experiments.—

1. *Liver-function Tests.*—Two groups of 18 animals each were used. All the animals in group I underwent partial hepatectomy, while the animals in group II underwent subtotal hepatectomy. Each of the main groups of animals were subdivided into three subgroups of 6 animals, each of the subgroups in group I being paired with a similar subgroup from

The total serum protein, serum albumin, serum alanine transaminase, and serum bilirubin were measured in each of these blood samples.

2. *Blood-glucose.*—Two groups of 6 animals each were used. The animals in group I were submitted to partial hepatectomy, while those in group II had a subtotal hepatectomy. Four control animals, treated as described above, were added to each group.

Blood samples were taken from all the animals before operation and then 6, 12, and 24 hours and 2, 3, 4, and 5 days after operation.

3. *Bromsulphophthalein Clearance.*—Two groups of 3 animals each were used. The animals in group I had partial hepatectomy and those in group II had subtotal hepatectomy. Four control animals were again added to each group, as described for the other experiments.

Five mg. of bromsulphophthalein (B.S.P.) were injected into the jugular vein of the animals and blood samples were taken from the opposite jugular vein at regular intervals up to 25 minutes after the initial injection. It was found that the highest value for serum B.S.P. was 1 minute after injection. This value was taken as 100 per cent and as the blood was cleared of B.S.P. the serum levels obtained were expressed as percentages of the value obtained at 1 minute. The blood-clearance studies were performed immediately after hepatectomy and at 24 hours, 7 days, and 10 days after operation.

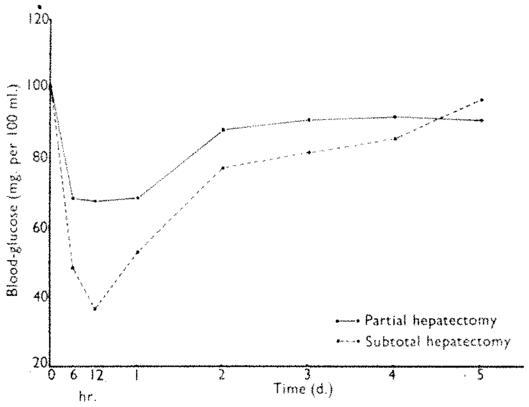

FIG. 1.—Changes in the blood-glucose levels after two-thirds partial hepatectomy and subtotal hepatectomy.

4. *Rose-Bengal Clearance.*—Similar groups of animals to those used to measure B.S.P. clearance were used to measure the clearance of radioactive Rose Bengal. Five μc. of ^{125}I Rose Bengal were injected into the jugular vein. The right leg of the anaesthetized rat was then isolated through a small hole in a thin lead screen and counts were made over the leg using a scintillation counter. The observations were made every minute up to the fortieth minute after the initial injection. Preliminary studies in our laboratory (Karran, Leach, and Blumgart, 1972) have shown this to be a reliable and reproducible method of assessing blood clearance of Rose Bengal.

Counts obtained were expressed as a percentage of the maximal value obtained 1 minute after injection. Rose-Bengal clearance studies were made immediately after operation and then 24 hours, 7 days, and 10 days after operation.

Biochemical Methods.—The total serum protein was measured using a micro-version of the standard method. Serum albumin was measured by a dye-binding method using brom-cresol green. The serum alanine transaminase was measured on an LKB reaction rate analyser using the method described by Wroblewski and Ladue (1956). The serum bilirubin was measured by a micro-version of the standard technique using diazotized sulphanilic acid.

To measure the blood-glucose 0·1 ml. of serum was added to 1 ml. of perchloric acid and centrifuged. Fifty μl. of the supernatant were added to 5 ml. of the colour reagent from a Boeringer sugar analysis kit. The solution was incubated at 37° C. for 15 minutes, and the colour reaction was read on a colorimeter using a 420-nm. filter.

To measure the serum B.S.P. 0·05 ml. of serum was added to 0·025 ml. of water and 0·3 ml. of $N/10$ NaOH. The test solution was read on a colorimeter at 540 nm. against a blank solution which used 0·3 ml. of $N/10$ HCl solution in place of $N/10$ NaOH. The serum B.S.P. level was then determined from a standard graph.

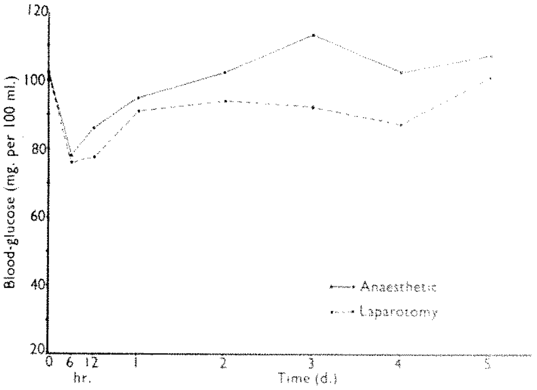

FIG. 2.—Changes in the blood-glucose levels after laparotomy and ether anaesthetic alone.

RESULTS

Our results show that metabolic changes following hepatectomy in the rat are related to the extent of liver resection.

1. Liver-function Tests.—*Table I* shows the changes in the total serum-protein levels in the two groups of hepatectomized animals. There was a fall in the total serum-protein levels after hepatectomy. This was significantly greater after subtotal hepatectomy at 24 hours ($P < 0·05$) and 48 hours ($P < 0·01$) postoperatively. The values had returned to within normal limits in both groups by the thirteenth postoperative day. A similar though less marked fall in the total serum protein was noticed in both control groups of animals during the early postoperative period (*Table II*).

There was no significant fall in the serum-albumin level following two-thirds partial hepatectomy. However, there was a marked fall in the serum-albumin level after subtotal hepatectomy. This fall in serum levels was maximal at 3 days after operation. Recovery to within normal limits had occurred by the thirteenth postoperative day.

There was a sharp rise in the serum alanine transaminase after hepatectomy. Despite wide variations around the mean values this rise in enzyme levels was much greater after subtotal hepatectomy. Enzyme levels had returned to within normal limits by the third postoperative day (*Table I*). There was no change in the serum alanine transaminase levels in the control groups (*Table II*).

There was a very slight rise in the serum-bilirubin levels during the first few days after two-thirds partial hepatectomy. However, there was a much greater rise in the serum bilirubin levels in the same period after subtotal hepatectomy. Serum-bilirubin levels had returned to within normal limits by the thirteenth postoperative day (*Table I*). *Table II* shows that there was no rise in the serum bilirubin in the control animals.

2. **Blood-glucose.**—There was a decrease in blood-glucose levels in both groups of hepatectomized animals during the first 48 hours after operation (*Fig.* 1). The changes were significantly greater after subtotal hepatectomy at 6 hours ($P < 0{\cdot}05$) and 12 hours ($P < 0{\cdot}001$) postoperatively. The blood-glucose levels had returned to normal within 48 hours after operation. There was a similar though less marked fall in blood-glucose in both groups of control animals (*Fig.* 2).

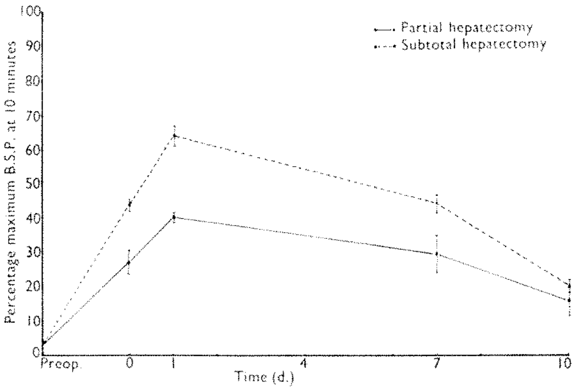

FIG. 3.—Percentage maximum serum levels 10 minutes after the injection of B.S.P. in the pre- and postoperative period after two-thirds partial hepatectomy and subtotal hepatectomy.

3. **B.S.P. Clearance.**—The mean values for the percentage maximal levels obtained at 10 minutes after the administration of B.S.P. in each of the clearance studies performed are shown in *Fig.* 3. There was quite a considerable delay in the clearance of B.S.P. immediately after hepatectomy. Twenty-four hours after operation there was even greater retention of B.S.P. and the changes were more marked in the subtotal hepatectomy group of animals. The rate of clearance of B.S.P. had almost returned to normal by the tenth postoperative day. Laparotomy did not produce a delay in B.S.P. clearance.

4. **Rose-Bengal Clearance.**—The mean values for the percentage maximal counts obtained at 10 minutes after the injection of ^{125}I Rose Bengal are shown in *Fig.* 4. There was a marked delay in the clearance of Rose Bengal immediately after operation, the changes being greater after subtotal hepatectomy. Twenty-four hours after operation there was an even greater delay in clearance but there was no significant difference between the clearance rates in the two groups of animals. The blood-clearance rates in both groups had returned almost to normal by the tenth postoperative day. Laparotomy did not produce a delay in the clearance of Rose Bengal.

DISCUSSION

It is difficult to relate the metabolic changes after hepatectomy in man to the degree of liver resection. The lobed liver of the rat allows easy partial hepatectomy of varying extent in a previously normal liver. The operative techniques do not leave large quantities of damaged or non-viable tissue attached to the liver remnant after partial hepatectomy. Furthermore, functional changes in the remnant are not influenced by the effects of previous disease, compensatory regenerative hyperplasia, and hypovolaemic hypotension.

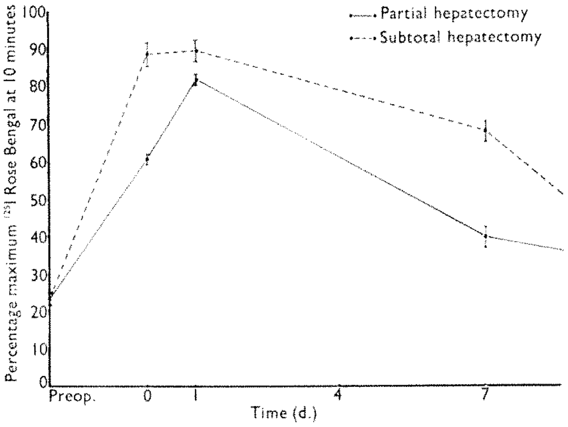

FIG. 4.—Percentage maximum counts 10 minutes after the injection of ^{125}I Rose Bengal in the pre- and postoperative period after two-thirds partial hepatectomy and subtotal hepatectomy.

Our experiments have shown that the metabolic changes after partial hepatectomy are related to the extent of liver resection. There is a well-recognized decrease in the serum levels of the total protein and albumin following partial hepatectomy in the rat (Chanutin, Hortenstine, Cole, and Ludwig, 1938; Bengmark, Olsson, and Rehnström, 1968). In our experiments the decrease in the serum levels of total protein and albumin was greater after subtotal hepatectomy than after two-thirds partial hepatectomy. A similar though less marked fall in the total serum-protein and serum-albumin levels occurred after laparotomy and ether anaesthesia alone. This latter finding suggests that the changes are at least in part related to the degree of stress to which the animal is submitted. However, it has been shown that there is a relative increase in the synthesis rate of albumin by the liver after partial hepatectomy but not following laparotomy (Chandler and Snider, 1970; Majumdar, Tsukada, and Lieberman, 1967). Other workers have demonstrated increases in protein synthesis 48 hours after partial hepatectomy (Schreiber, Urban, Zahringer, Reutter, and Frosch, 1971), and recent studies in our own laboratory have indicated an increase in protein synthesis within 12 hours of operation (Karran and others, 1972).

Elevation of the serum-alanine-transaminase level is thought to represent a reaction to acute cell injury (Wroblewski, 1959). We have shown that the rise in this enzyme is greater after subtotal hepatectomy. This may reflect the greater degree of cell injury in the remaining liver tissue after this operation as compared with the two-thirds partial hepatectomy. However, others have suggested that hypertransaminasaemia after liver resection may be related to increased pressure within the bile-ducts in the immediate postoperative period (Braun, Papp, and

Horvath, 1959; Almersjo, Bengmark, Hafstrom, and Olsson, 1969). We find this difficult to accept since T-tube drainage does not appear to affect the pressure within the biliary-duct system after experimental liver injury in dogs (Lucas, Lenaghan, and Walt, 1969). This observation does not, however, exclude a cholestatic effect at the canalicular level owing to hepatocyte engorgement or other factors.

Although McDermott, Greenberger, Isselbacher, and Weber (1963) reported a fall in the blood-sugar level after the resection of 70–90 per cent of the liver in man, neither Pack and Molander (1960) nor Lin and Chen (1965) found any significant change in the blood-sugar level of their patients. Similarly, Aronsen and others (1969) showed no change in the blood-sugar level after major hepatic resection. However, the latter authors administered large quantities of intravenous invertose during the postoperative period. Other workers have recently reported hypoglycaemia after liver resection for injury (Blumgart and Vajrabukka, 1972). In our experiments we noted a fall in the blood-glucose level during the first 24–48 hours after hepatectomy and this fall was significantly greater after subtotal hepatectomy. Similar findings have been reported by Weinbren and Dowling (1972). Although the low blood-sugar level found in the subtotally hepatectomized animals may reflect the effects of shock or liver hypoperfusion it is known that glycogen disappears from hepatocytes after partial hepatectomy (Harkness, 1957) and begins to reappear by about the twenty-fourth postoperative hour. Alterations in the energy metabolism in regenerating liver tissue have been reported (Simek, Chmelar, Melka, Pazderka, and Charvat, 1967) which may result in a decrease in liver-cell glycogen and a subsequent reduction in the reserve store for glucose. However, impaired gluconeogenesis may be equally responsible for the observed changes. We also noticed a slight fall in the blood-glucose level in the control animals. This may be the result of decreased food intake during the immediate postoperative period.

Weinbren and Billing (1956) have demonstrated a reduced capacity for the liver to clear a bilirubin load in the first 24 hours after two-thirds partial hepatectomy in the rat. They suggested that this was probably due to the loss of liver tissue and immaturity of the remaining liver cells during the early phases of the proliferative response. Despite this reduced capacity to clear bilirubin, we have shown no significant increase in the serum-bilirubin level after two-thirds partial hepatectomy. However, after subtotal hepatectomy there was a rise in the serum-bilirubin level which was maximal 24 hours postoperatively.

The delay in the blood clearance of B.S.P. and ^{125}I Rose Bengal immediately after operation is almost certainly related to the amount of liver tissue removed. It is of interest that there was an even greater delay in the blood clearance of both compounds 24 hours after operation and that the delay in the clearance of B.S.P. at this time was more marked in the subtotally hepatectomized animals. This delay, together with the reduced capacity of the partially hepatectomized liver to deal with bilirubin at this time, may reflect the inability of regenerating liver cells to excrete these substances. It is tempting to relate the delay in the proliferative response of the liver remnant after subtotal hepatectomy (Weinbren and Woodward, 1964) to similar causes.

The results of our investigations clearly show that the metabolic changes after liver resection in the rat are related to the amount of liver tissue removed. While the effects of liver resection in man may be influenced by pre-existing disease and by shock, due allowance should be made for the greater disturbance in metabolic function occasioned by the more extensive resections.

THE LEUCOCYTE COUNT IN ACUTE APPENDICITIS

By P. W. R. LEE
GENERAL INFIRMARY, LEEDS

SUMMARY

The leucocyte count was estimated in 100 consecutive cases of pathologically proved appendicitis. It is concluded that although a white-cell count below 10,000 per c.mm. does not exclude the diagnosis of acute appendicitis, such a result should prompt further review and consideration of the diagnosis.

IT has long been recognized that the white-cell count is elevated in acute appendicitis; however, little more precise information regarding the frequency and degree of elevation is available. This paper reviews the leucocyte count in 100 consecutive cases of pathologically proved acute appendicitis which were examined and operated upon by the author.

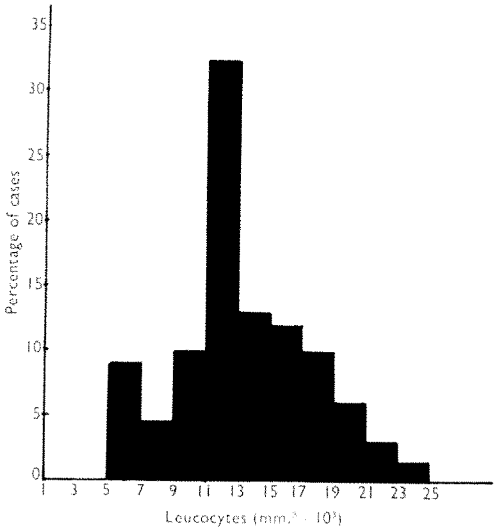

FIG. 1.—The leucocyte count in patients with acute appendicitis (100 patients).

MATERIAL AND METHODS

Over a period of 18 months, initially at the Royal South Hants Hospital, Southampton, and later at the General Infirmary, Leeds, a routine preoperative white-cell count was performed on each patient in whom the diagnosis of acute appendicitis was suspected. The leucocyte counts were performed by haematology technicians using a Coulter Cell Counter. The diagnosis of acute appendicitis was considered confirmed only when pathological examination of the removed appendix showed acute inflammatory changes. No attempt was made in this survey to correlate the level of the white-cell count with the degree of inflammation.

RESULTS

The ages of the patients ranged from 8 to 70 years and the white-cell count from 5500 to 23,500 per c.mm. Eighty-two of the patients (82 per cent) had a white-cell count of greater than 10,000. Of the remaining 18 per cent, 12 per cent had a count of between 9000 and 10,000. The distribution of the level of the white-cell count in the 100 patients is shown in *Fig.* 1.

DISCUSSION

Because of the wide variation in the range of the normal values of the white-cell count in healthy persons it is inevitable that some overlap will exist between the leucocyte counts of a group of healthy subjects and those of patients with acute appendicitis. However, 95 per cent of the population have a white-cell count of between 5000 and 10,000 (Hardison, 1968), and thus it is seen that the great majority of the patients with acute appendicitis in the present series had an appreciable rise in the leucocyte count.

The results of this series are comparable with those of the other reported series. Sasso, Hanna, and Moore (1970) showed a white-cell count of over 10,000 in 90 per cent of a series of 525 patients, whilst Lansden (1963) showed a significant leucocyte elevation in 84 per cent of 1000 cases of children with acute appendicitis. It is suggested that the routine white-cell count—a simple and non-time consuming investigation—is valuable in the assessment of a possible case of acute appendicitis.

Acknowledgements.—The author wishes to thank the Surgical Consultants at the Royal South Hants Hospital, Southampton, and at the General Infirmary, Leeds, for permission to study cases under their care.

INTUSSUSCEPTION OF THE APPENDIX

BY R. H. L. DOWN AND T. BATES
LUTON AND DUNSTABLE HOSPITAL, BEDFORDSHIRE

SUMMARY

Two cases of intussusception of the appendix are reported. In both cases there was a palpable tumour within the caecum and a short thickened appendix. Both intussusceptions were predominantly mucosal and of a type not previously described.

INTUSSUSCEPTION of the appendix was first reported by McKidd in 1858 and since then about 130 cases have been recorded. The condition may mimic acute appendicitis or carcinoma of the caecum, but the diagnosis can only be made with certainty at operation.

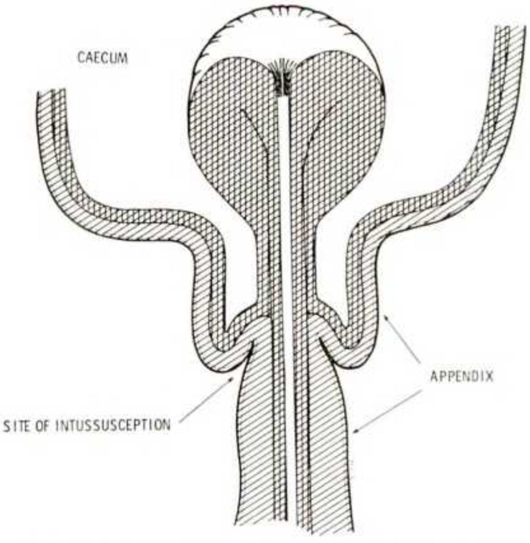

FIG. 1.—*Case* 1. Diagram of intussusception of the appendix. This shows that although there is a muscular intussusception the intracaecal tumour is oedematous intussuscepted appendicular mucosa.

McSwain (1941) described four types of intussusception of the appendix, but Paul and Ferraro (1967) modified this classification into five types. These may be simple or combined with intestinal intussusception. The great majority of cases are in fact inversion of the appendix (Jacobs, 1963) which may start at the tip of the appendix or at its base or may be complete. True intussusception, however, starts at a point between the tip and the base of the appendix, and the apex of the intussusceptum usually progresses proximally. The 2 cases reported here are of a type not previously described.

CASE REPORTS

Case 1.—A 23-year-old man presented in August, 1972, with a 10-hour history of vomiting and the sudden onset of severe pain in the right iliac fossa 2 hours before admission. There had been no previous abdominal pain or alteration in bowel habit. On examination there was marked localized tenderness in the right iliac fossa but no palpable mass.

At emergency operation through a gridiron incision a discrete polypoid tumour 2 cm. in diameter was palpable within the caecum. This arose from the base of the appendix which was thickened but not inflamed. It was subcaecal in position, 3·5 cm. in length, and had a thin mesentery. The tumour was recognized as an intussusception of the appendix and an attempt was made to reduce this by traction. A short segment of muscular intussusception was reduced 1 cm. distal to the base of the appendix. However, this did not appreciably change the size of the caecal tumour (*Fig.* 1). The greater part of the tumour was then expressed into the appendicular lumen where it was thought to be either excess mucosa or faeces. An attempt was made to carry out formal appendicectomy, but the muscle coat was so thick that the ligature slipped off and a tube of appendicular mucosa 1·5 cm. in length extruded from the stump. After excision of the redundant mucosa no residual tumour could be felt within the caecum and the appendix stump was ligated and inverted. The patient was discharged well on the fifth postoperative day.

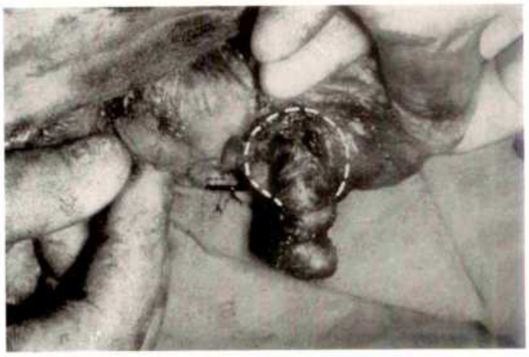

FIG. 2.—*Case* 2. Photograph of the short thickened appendix. The caecal tumour is outlined.

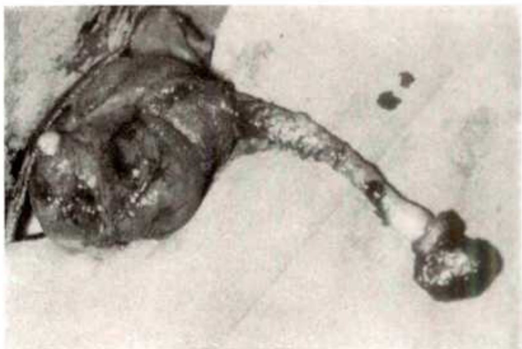

FIG. 3.—*Case* 2. Photograph showing the tube of appendicular mucosa that was reduced after division of the muscle coat of the appendix.

Histology of the appendix showed fibrous obliteration of the distal third of the appendix but a good lumen in the proximal portion, with marked muscular hypertrophy. The cuff of excised mucosa was oedematous.

Case 2.—A 27-year-old woman presented as an out-patient in May, 1969, with a recent history of severe cramping pain in the right iliac fossa lasting several hours. Physical examination was normal apart from some tenderness in the right iliac fossa. Interval appendicectomy was advised, but the patient became pregnant and the operation was postponed. She was seen again in August, 1971, having had six similar attacks of pain. On examination there was tenderness in the right iliac fossa but no palpable mass.

In October, 1971, an elective operation through a grid-iron incision was performed. There were adhesions surrounding the appendix which was not acutely inflamed but was only 2 cm. in length (*Fig.* 2). It was broad at the base and its mesentery was free of fat. There was a smooth firm mass 1·5 cm. in diameter palpable within the caecum adjacent to the base of the appendix which was thought to be a carcinoma. The incision was extended and the caecum was mobilized. It was then recognized that the tumour might be an intussusception of the appendix although the muscle coat did not appear to be intussuscepted. The muscle was circumcised near the base of the appendix and, by traction on the distal part, a tube of mucosa about 8 cm. in length was withdrawn (*Fig.* 3). As the mucosal intussusception was reduced the tumour within the lumen of the caecum became smaller and finally disappeared. Routine appendicectomy with inversion of the stump was then carried out. Postoperatively the patient made a good recovery and was discharged on the fifth postoperative day.

Histology of the appendix showed evidence of past inflammation with muscular hypertrophy. The tube of reduced mucosa was oedematous.

DISCUSSION

The diagnosis of simple intussusception of the appendix is rarely made preoperatively. Cases that present as an emergency are usually explored for acute appendicitis. Barium-enema examination may occasionally be diagnostic in those cases with recurrent attacks of pain (Skarby, 1941), but in the majority of cases the caecal filling defect is thought to be a carcinoma (Howard, Ellis, and Delaney, 1970).

The caecal tumour in both the present cases was oedematous intussuscepted appendicular mucosa. In *Case* 1 a true intussusception of the appendix was demonstrated, but in spite of fully reducing the muscular intussusception the mucosal intussusception remained palpable within the caecum. In *Case* 2 an extensive mucosal intussusception of the appendix was reduced. Although no muscular intussusception could be shown at operation this is suggested by the history of recurrent attacks of pain and the finding of a short thick appendix with a thin mesentery (Forshall, 1953). This type of predominantly mucosal intussusception has not previously been reported.

Various pathological factors have been suggested as the cause of appendicular intussusception, including roundworms (McKidd, 1858), mucocele (Morgan, 1937; Welch, Hellwig, and Foeneke, 1962; Mann, Wolf, and Greenblatt, 1964), endometriosis (Fink, Santos, and Goldberg, 1964; Howard and others, 1970), carcinoid (Hickinbotham, 1951) and lymphoid hyperplasia (Wakeley, 1939). However, Rolleston (1898) suggested that prolapse of the mucosa and subsequent intussusception may result from the appendix expelling a faecalith by peristalsis. This theory was based on the incidental finding at autopsy of a faecalith impacted within the appendicular mucosa which had prolapsed into the caecum. Although no faecalith was found in the present cases, Rolleston's suggestion that a faecalith initiated the intussusception is attractive. It is suggested that the attempt to extrude a faecalith produces mucosal oedema, which then acts as the apex of the intussusceptum once the faecalith has been expelled into the caecum.

Failure to recognize intussusception of the appendix at operation may result in caecotomy (Day, 1963; Howard and others, 1970) or right hemicolectomy (Campbell and McCormick, 1959; Weiner and Sala, 1962). Right hemicolectomy for this condition has been reported as a result of the use of a 'no-touch' technique, following a radiological diagnosis of carcinoma of the caecum (Howard and others, 1970). When a tumour is present within the caecum it is important to exclude intussusception of the appendix, since the correct management of this condition is reduction and appendicectomy.

Acknowledgements.—We wish to thank Mr. R. V. Fiddian for his encouragement and permission to publish details of patients under his care, and also Miss S. Dandre who drew the diagram, Mr. J. Harrison who produced the photographs, and Mrs. M. Parker for typing the manuscript.

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

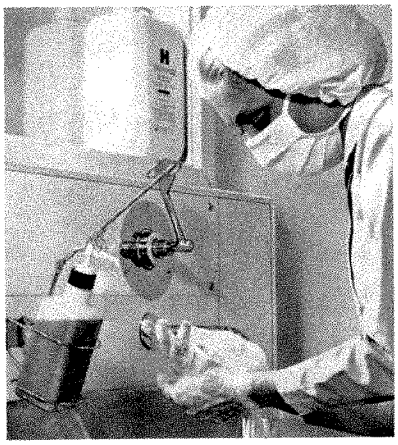
Now ICI bring to surgical scrubs the proven advantages of Hibitane in

TRADE MARK

hibiscrub



Antibacterial Activity

From the bacteriological point of view the demand is for a surgical scrub which combines maximum antibacterial activity with pronounced residual effect.

'Hibiscrub' fulfills these requirements. It is not only rapidly effective against both gram positive and gram negative organisms but also exhibits good residual activity – a major advance in the development of surgical scrubs.

Hand Care

The effect of prolonged usage on the hands of surgical staff is a critical factor in the acceptability of any surgical scrub. Sensitivity reactions, excessive detergency etc., can lead to the abandonment of certain scrub regimes.

'Hibiscrub' is positively pleasant to use – nurses using it regularly have reported on the excellent condition of their hands.

AN UNUSUAL PRESENTATION OF GAS GANGRENE

By ALISTAIR FRASER-MOODIE*

ST. HELIER HOSPITAL, CARSHALTON, SURREY

SUMMARY

Gas gangrene is now uncommon in this country, particularly as a postoperative complication of elective abdominal surgery. A case of a patient who developed gas gangrene of the scrotum after a sigmoid colectomy for diverticulitis is described. A search through the relevant literature failed to reveal any similar cases.

CASE REPORT

A. M., a 69-year-old retired chauffeur, was admitted to St. Helier Hospital, Carshalton, on 11 Aug., 1970, for investigation.

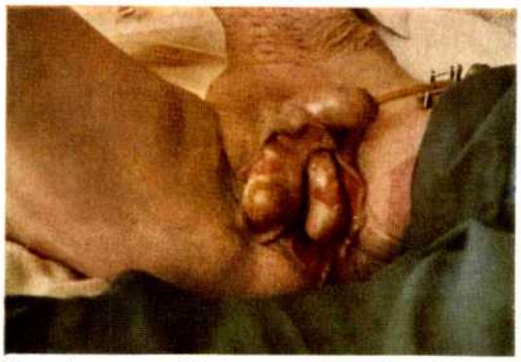

FIG. 1.—Appearance of the scrotum after extensive débridement and hyperbaric oxygen treatment.

He complained of a persistent ache in the lower left quadrant of his abdomen for several months which was relieved by passing wind or a motion. Previously he had opened his bowels daily, but now he strained a lot and only passed motions twice a week. Over a year he had lost 10 kg. in weight. He had been a mild diabetic for 20 years, but was well controlled on a low-carbohydrate diet.

On examination the patient had a palpable tender sigmoid colon. Sigmoidoscopy to 15 cm. showed no abnormality. A barium-enema examination demonstrated gross diverticular disease of the large bowel. The possibility of a carcinoma could not be excluded, and on 13 Sept. a laparotomy was performed after the bowel had been prepared with neomycin and phthalylsulphathiazole. Gross diverticulitis involving mainly the sigmoid colon with adhesions to the pelvic wall and bladder was found. Sigmoid colectomy was performed and a drain to the anastomosis was brought out through the abdominal wall. A right transverse colostomy was fashioned to protect the anastomosis.

Histological examination of the specimen confirmed the diagnosis of diverticulitis, and there was no evidence of malignancy.

The patient's postoperative course was uneventful for 10 days, apart from a mild chest infection which was treated with physiotherapy and ampicillin. However, on the tenth postoperative day he suddenly developed a pyrexia of 39·5 °C. He then experienced pain in his scrotum, which swelled up rapidly to the size of a cricket ball in the next 6 hours. By that time the soft tissues of his perineum were crepitant to touch, and finally two gangrenous areas appeared on his distended scrotum. The patient became confused and his general condition deteriorated rapidly.

A clinical diagnosis of gas gangrene of the scrotum and perineum was made and the patient was immediately transferred to Heatherwood Hospital, Ascot, for hyperbaric oxygen therapy. After 2 hours of hyperbaric oxygen treatment an extensive débridement was carried out under a general anaesthetic. All the offensive necrotic tissues of his scrotum and perineum were excised until healthy tissues were exposed, and the raw areas were left to granulate. From the excised tissues *Clostridium welchii* and *C. septicum* were cultivated anaerobically, and *Proteus vulgaris* with *Escherichia coli* aerobically.

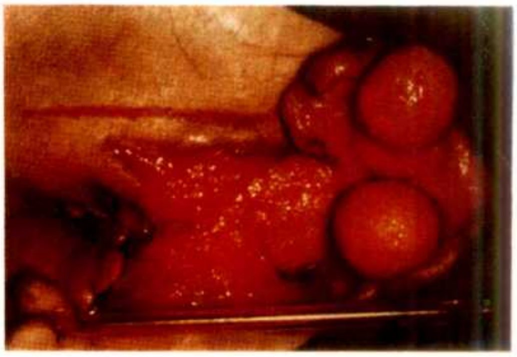

FIG. 2.—The scrotum and perineum after exploration of the wound. The catheter shown could be inserted 20 cm. into the abscess cavity.

He was treated four times a day with 2 MU. of benzyl penicillin for the anaerobic infection and 500 mg. of ampicillin for the aerobic infection.

The patient's general condition slowly improved with intensive nursing care and regular medical attention. Two-hourly hyperbaric oxygen treatments at 3 atmospheres pressure were continued twice a day for a week. Supportive measures included frequent hydrogen peroxide dressings, saline baths twice a day, and a blood transfusion of 4 pints. After 3 days cultures no longer grew anaerobic organisms and after 2 weeks the patient was transferred back to St. Helier Hospital (*Fig.* 1).

Here his nursing care was continued for a further 7 weeks as he was unable to look after himself. He became depressed by his long illness and regularly complained of pain in his perineum. Wound cultures only grew the same aerobic organisms, *E. coli* and *P. vulgaris*, both of which were sensitive to ampicillin, on which he continued throughout his illness. The edges of the wound healed slowly by granulation but there was a persistent offensive discharge, presumably from an intrapelvic source. Therefore on 8 and 22 Oct. the wound was explored under a general anaesthetic. On each occasion a huge pelvic abscess anterior to the rectum was laid open and drained. *Fig.* 2 shows a catheter which could be inserted 20 cm. into the cavity.

---

* Present address: Royal Postgraduate Medical School, Hammersmith Hospital, London W12 0HS.

After the last anaesthetic the patient's condition gradually deteriorated again. He became disorientated with a high swinging temperature. The pain was now severe in his right thigh, and radiographs showed small gas bubbles which were not evident clinically (*Fig.* 3).

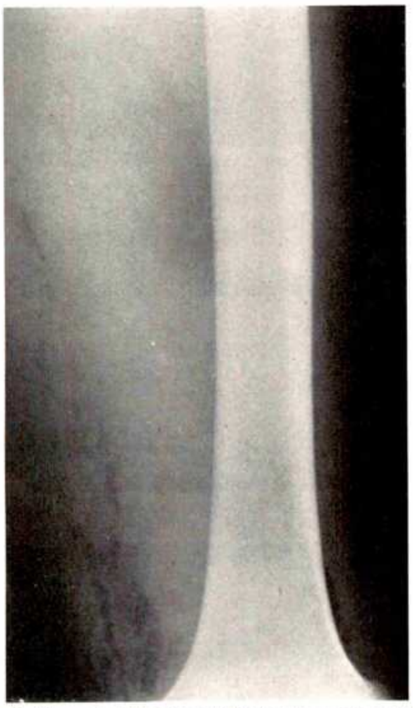

FIG. 3.—Radiograph of the right thigh showing small gas bubbles.

On 2 Nov. the patient was transferred back to Heatherwood Hospital. On admission the whole of his right thigh was crepitant to touch, with gangrenous areas below the knee. Massive doses of benzyl penicillin and frequent hyperbaric oxygen treatments were recommenced but he died within 48 hours.

No post-mortem was carried out.

DISCUSSION

The clostridial organisms probably originated from the patient's own bacterial flora—an auto-infection. This elderly diabetic was particularly susceptible to gas gangrene after a bowel resection for several reasons. There may well have been a poor circulation to the anastomosis, with areas of necrotic tissue and a weakened inflammatory response systemically. The large-bowel anastomosis leaked, giving rise to the huge pelvic abscess that was drained twice.

Clostridial organisms frequently inhabit the alimentary tract and are readily recoverable from the faeces (Sterne and Von Huyningen, 1958). The antibiotic bowel preparation offered little resistance to clostridia and so these organisms could reach the perineum and scrotum directly from the bowel. The air of operating theatres has in the past been shown to contain the spores of these organisms, indicating another possible source of infection (Lowbury and Lilly, 1958).

The patient died 2 months after the original operation for diverticulitis from gas gangrene of the right leg as a result of the spread of residual organisms inside the pelvis through the thigh muscles. These organisms can remain dormant in a wound for many years before a patient develops gas gangrene (Hendry, 1930). Once established, the infection can spread quickly through healthy muscle, but always in the direction of the fibres (Anderson, 1967).

In the present case *E. coli* and *P. vulgaris* were cultivated from the wound throughout the patient's illness. Aerobes and anaerobes act together to digest protein most effectively—an example of bacterial synergism (Meleney, 1931).

A review of 7 cases of gas gangrene of the scrotum and perineum showed this condition to be 'a distinct complication of perianal abscesses and fistulae' (Himal and Duff, 1967).

Gas gangrene of the thigh owing to the spread of infection from an intra-abdominal source has rarely been reported. The sources in cases recorded in the literature were: from an appendix abscess (Gordon, 1936); from diverticulitis (Dawson and Fiardy, 1948; Nichols, 1961); from a carcinoma of the colon (Wyman, 1949).

Few bacterial infections are so virulent and in the present case prompt recognition and treatment were not enough. Perhaps intramuscular penicillin cover throughout the operation would have prevented gas gangrene. There was, however, no indication for this preoperatively.

This case serves as a reminder of this terrifying condition, as gas gangrene remains a constant threat to the safety of surgical patients, striking unexpectedly, even after elective surgery.

Acknowledgement.—I should like to thank Mr. B. P. Flannery, F.R.C.S., Consultant Surgeon, St. Helier Hospital, Carshalton, for allowing me to publish this case.

THE SURGICAL MANAGEMENT OF AMOEBIASIS IN CHILDREN

BY LEWIS SPITZ

CONSULTANT PAEDIATRIC SURGEON, UNIVERSITY OF WITWATERSRAND AND BARAGWANATH HOSPITAL, JOHANNESBURG

SUMMARY

Five children with severe complications of acute amoebic dysentery are described. The results of a simple defunctioning proximal ileostomy are encouraging. Prior administration of anti-amoebic therapy and postoperative intensive medical care are mandatory for a successful outcome.

CONSERVATIVE medical measures are usually sufficient for the successful management of patients suffering from severe amoebiasis. However, complications such as acute intestinal perforation, which is a relatively common occurrence in children (MacDougall, 1960), complete intestinal obstruction, and rupture of an hepatic or pulmonary abscess develop in an estimated 0·5 per cent of dysenteric cases (Wray, Stark, Brackney, and Moretz, 1964). In such cases the clinician is confronted with the choice between continued medical therapy and surgical intervention in a severely debilitated child. Both these courses are accompanied by an extremely high mortality-rate (Wijesundera and de Silva, 1962; Grigsby, 1969).

Table I.—DETAILS OF THE CASES IN THE PRESENT SERIES

CASE	AGE AND SEX	DIAGNOSIS	INDICATION FOR SURGERY	OPERATIVE PROCEDURE	SUBSEQUENT COURSE	RESULT
1. J. R.	5 yr. M.	*E. histolytica* in stool	Acute intestinal perforation	Terminal defunctioning ileostomy	1. Intractable post-amoebic ulcerative colitis with strictures 2. Colectomy and ileorectal anastomosis	Alive and well
2. F. M.	3 yr. 7 mth. F.	Stools negative Latex C.F.T. positive	Rupture of liver abscess Acute toxic megacolon	1. Drainage of liver abscess 2. Terminal defunctioning ileostomy	1. Complete resolution 2. Closure of ileostomy	Alive and well
3. P. M.	2 yr. 3 mth. F.	Stools negative Latex C.F.T. positive	External intestinal fistula with distal obstruction	1. Subtotal colectomy 2. Ileostomy	Ileosigmoid anastomosis	Alive and well
4. A. M.	2 yr. 6 mth. M.	Stools positive Latex C.F.T. positive	Intestinal obstruction	Terminal defunctioning ileostomy	1. Intractable post-amoebic ulcerative colitis with strictures 2. Colectomy and ileorectal anastomosis	Alive and well
5. D. M.	1 yr. 3 mth. M.	Stools negative Latex C.F.T. positive	Intestinal obstruction	Right transverse colostomy	1. Intractable post-amoebic ulcerative colitis with strictures 2. Colectomy and ileorectal anastomosis	Alive and well

This report documents the successful surgical management of 5 young children with life-threatening complications of amoebiasis at Baragwanath Hospital in the period from April, 1971, to November, 1972.

CLINICAL CASES

The 5 children varied in age from 15 months to 5 years.

All 5 patients were severely toxic and dehydrated on admission. Anti-amoebic and antibiotic therapy was commenced from the outset on the clinical diagnosis of amoebiasis, which was subsequently confirmed by laboratory investigations (*Table I*). *Cases* 1 and 2 developed complications early in the course of the disease. The first case developed an acute perforation of the transverse colon, for which a simple defunctioning ileostomy was performed. Rupture of an extensive right hepatic abscess and toxic megacolon occurred in the second child. A defunctioning ileostomy was created and the liver abscess was evacuated of 800 ml. of purulent material by means of an indwelling catheter (*Fig.* 1). Three months later, following complete resolution of the pathological process, the ileostomy was closed. *Case* 3 developed an external intestinal fistula at the umbilicus after 2 months of intensive medical therapy. Owing to the persistence of distal obstruction it failed to close on conservative treatment. Laparotomy revealed a perforation of the caecum with a fistulous tract to the umbilicus. The transverse colon was extensively strictured. A subtotal colectomy and defunctioning ileostomy were performed. In *Cases* 4 and 5 extensive stricture formation of the colon resulted in complete intestinal obstruction after many weeks of medical therapy. Because of severe debility in both cases, simple defunctioning proximal enterostomies were performed.

The early postoperative course was extremely stormy in all the cases. Aggressive antibiotic therapy, intravenous alimentation, and general intensive care were required.

Severe intractable post-amoebic ulcerative colitis, necessitating subtotal colectomy and ileorectal anastomosis, developed in 3 of the 4 cases in which the colon was left in situ (*Cases* 1, 4, and 5; *Figs.* 2 and 3). All the children are now alive and free of the disease.

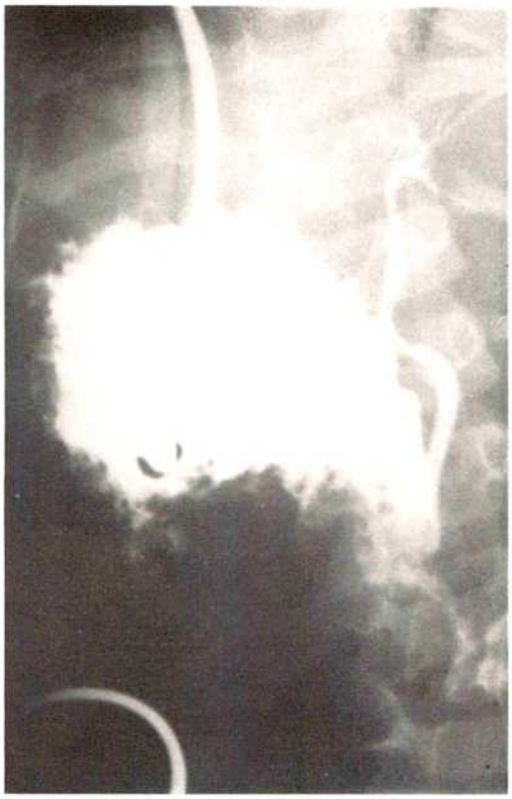

FIG. 1.—*Case* 2. Sinogram showing a large right hepatic abscess cavity with free drainage into the biliary system.

DISCUSSION

Pathology and Pathogenesis.—*Entamoeba histolytica* produces lesions of the colonic mucosa by a process of active locomotion and by the secretion of a cytolytic substance. The pathological process is usually confined to the mucosa and submucosa. Penetration of ulcers into the muscular wall of the intestine is rare and usually slow, with serosal inflammation encouraging adhesions to adjacent viscera and omentum. Perforation occurs most frequently in the caecum, ascending colon, and rectosigmoid (Keen, Gilmore, and von Stone, 1956) and is commonly extraperitoneal or into an area sealed by adhesions. Amoebic abscesses may follow retroperitoneal colonic perforations, and occasionally internal or external fistulas develop (Dinner and Bader, 1961). Intraperitoneal perforation with generalized peritonitis carries a high mortality-rate, especially in children (Wijesundera and de Silva, 1962; Powell and Wilmot, 1966b; Raffensperger, Szanto, Saunders, and Woodward, 1967).

Strictures result from ulceration of the intestinal wall with subsequent scarring. The stenotic area may be narrow or broad and most frequently involves the ascending colon and rectosigmoid regions.

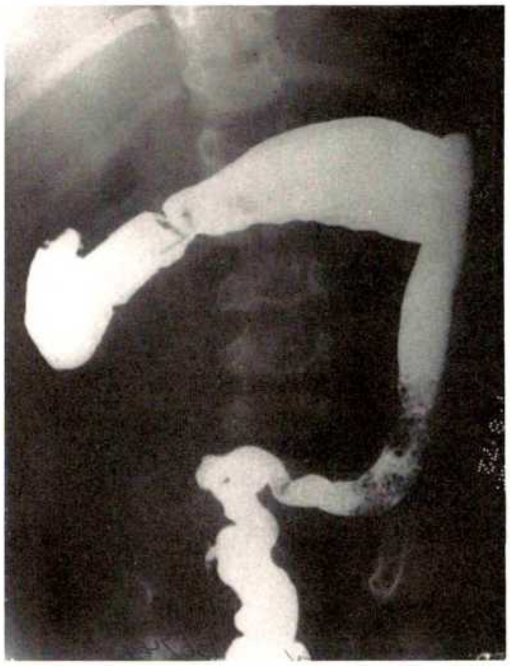

FIG. 2.—*Case* 4. Barium-enema film showing a blind fistulous tract in the mid-rectum, loss of haustral pattern, and stricture formation.

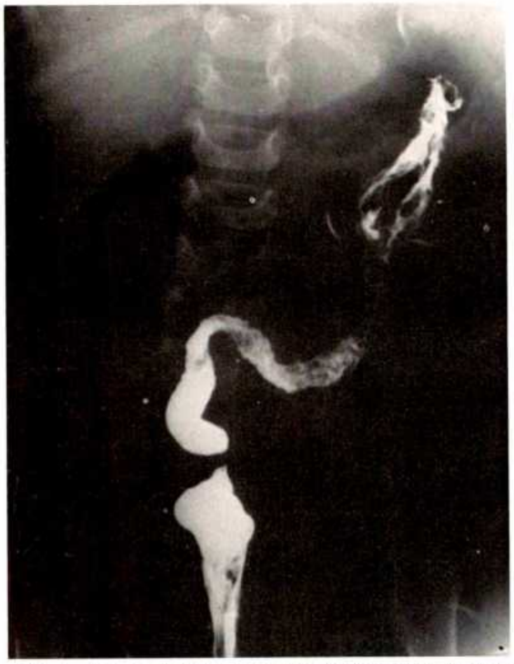

FIG. 3.—*Case* 5. Barium-enema film showing a stricture in the lower rectum and extensive pseudopolypi formation in the distal colon.

Multiple strictures are occasionally encountered in chronically infected patients. The majority of stenoses resolve on amoebicides and antibiotics (Turner, Lewis, Hayes, and Ziment, 1971).

The development of post-amoebic ulcerative colitis is almost entirely confined to patients with severe amoebic dysentery (Bank, Burns, Marks, and Stein, 1971). The severity is related to the degree and extent of the initial damage to the bowel wall (Powell and Wilmot, 1966a). Strictures are common. The course of most cases is that of slow progressive improvement. A few cases experience a steady downhill course, and for them colectomy may be indicated on the basis of intractability (Stein and Bank, 1970).

Diagnosis.—The most common presenting feature in children with severe amoebiasis is bloody mucous diarrhoea, accompanied by oedema and corrugation of the rectal mucosa. Sigmoidoscopically, the colonic mucosa is ulcerated and friable. Confirmation of the clinical diagnosis requires the demonstration of *E. histolytica* by microscopic examination of the stools, rectal scrapings, or rectal biopsies. Failing this, the latex complement-fixation test should be carried out.

Treatment.—In acute amoebic infection the need for initial intensive anti-amoebic and antibiotic chemotherapy cannot be emphasized too strongly. These drugs should be commenced immediately the clinical diagnosis is made (Rives, Heibner, and Powell, 1955; Pelàez, Villazòn, and Zaraboso, 1966). The worst therapeutic failures occur in patients in whom the amoebic cause remains unrecognized and in whom surgical treatment is undertaken without the prior administration of amoebicidal drugs (Chen, Chen, and Lin, 1971). Continued conservative medical management in the presence of life-threatening complications such as intestinal perforation with generalized peritonitis, intestinal obstruction, or fulminating amoebic colitis with toxic megacolon carries a high mortality. Only 5 of Barker's (1958) 19 patients with colonic perforation survived therapy. In the series of Powell and Wilmot (1966b) of 75 patients with generalized peritonitis complicating severe amoebic colitis who were treated conservatively only 44 patients survived when the onset of peritonitis was slow and insidious. In patients with established peritonitis on admission or with the rapid onset of peritonitis the outcome was almost invariably fatal, especially in childhood. Emergency surgical intervention should be strongly considered when general and abdominal signs deteriorate markedly after 24–48 hours of intensive anti-amoebic therapy or in the presence of an acute episode such as an acute intestinal perforation or sudden increase in abdominal distension (Stein and Bank, 1970). The poor general condition of these patients is not conducive to extensive surgical procedures, such as colectomy. A proximal defunctioning ileostomy (Theron, 1947; Rives and others, 1955; Stein and Bank, 1970) is a life-saving procedure in children when combined with aggressive anti-amoebic and antibiotic chemotherapy, prolonged intravenous alimentation, and general intensive care.

The development of intractable post-amoebic ulcerative colitis with severe stricture formation necessitated subsequent subtotal colectomy in 3 of the 4 cases in whom the colon was left in situ, indicating the extreme degree of the initial pathological process.

CHOLEDOCHOSCOPY IN CHOLEDOCHOLITHIASIS

By C. J. LONGLAND
ROYAL INFIRMARY, GLASGOW

SUMMARY

Stones are overlooked in the bile-ducts during operations for gall-stones sufficiently often to pose a continuing problem. The choledochoscope, first described 50 years ago, has recently been developed to a degree which makes it valuable in locating common-duct stones, besides permitting observation of changes in the ducts which are not otherwise demonstrable.

At 37 duct explorations, among a total of 135 gall-stone operations, endoscopy was found valuable in clarifying equivocal pre-exploratory cholangiograms, or on occasion taking their place, and in detecting stones not removed using the usual methods of detection. It is suggested that endoscopy is quicker and more readily repeatable than post-lithotomy cholangiography, is unaffected by bubbles entering the duct system, and avoids exposure of staff and patient to X-rays. However, it should be used in conjunction with pre-exploratory cholangiography.

THIS communication is based on the findings at operations for gall-stones at which a flexible fibre-optic choledochoscope was used to examine the interior of the extrahepatic bile-ducts.

CHOLEDOCHOSCOPES

There has never been a widespread demand for a choledochoscope, probably because unlike other endoscopes its use must be confined to peroperative endoscopy.

The first choledochoscope, virtually a speculum, was described by Bakes of Brno in 1923. The next instrument, a modified angled cystoscope, appeared in 1942 (McIver, 1942). The most widely employed rigid instrument was that of Wildegans of Berlin; this choledochoscope underwent considerable development allowing the use of instruments for biopsy and diathermy (Wildegans, 1958). Reports from a number of countries in Europe and America describe some hundreds of endoscopies with this instrument almost without incident; the reports are generally favourable to its use and suggest that it should take over part of the role of the cholangiogram (Wildegans, 1958; Griesmann, 1959; Jelink, 1959; Brocks, 1960; Shore and Lippman, 1962; Schein, 1969.)

The first flexible fibre-optic instrument appeared from the American Cystoscope Manufacturers Inc. in 1965 and is the instrument used in this series. It has a length of 50 cm. and a diameter of 6 mm. The eye-piece is adjustable for the individual eye, and a focusing device allows sharp definition of objects up to contact with the objective lens. The instrument is sterilized in ethylene oxide gas, and for use is attached to a light source and a supply of sterile saline which passes through an irrigation channel to wash out and fill the ducts. A teaching attachment allows a second viewer to watch the field under view, but there is no channel for instruments.

It is a straightforward matter to insert the illuminated endoscope upwards through the usual choledochostomy to and beyond the confluence of the left and right hepatic ducts which is marked as a rule by a carina-like eminence; beyond it secondary branchings may be seen. To enter the lower duct the instrument must be bent into a U-shape, and insertion is sometimes impeded by the overhanging ribs. The bend through 180° has the effect of reversing the direction of apparent movement of the object in the vertical axis which has to be allowed for in manipulating the viewing tip to scan the interior of the lower duct. The sphincter can usually be brought into view and the whole common duct thus examined. Thorough irrigation and a clear viewing medium are as essential as in cystoscopy.

THE PRESENT SERIES

In this series of gall-stone cases there were two main indications for choledochoscopy: to look for residual stones after choledocholithotomy before concluding the operation, and to explore ducts which have been opened for possible stones on indirect evidence without any having been demonstrated by palpation or radiography.

No complications were met and sepsis has not increased as a result of choledochoscopy; no special precautions were observed. The patients ranged in age from 19 to 74 years, with a mean of 55 years; there was no mortality.

Choledochoscopy was carried out at 37 operations on 35 patients among a total of 135 operations for gall-stones (27 per cent of operations). Stones were found in the ducts on 26 occasions in 24 patients; no stones were present in the remaining 11 ducts.

At 24 of the operations when stones were present as many of the stones as possible were first removed by the customary blind techniques; only afterwards was the choledochoscope inserted to search for more stones. Endoscopy used in this way has been classified as 'post-lithotomy' choledochoscopy. At the other 13 operations the uses made of endoscopy varied and have been classified as 'exploratory' choledochoscopy. This group includes the 2 remaining duct-stone cases; in both these cases post-lithotomy choledochoscopy was not employed because sphincterotomy was required to extract the stones and this was adequate to allow the passage of any stones which might have been missed.

POST-LITHOTOMY CHOLEDOCHOSCOPY

At the 24 operations in this group choledochoscopy was carried out after stones had been removed from the ducts. Signs of residual stone were seen in 11 instances (46 per cent), and the ducts appeared clear of stones in the other 13. In the latter cases the operation was terminated and a T-tube was inserted on 12 occasions; in 1 case a choledochoduodenostomy was substituted because of gross dilatation of the duct.

When residual stones were seen efforts were made to remove them with the help of repeated choledochoscopy, until either the duct seemed clear of stones or any in view could not be retrieved, as was the case in 2 patients with stones lodged in hepatic ducts. Though more have been needed, one or two reinsertions of the choledochoscope usually sufficed in the search for and the removal of residual stones, after which the operation was terminated with the insertion of a T-tube in 8 cases. In 3 cases, when stones could not be removed or permanent drainage was needed, a choledochoduodenostomy replaced the T-tube.

Thus, there were 20 patients with T-tubes available for postoperative cholangiograms, and in *Table I* the choledochoscopy findings for these patients are compared with the cholangiograms. The 4 patients with choledochoduodenostomies are excluded.

Table I.—CHOLEDOCHOSCOPY FINDINGS COMPARED WITH THE POSTOPERATIVE CHOLANGIOGRAM IN 20 PATIENTS IN THE POST-LITHOTOMY GROUP

CHOLEDOCHOSCOPY FINDINGS		POSTOPERATIVE CHOLANGIOGRAM	
		No Stone	Missed Stone
Ducts clear	12	11	1
Residual stones seen and removed	5	4	1
Residual stones suspected —not removed	3	0	3
Total 20	20	15	5

Table I shows that at 12 endoscopies the ducts appeared clear after the initial removal of stones, but the subsequent cholangiograms indicated that stones had been missed in 1 patient. Reoperation was required, when the missed stones were easily seen with the endoscope; they were removed and a choledochoduodenostomy was constructed. At 5 endoscopies residual stones were seen after the initial removal; following further removals and repeat choledochoscopies the ducts appeared clear. However, the postoperative cholangiograms showed that yet more stones had been missed in 1 patient. Again, stones were visualized by endoscopy at reoperation in this patient, but one of the stones could not be extracted and a choledochoduodenostomy was performed. At the remaining 3 operations residual stones were thought to have been seen by choledochoscopy after the initial removal. Two of these were the first 2 endoscopies of the series, and in both cases further exploration failed to retrieve any more stones; accepting this, the endoscopic appearances were ascribed to debris and not to compact stone. The operations were consequently terminated, only to have the endoscopic impression confirmed by the postoperative T-tube cholangiograms. Similar appearances suggestive of stone were encountered at a third and later operation; therefore before closing the abdomen a T-tube cholangiogram was performed which, however, did not confirm the presence of a residual stone; nevertheless, the postoperative cholangiogram a week later revealed a missed stone. In each of these 3 patients the missed stones were small and single and were later passed spontaneously without secondary operations; they were partly concealed from the view of the endoscope in the lower duct by webs of fibrin.

EXPLORATORY ENDOSCOPY

Pre-exploratory cholangiography was employed in most of the 13 patients in this group. Endoscopy was performed to clarify, or in a few instances to replace, cholangiography.

In 3 patients the cholangiograms were normal, but because of preceding jaundice or pancreatitis the ducts were opened. However, endoscopy showed no signs of stone. In 2 patients stones were demonstrated by the cholangiograms and endoscopy followed. One of these patients had previously undergone choledocholithotomy without endoscopy; it was of interest that the stones missed at the previous operation were readily seen with the endoscope and duly removed through a transduodenal sphincterotomy. In the other patient a stone thought to have been shown in the ampulla on the cholangiogram could not be confirmed visually, the lower duct being poorly seen. However, the ampulla was approached transduodenally and after division a stone was found and removed.

In the remaining 8 patients pre-exploratory cholangiograms were either of dubious significance because contrast material did not enter the duodenum or were of poor quality or were not available. There were indications for opening the ducts in each case. No stones were seen. Postoperative T-tube cholangiograms were available for all 13 patients and confirmed the absence of stones in each.

Among the 4 patients with sphincters impermeable to contrast medium, 1 was seen to have a mild cholangitis probably associated with recent pancreatitis, and another, shortly after an attack of severe colic, showed haemorrhages at the sphincter, the damage presumably being due to the passage of a stone.

Endoscopy before removing stones did not provide additional diagnostic information in the 5 patients in whom the cholangiograms were normal or showed stones. However, in the remaining 8 cases, when cholangiography alone was inconclusive or not available, endoscopy not only resolved the question of the presence or absence of stone but also showed inflammatory and traumatic consequences of preceding events which were otherwise not demonstrable.

DISCUSSION

Though choledochoscopy is not limited to searching for duct stones this is its major function. Pre-exploratory cholangiography provides the best means of ascertaining whether there are stones in the intact duct system, but it can by no means always indicate their number. Indeed, how to ensure that ducts are completely cleared of multiple stones remains a major problem in gall-stone surgery; to achieve it can tax technique to the limit.

In the present series choledochoscopy undoubtedly reduced the number of duct stones which were missed. In the group of 11 ducts in which residual stones were seen by post-lithotomy choledochoscopy, the remaining stones were removed in 4 cases and choledochoduodenostomies were provided to facilitate the escape of stones in 3 other cases. Of the remaining 4 cases in which mainly small stones were left in the ducts, it can safely be said that with greater experience of endoscopy there would have been fewer errors, bearing in mind that the first 2 endoscopies of the series contributed 2 of the missed stone cases and that signs of stone were seen in 3 of the 4 cases.

Two secondary operations were required among 24 patients with duct stones who had endoscopy at the primary operation (8 per cent). They are equivalent to 1·5 per cent of the 135 operations for gall-stones carried out during the period reviewed. This compares with 3 per cent of secondary operations for missed stones found by Glen (1972) among all operations for benign biliary disease.

Table II summarizes the findings for the whole series of 37 endoscopies in relation to locating stones. There were no false-positive findings in ducts shown to be free of stones by subsequent cholangiography.

Table II.—RESULTS OF ENDOSCOPY IN 37 OPERATIONS

Presence of Stones in Duct	*No. of Operations*	
Present	26	False negatives 6
Not present	11	False positives 0

False-negative findings, i.e., stones missed, are known to be 5 from the post-lithotomy group and 1 from the exploratory group of choledochoscopies, making a total of 6 in 26 endoscopies, which is a rather high figure. If the first 2 endoscopies are excluded because of lack of experience, the number of false negatives becomes 4 of 24 examinations of ducts in which stones were certainly present, an incidence of 17 per cent. In fact, a poor view was obtained in 1 of these 4 cases, and a stone consequently not seen by endoscopy but shown by the preliminary cholangiogram was successfully removed. The two investigations are complementary and neither should be considered entirely in isolation; however, good visualization steadily becomes easier to achieve and in consequence the number of false negatives should decrease.

Operative cholangiography after stone removal and before closure of the abdomen offers a means of assessing clearance of the ducts. Compared with radiography choledochoscopy is quicker, much more readily repeatable, and introduces no radiation hazard to the patient or the staff. Furthermore, after removing stones and dilating the sphincter, bubbles entering from the duodenum or through the T-tube may cause real difficulty in interpreting the radiographs but they do not affect the endoscopic interpretation.

It is well recognized that practice is necessary to interpret appearances and to obtain useful information by endoscopy of any kind. The problem for choledochoscopy in this respect is a real one because individual surgeons are likely to use it sporadically (in this series it was used in about 1 in 4 operations for gall-stones). Undoubtedly simulation could be employed to remedy this failing, using suitable tubes as ducts and photography to portray normal and abnormal appearances. Important points in relation to stone are the inflammatory changes which are often present, including fibrin strands and veils sometimes tinged here and there with yellow. They may readily conceal small stones. Again a small free-floating stone may only be glimpsed as it moves along a wide duct in the stream of irrigating fluid. The cholesterol stone appears bright yellow in the strong illumination and anything with this colouring needs close scrutiny; a well-defined edge marks it as a stone which if only seen briefly warrants a careful continuing search.

The fibre-optic flexible choledochoscope is undergoing further development, and a model incorporating useful advances and excellent vision is already available from Japan. The endoscope seems likely to find a specific place in the armamentarium of biliary surgery, for though expensive and requiring care in handling and maintenance its use can contribute much to the difficult problem of avoiding secondary operations for duct stones.

DIAGNOSTIC YIELD OF FIBRE-OPTIC ENDOSCOPY IN THE OPERATED STOMACH

BY P. B. COTTON, M. T. ROSENBERG, A. T. R. AXON, M. DAVIS, J. W. PIERCE, A. B. PRICE,
G. W. STEVENSON, AND R. WALDRAM
ST. THOMAS'S HOSPITAL AND BROOK GENERAL HOSPITAL, LONDON

SUMMARY

Fibre-optic instruments have been used on 212 occasions to examine 177 patients who were symptomatic after peptic ulcer surgery. A diagnosis other than gastritis was reached in 83 patients, including 46 ulcers. Five ulcers were not seen—4 as a result of using inadequate equipment early in the series. Radiology detected only 60 per cent of the ulcers and raised many false-positive diagnoses. Expert review of the radiographs corrected many originally mistaken interpretations. Retained suture materials were seen by endoscopy and removed using biopsy forceps. Gastric mucosal congestion and gastritis were common in the operated stomach, but the clinical significance of these changes remains obscure in the absence of a control series. Fibre-optic endoscopy is now an essential part of the investigation of patients who are symptomatic following ulcer surgery.

WHILST most operations for peptic ulcer are successful, up to 20 per cent of patients remain symptomatic and about 5 per cent develop recurrent or anastomotic ulceration (Goligher, Pulvertaft, Irvine, and others, 1972). The diagnosis and management of these patients can prove difficult. The patient whose symptoms return unchanged shortly after a vagotomy and drainage operation for a duodenal ulcer is very likely to harbour a recurrence. However, all too often the symptoms are atypical and the history is distorted by previous surgery and experience. Acid studies may be helpful but in themselves cannot prove the presence or absence of ulceration. Properly performed insulin testing is a reliable guide to the completeness of vagotomy, but the collection of acid in patients who have undergone partial gastric resection may be difficult and the results unreliable (Baron, 1970; Scobie and Rovelstad, 1965). Radiology of the operated stomach can be equally difficult (Fawcett, Johnston, and Duthie, 1969; Kim and Evans, 1959). Although a stomal or recurrent ulcer can sometimes be shown unequivocally, surgical distortion frequently reduces the confidence of the radiologist in diagnosing or excluding an ulcer. The large folds of a pyloroplasty or around a gastrectomy stoma produce confusing radiological appearances.

Fibre-optic endoscopes have come into routine use for examination of the oesophagus, stomach, and duodenal bulb. The latest instruments are well suited to the difficulties encountered in the distorted stomach, providing extreme flexibility and manœuvrability, with good suction, biopsy, and washing facilities (Cotton and Williams, 1972). In a total experience of over 2000 endoscopies we have been impressed by the diagnostic yield obtained in many patients with symptoms following ulcer surgery. The results of a small series are presented here.

PATIENTS AND METHODS

Two hundred and twelve examinations have been performed in 177 patients who were symptomatic following a variety of operations for peptic ulceration (*Table I*). The time intervals from the original operation to endoscopy were: partial gastrectomy, 2–42 years (mean, 11 years); vagotomy and pyloroplasty, 2 months to 12 years (mean, 4 years); vagotomy and gastro-enterostomy, 1–23 years (mean, 10 years).

Table I.—PREVIOUS OPERATIONS PERFORMED IN THE PATIENTS EXAMINED

PREVIOUS OPERATION	NO. OF EXAMINATIONS	NO. OF PATIENTS
Partial gastrectomy		
Polya	83	72
Billroth-I	16	14
Vagotomy and pyloroplasty	69	61
Vagotomy and gastro-enterostomy	28	17
Other	16	13
Total	212	177

Five symptom groups were distinguished: 48 patients had 'typical' dyspepsia (discomfort with a definite relation to food with relief being obtained from alkalis); 75 patients had less well-defined abdominal discomfort, including atypical pains and vomiting; 18 patients complained mainly of heartburn, 17 patients presented with acute gastro-intestinal bleeding; 19 patients had iron-deficiency anaemia.

Examinations were mainly performed on out-patients using a local anaesthetic throat spray and intravenously administered atropine, 0·6 mg., and diazepam, 5–30 mg. The aim was to examine the entire oesophagus and stomach and the proximal duodenum and/or jejunal loops in every patient. The oesophagus could not be examined early in the series when only a lateral-viewing gastroscope was available. Olympus models GFB and GFBK were used alone on 26 occasions. Forward-viewing oesophagogastroduodenoscopes were used 166 times (American Cystoscope Makers Models 7089, 7089A, 7089J, 7089P on 111 occasions, and Olympus Model GIFD on 45 occasions), supplemented at the same examination of 31 patients by the use of the lateral-viewing Olympus JFB duodenoscope. This instrument was used alone on a further 20 patients. Follow-up information at 6–36 months was obtained by examination of the patients' records.

RESULTS

Examinations were satisfactorily completed in all the patients without complications. Twenty patients underwent repeat examinations (1 case on 9 separate occasions). *Table II* lists the diagnosis reached by endoscopy in 83 patients. No diagnosis (apart from gastritis, discussed below) was made at the time of endoscopy in the remaining 94 patients; for 84 of the latter group, adequate follow-up information was available. Seven lesions which were missed by endoscopy have subsequently been discovered: 3 recurrent duodenal ulcers after pyloroplasty (while no duodenoscope was available), 2 gastric cancers (1 beyond a mid-gastric stenosis, and 1 diagnosed visually and on biopsy as a benign gastric ulcer), 1 anastomotic ulcer (bleeding profusely), and 1 gastric ulcer in a deep pit near a gastrectomy stoma. In another 11 patients symptoms have been explained by a lesion outside the oesophagus, stomach, and duodenum: pancreatic cancer (1), gall-stones (2), jejunal adhesions (5), colonic cancer (3). Of the remaining 66 patients, 49 are apparently well or much improved, 7 are receiving psychiatric treatment, and 10 continue to complain of disabling but often atypical symptoms (3 having undergone negative laparotomies).

Table II.—ENDOSCOPIC DIAGNOSES (EXCLUDING GASTRITIS) IN 177 PATIENTS

Comparison with Radiology.—Forty-six out of the known total of 51 ulcers were visualized by endoscopy. *Table III* provides a comparison with radiology in ulcer diagnosis. Thirty-nine of the known ulcer patients underwent barium-meal examination within 3 weeks of endoscopy; ulcers were diagnosed in only 23 cases (i.e., 40 per cent were missed). In 18 other patients from the whole series ulcers were suspected radiologically (with varying degrees of confidence) which were not confirmed by endoscopy or subsequent follow-up. Six out of 7 gastric cancers were diagnosed from the barium-meal examination but the 1 small oesophageal cancer was missed. In 8 other patients radiology incorrectly raised the possibility of malignancy, usually near a gastrectomy stoma.

A total of 109 barium-meal examinations was reviewed without knowledge of the clinical status by two radiologists with particular interest in gastro-intestinal diagnosis. Ten out of 22 previously false-positive or false-negative reports of ulcer or tumour were corrected. Hiatus hernia and/or oesophageal reflux was seen radiologically in 10 of the 12 patients shown endoscopically to have oesophagitis; by contrast oesophagitis was not apparent endoscopically in 4 other patients with radiological evidence of hiatus hernia. Barium-meal examinations did not detect erosions, small metaplastic polyps, or retained suture material.

Retained Suture Material.—Twenty-eight sutures were seen endoscopically in 13 patients, in 8 of whom the sutures were closely associated with ulcers at the suture line. Retained sutures were discovered at 1, 2, 12, and 16 years after gastro-enterostomy, 3 months, 1, 2, 2, 2, and 3 years after pyloroplasty, and 1, 4, and 5 years after partial gastrectomy. Attempts were made to remove the sutures in 8 patients, using the endoscopy biopsy forceps, with success in 6 cases. Of the latter cases, 3 patients appear to be definitely improved at 3, 7, and 9 months, and 1 is unchanged at 1 year. In 2 patients symptoms returned at 3 and 4 months, further sutures were removed, and the patients are well at 1 and 2 years respectively. Two ulcers healed when associated sutures were removed.

Table III.—COMPARISON OF ENDOSCOPY AND RADIOLOGY IN ULCER DIAGNOSIS

TYPE OF ULCER	KNOWN ULCERS	ENDOSCOPY		RADIOLOGY			
		Positive	Negative	Positive	Negative	Not done	False Positive ?
Gastric	8	7	1	5	2	1	3
Anastomotic	20	19	1	6	7	7	4
Duodenal	23	20	3	12	7	4	11
Total	51	46	5	23	16	12	18

Of the other 7 patients with sutures, 3 have undergone suture-line resection and further ulcer surgery, with the apparent cure of symptoms. One patient was found at operation to have a large carcinoma of the pancreas, another patient awaits further operation, and 1 patient has been lost to follow-up. In the final patient the suture material disappeared spontaneously before repeat endoscopy.

Mucosal Congestion and Gastritis.—After a partial gastrectomy or drainage operation, bile reflux into the stomach was often profuse, requiring endoscopic suction and the instillation of silicone materials to ensure a complete mucosal view. Mucosal congestion (and easy bleeding) of the gastric mucosa was a common finding, particularly near the stoma. The significance of this often dramatic appearance is obscure and further information has been sought by multiple endoscopic mucosal biopsies. *Table IV* gives the figures for the visual and histological changes in a total of 54 patients who were not found to have recurrent ulcer following gastric resection. Histological abnormalities were present in more than half of the patients biopsied, but showed only poor correlation with visual abnormalities.

Table IV.—Comparison of the Visual and Histological Changes in 54 Patients without Recurrent Ulcer after Gastric Resection

Histology	Visual Appearances of Gastric Mucosa*			
	Body		*Stoma*	
	Normal	Congested	Normal	Congested
Normal	19	6	1	10
Superficial gastritis	6	14	2	28
Atrophic gastritis	1	2	—	3
Acute gastritis	3	3	—	1
Total	29	25	3	42

* Stomal biopsies were taken (in all but 9 patients) within 2 cm. of the stomal margin, and body biopsies from the mid-portion of the gastric body.

Histological changes of the gastric body mucosa (mid-greater curvature) were also common in patients who had undergone vagotomy and pyloroplasty. In 9 patients with recurrent duodenal or pyloric canal ulcer the body mucosa showed normal histology in 5 cases and superficial gastritis in 4 cases. In 31 other patients with no evidence of an ulcer histological findings were: normal, 7; superficial gastritis, 20; atrophic gastritis, 3; acute gastritis, 1.

Diagnostic Significance of Symptomatology and Insulin Testing.—Of the 51 patients known to have recurrent gastric, duodenal, or anastomotic ulceration, 29 had typical dyspeptic symptoms, 14 had vague and atypical distress or predominant vomiting, and 8 had no dyspepsia at all (4 presented with acute bleeding and 4 with anaemia). Looked at in reverse, there was a total of 48 patients in the whole series who were classified as having typical dyspepsia. Twenty-eight of these patients were found to have ulcers, 2 had cancers, 2 had retained sutures, 2 had anastomotic stenosis, and no lesion (apart from gastritis) was discovered in 14 cases.

Insulin tests were carried out on 37 of the patients who had previously undergone vagotomy (none was done within 6 months). Twenty patients showed an early positive response to the test. Of these, 9 were found to have an ulcer. No ulcers were found in 4 patients with a late positive response, but of 13 patients with a negative response, 3 harboured ulcers.

DISCUSSION

When a patient returns with symptoms after peptic ulcer surgery it is essential to know whether or not a recurrent ulcer is present. Many authors have stressed the difficulties in radiological diagnosis following gastric resection (Samuel, 1954). In a randomly selected series of 60 radiographs of patients who had undergone Billroth-I operations, Kim and Evans (1959) found that more than half showed some irregularity of the lesser curvature, with 5 pseudo-ulcers and 3 pseudo-tumours, in addition to confusing folds around the stoma. Such folds may obscure stomal ulcers (Gabrielsson, 1972) or falsely simulate them. Ulcers were seen radiologically in only 52·3 per cent of a series of 325 patients with proved recurrent gastrojejunal ulceration at the Mayo Clinic (Wychulis, Priestly, and Foulk, 1966) and in 50 per cent of a series of 125 patients reported by Hirschowitz (1970). Barium-meal examination showed ulcers in only 4 out of 14 patients with suture-line ulcers (Small, Smith, Faulkner, Sircus, and Bruce, 1968). Block and Wolf (1965) and Gleeson and Ellis (1968) stressed the difficulties in diagnosing recurrent ulceration in the presence of a pyloroplasty. Reporting a series of 74 patients with recurrent duodenal or gastrojejunal ulceration following vagotomy and drainage, Fawcett and others (1969) stated that radiology was 'seldom helpful', ulcers being detected in only 47 per cent of cases. By contrast, Williams and Toye (1970) said that radiological studies have great value in this situation. The original assessment of radiographs from their 24 symptomatic patients provided 4 false-negative and 2 probable false-positive results; only on expert review were these reports corrected.

In our series radiography detected 60 per cent of the ulcers while endoscopy showed 90 per cent of them. Of 126 other patients, radiography raised a possible diagnosis of ulceration in 18 cases and of tumour in 8, which could not subsequently be substantiated. Expert review corrected 10 out of the 22 false-negative or false-positive reports. Results from our own series do not reflect the overall accuracy of radiology in the operated stomach, since patients were often selected for endoscopy because of equivocal or negative radiographic findings.

The overall accuracy of endoscopy in the operated stomach is equally relevant and difficult to ascertain. Gastroscopy and gastrophotography have been advocated (Gear and Dowling, 1970; Kasugai, Kato, Takase, and others, 1966; Gabrielsson, 1972) and dismissed (Wychulis and others, 1966; Goligher and others, 1972). Hirschowitz (1970) claims to have detected 90 per cent of 125 recurrent ulcers by gastroscopy. However, these facts and references are now less relevant, since gastroscopy alone is obsolete and oesophagogastroduodenoscopy should be performed. Four of the 5 ulcers were missed in the present series while using only a lateral-viewing gastroscope, which cannot enter a pyloroplasty and often gives an incomplete survey beyond a gastro-enterostomy stoma. It is clear that patients should be examined with a modern, fully manœuvrable forward-viewing instrument with good suction and biopsy facilities (ACMI Model 7089P or Olympus GIFD). In most cases this will provide a complete survey of the oesophagus, stomach, pyloroplasty, and duodenal bulb, or stoma and jejunal loops. Sometimes, the pouches of a pyloroplasty, or the areas of jejunum just beyond a stoma, may be difficult to visualize with a forward-viewing instrument. In such circumstances there should be no hesitation in also using a lateral-viewing fibrescope at the same examination; the highly flexible Olympus JFB duodenoscope is particularly well suited to this task.

Considerable reliance is usually placed upon the results of insulin testing in patients who are symptomatic after vagotomy. In this series less than half of the patients with positive insulin tests were found to have ulcers, and there were 3 patients with recurrent ulceration in the presence of negative insulin tests. One of these ulcers was associated with retained suture material. This has been recognized as the cause of anastomotic ulceration for many years (Tanner, 1951), but some surgeons continue to use non-absorbable material, which can ulcerate through from the seromuscular layer. In the present series 7 out of the 20 anastomotic ulcers were associated with suture material. Sutures have previously been removed endoscopically with clinical benefit (Tanner, 1951; Kasugai and others, 1966; Gear and Dowling, 1970) but the significance of suture material in the absence of ulceration is open to question (Hirschowitz, 1970). Endoscopic removal of sutures appears to have alleviated dyspeptic symptoms in several of our patients. We have seen small anastomotic ulcers and erosions heal and recur in association with suture material, but have also seen sutures disappear entirely between examinations.

The mucosa of the operated stomach frequently appears congested or atrophic with easy contact bleeding. These appearances are particularly marked around a gastro-enterostomy stoma ('stomatitis'; *Table IV*) and are attributed to the reflux of duodenal or jejunal juice, which may be profuse at endoscopy.

It is easy to assume that these changes are an important cause of dyspeptic symptoms, particularly since biopsies usually show evidence of gastritis (*Table IV*), and when definitive lesions provide a diagnostic label for only half of the patients investigated (*Table II*). Such an assumption is quite invalid in the absence of a control series. We are unaware of any systematic endoscopic study of asymptomatic patients following ulcer surgery, but there is abundant evidence that gastritis is very common. Mucosal biopsies taken by capsule from healthy individuals following partial gastrectomy have shown some degree of gastritis in 44–66 per cent (Coghill and Wynne-Williams, 1958; Lees and Grandjean, 1958; Johnson, 1966; Camarinos, Brus, Jacob, and others, 1970), our own figure for symptomatic patients being 56 per cent (*Table IV*). In 86 patients 10–18 years after vagotomy and pyloroplasty Stempien (1971) found superficial and atrophic gastritis in 86 per cent. Patients with postoperative gastritis are less likely to have recurrent duodenal ulceration (Johnson, 1966). Thus, one should not assume that mucosal congestion or chronic gastritis is a cause of symptoms. Acute gastritis may be associated with treatable super-infection of the upper gut.

The incidence of chronic gastritis increases with the length of time after operation (Price and Cotton, 1973). Endoscopy has a useful role to play in monitoring the development of gastric atrophy and intestinal metaplasia, which may well be important in regard to the increased risk of malignancy in the resected stomach (Kobayashi, Proka, and Kirsner, 1970). Endoscopy and biopsy are also useful in following the course of gastric ulcers left in situ following non-resective surgery (i.e., vagotomy and drainage procedure).

The present series refers only to patients who are symptomatic after leaving hospital. Endoscopy may occasionally be useful in the early postoperative period. While radiology is usually adequate in detecting hold-up at an anastomosis, endoscopy can often distinguish between its different causes (ulceration, oedema, sutures) and we have relieved the obstruction in 1 patient by passing an instrument through an oedematous stoma. Demaret, Hirschowitz, and Luketic (1971) have pointed out that the relationships of the efferent and afferent loops to the stoma of a gastro-enterostomy are more easily assessed by endoscopy than radiology and stressed the complications of the 'double-barrelled' stoma.

Attention to detail can improve the diagnostic yield of barium-meal examinations in the operated stomach. However, it is clear that the investigation of symptomatic patients is incomplete, and may be inadequate, without properly performed endoscopy.

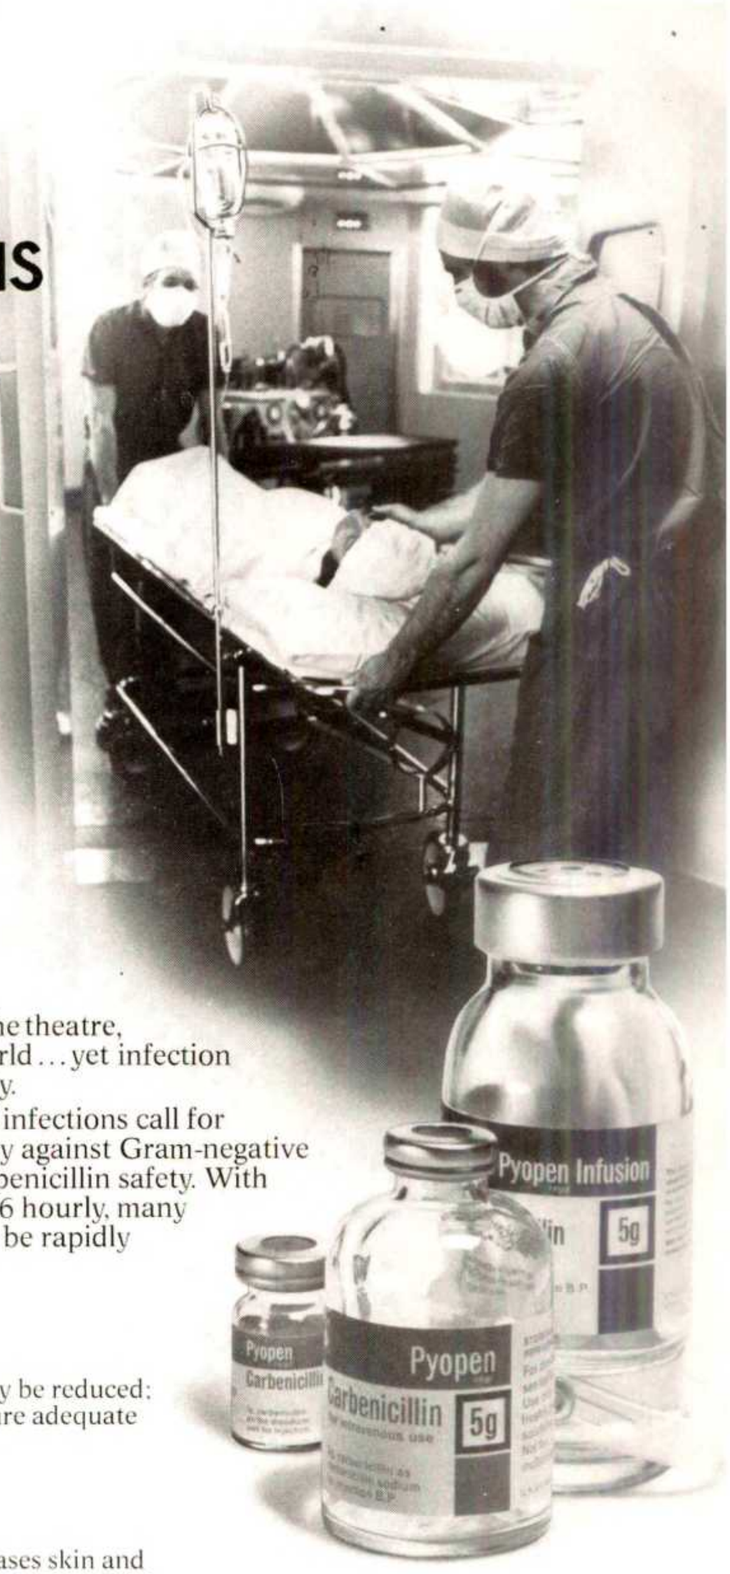
When pseudomonas threatens the success of surgery



Pyopen

The skill of the surgical team, hours in the theatre, the most advanced techniques in the world ... yet infection can still throw the outcome into jeopardy.

Post-operative pseudomonas or proteus infections call for Pyopen. Only Pyopen offers good activity against Gram-negative organisms with the added advantage of penicillin safety. With intravenous Pyopen, at a dosage of 5g 4-6 hourly, many dangerous post-operative infections can be rapidly controlled.

Adult Dosage
5g I.V. 4-6 hourly.
In patients with renal impairment dosage may be reduced: monitoring is advisable in these cases to ensure adequate serum antibiotic levels.

Contra-indication
Penicillin hypersensitivity.

Side-effects
As with other injectable penicillins. In rare cases skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen-by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England.

*regd

SEPTRIN TACTI

first

SEPTRIN ensures coverage against all likely bacterial pathogens.

fast

SEPTRIN rapidly obtains effective blood levels with simple twice daily dosage.

decisive

SEPTRIN crushes bacterial resistance with a bactericidal action which differs essentially from that of the antibiotics

Superior to either ampicillin or tetracycline as judged by reduction in sputum purulence or sputum volume.[1-2]

"…not only are the two primary pathogens, *Strep pneumoniae* and *H influenzae*, sensitive, but so are the secondary invaders such as klebsiella which often replace them after antibiotic treatment."[3]

"…can only be considered excellent on the criteria originally specified, namely the elimination of the infecting micro-organism."[4]

COLONOSCOPY IN THE DIFFERENTIAL DIAGNOSIS OF CARCINOMA FROM DIVERTICULITIS OF THE SIGMOID COLON

By ALAN C. B. DEAN and J. P. NEWELL

DEPARTMENT OF SURGERY, UNIVERSITY OF EDINBURGH, AND THE ROYAL INFIRMARY, EDINBURGH

SUMMARY

1. Thirty-six patients in whom barium-enema examination had suggested the possibility of carcinoma in a segment of diverticular disease were examined by colonoscopy.

2. Colonoscopy is particularly difficult in such patients and it failed to examine the diseased segment in 17 cases.

3. Colonoscopy gave a firm diagnosis of carcinoma in 4 cases, excluded it in 5, and was helpful in another 9. There was 1 false negative.

COLONOSCOPY is becoming increasingly recognized as a valuable diagnostic procedure in patients with disease of the colon. Its advantages over sigmoidoscopy with a rigid instrument are that it allows examination of a much greater extent of the bowel with less discomfort to the patient (Dean and Shearman, 1970). The extent of the bowel examined is dependent on careful cleansing of the bowel and on its configuration. Sharp bends cannot always be negotiated and in practice it may be difficult or impossible to advance the instrument right through the sigmoid colon. The sigmoid colon offers difficulties to the radiologist too, particularly in distinguishing carcinoma from areas of narrowing in diverticulitis. This paper describes the use of the colonoscope in patients presenting this diagnostic problem.

PATIENTS

Thirty-seven patients have been studied: 22 females and 15 males, the average age being 69 years (range, 59–84 years). All the patients had had one or more barium-enema examinations which had shown diverticular disease in the sigmoid colon with a narrowed segment raising the suspicion of a coexisting carcinoma. The barium-enema films of 2 of these patients are shown in *Figs.* 1 and 2. In some cases this doubt persisted after repeating the barium-enema examination with an intravenous injection of an anticholinergic drug.

All the patients were examined at least 6 weeks after any acute exacerbation of diverticulitis. They were prepared by taking a laxative, usually Senokot, the night before the examination, followed by a thorough bowel wash-out on the morning of the examination. This was not always easy in older patients with disease in the sigmoid colon. The patients were examined without any premedication unless they were unduly apprehensive, when an intravenous injection of up to 2 mg. of phenoperidine and 10 mg. of droperidol, depending on the patient's weight, was given. Intravenous Pro-banthine (15 mg.) was given to some patients in an attempt to facilitate the passage of the instrument through acutely angulated or narrowed segments. The patients were examined in the left lateral position.

THE INSTRUMENT

The short colonoscope (Olympus CFSB) was used on the first 19 patients. It has an effective length of 75 cm. and the tip can be moved through 180° (110 up and 70° down) in one plane. In 6 of these patients the examination was repeated using the long colonoscope (Olympus CFLB), not because of its greater length but because its tip can be moved through 180 in two planes at right angles to each other and it is thus easier to manœuvre it around acute bends. This instrument alone was used in the last 17 patients.

RESULTS

The results are summarized in *Table I.*

In 17 of the 36 patients the examination was a failure, usually because the instrument could not be passed into the diseased segment owing to sharp angulation of the bowel. In 3 cases inadequate bowel preparation was also responsible. Of the 19 patients in whom the examination was successful, 4 were shown to have carcinoma and in 5 the whole of the suspicious segment was examined without any sign of carcinoma being seen. In 9 cases the full length or the whole circumference of the suspicious segment could not be inspected, but sufficient was seen for carcinoma to be excluded with reasonable confidence. These 14 patients in whom no carcinoma was seen have now been followed up for periods of from 6 months to 2 years, 2 having had sigmoid colectomy, and so far in no case has the subsequent course shown that carcinoma was present. In the 1 false negative the narrowed segment was examined and found to be rigid but the mucosa was intact. Laparotomy 2 weeks later showed that the bowel was invaded by transperitoneal spread from carcinoma of the stomach.

Table I.—RESULTS OF EXAMINATION BY COLONOSCOPY IN 36 PATIENTS WITH A NARROWED AREA IN THE SIGMOID COLON SHOWN BY BARIUM-ENEMA EXAMINATION

NO. OF PATIENTS	MEAN DISTANCE AND RANGE EXAMINED (cm.)	CARCINOMA DIAGNOSED	CARCINOMA EXCLUDED	CARCINOMA NOT SEEN	FALSE NEGATIVE	FAILURE
19	37 29–60	4	5	9	1	—
17	28 17–36	—	—	—	—	17

In 6 patients in whom difficulty was encountered with the short colonoscope the examination was repeated using the long colonoscope in the hope that the increased manœuvrability would enable further advance. In 2 cases this instrument allowed a successful examination, but in the other 4 patients only a few more centimetres of bowel could be examined and the examination was still unsuccessful. In the latter part of the study the long colonoscope seemed to achieve better results, but increasing experience may also have been responsible.

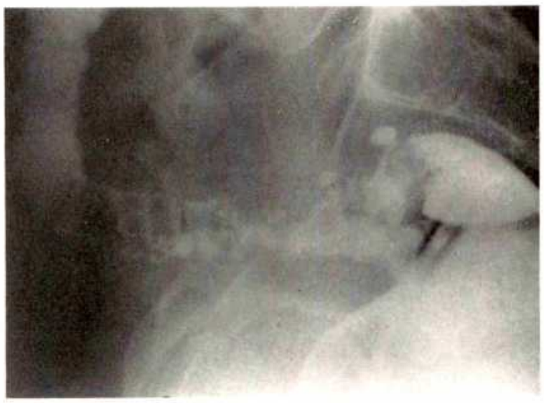

FIG. 1.—Diverticular disease in the sigmoid colon of a 74-year-old man. Persistent narrowing and irregularity are suggestive of carcinoma, but colonoscopy showed no evidence of tumour. A repeat barium-enema examination 1 year later showed diverticular disease with no evidence of carcinoma and the patient remains symptom-free.

DISCUSSION

The sigmoid colon is probably the most difficult part of the colon for the radiologist to examine. This is due to the configuration of the bowel, with tortuous segments of colon overlying each other in many views, and to the nature of the diseases occurring there. In patients with radiological appearances of diverticular disease it may be very difficult to determine whether an area of persistent narrowing is due to diverticulitis or to a carcinoma (Shanks and Young, 1969), and often laparotomy is undertaken in case a carcinoma is lurking undiagnosed in the abnormal segment. Even at laparotomy the distinction between carcinoma and diverticulitis can be extremely difficult. The present study was undertaken to assess the value of colonoscopy in this situation.

The narrowing, sharp angulation and fixation so often present make this a particularly difficult group of patients to examine, and in 17 patients the instrument could not be passed into or through the diseased segment. This was due not only to acute angulation of the bowel and inability to distend it with air but also in some cases to continuous soiling with liquid faeces coming through the narrow segment. The instrument must be advanced under visual control in the direction of the lumen and if the bowel cannot be distended this may be impossible. Because of the risk of damage to the inflamed bowel analgesic drugs were not given and sedation was avoided whenever possible. No patient was examined less than 6 weeks after an acute episode of diverticulitis. Pro-banthine was not found to be helpful in facilitating a difficult examination.

In 19 patients colonoscopy was successful in viewing all or most of the suspicious segment. The cases where the whole segment was viewed satisfactorily tended to be those with more localized disease. In 4 patients a carcinoma was diagnosed and in 5 cases no evidence of carcinoma was seen. In these 9 patients the examination was obviously of value, and their subsequent course has confirmed the accuracy of the diagnosis in each case.

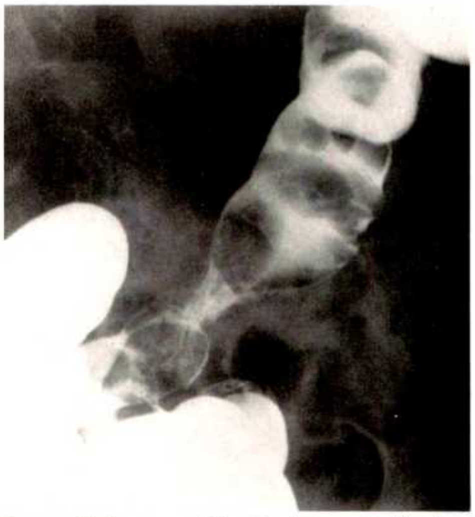

FIG. 2.—Barium-enema film after intravenous Pro-banthine in an 84-year-old woman. Stenosis of the sigmoid colon was diagnosed radiologically as either carcinoma or localized diverticular disease. Colonoscopy was negative. A repeat barium-enema examination 14 months later showed minimal narrowing only. The diagnosis was, therefore, uncertain but laparotomy was avoided on the evidence of colonoscopy.

The false negative was due to infiltration of the colon from the peritoneal surface by a gastric carcinoma. Fortunately the misleading impression at colonoscopy did not adversely affect the outcome in this case since laparotomy was undertaken, but it emphasizes that the greatest caution is needed before claiming to exclude carcinoma because no evidence of it has been seen at endoscopy.

In the remaining 9 patients the whole sigmoid colon could not be examined satisfactorily because of failure to pass an acute bend at or above the apex of the sigmoid loop, or because the upper part of the sigmoid colon had not been adequately cleared of faeces, or because the whole circumference of the bowel could not be seen throughout the examination. In these cases enough of the narrowed segment was seen for it to be judged very unlikely that a carcinoma was present. No case of carcinoma has since occurred in this group. The technique is thus a useful addition to radiology in patients presenting this difficult diagnostic problem, and may avoid an unnecessary laparotomy when the lesion is benign and expedite it when the lesion is malignant.

Acknowledgements.—We wish to thank the surgeons and physicians in the Royal Infirmary, Edinburgh, who have referred some of these patients for examination, and the nursing staff for undertaking the careful preparation of the patients. We are grateful to the Ernest and Minnie Dawson Cancer Trust for a generous grant for the purchase of the Olympus CFLB colonoscope.

EMERGENCY OESOPHAGEAL TRANSECTION IN UNCONTROLLED VARICEAL HAEMORRHAGE

BY P. GEORGE, C. BROWN, G. RIDGWAY, B. CROFTS, AND S. SHERLOCK

ROYAL FREE HOSPITAL, LONDON

SUMMARY

The results of emergency oesophageal transection are described. The overall operative mortality-rate was 45 per cent. There were no operative deaths in the patients with extrahepatic obstruction and normal liver function. The operative mortality-rate for the patients with cirrhosis was 53 per cent, or a salvage rate of 47 per cent if one considers that this is a highly selected group of patients (albeit negatively)—patients with impaired liver function who had not responded to intensive medical treatment and who were still bleeding at the time of surgery.

SINCE 1964 at the Royal Free Hospital, London, oesophageal transection has been performed as an emergency procedure for uncontrollable haemorrhage in 35 patients with oesophageal varices.

Bleeding from oesophageal varices accounts for only 0·01 per cent of hospital admissions in Britain and for approximately 3·0 per cent of patients admitted with haematemesis and melaena (Desmond and Reynolds, 1972).

The management of patients with bleeding oesophageal varices poses a difficult problem. Irrespective of the method of management the results have been depressing, with mortality-rates ranging from 30 to 80 per cent (Sherlock, 1964; Orloff, Halasz, Lipman, Schwabe, Thompson, and Weidner, 1967).

MEDICAL MANAGEMENT

The blood-loss is replaced, ideally 50 per cent of the loss with fresh blood. Vitamin K is given parenterally.

Measures are taken to prevent hepatic pre-coma. Enemas or colonic wash-outs are given. Neomycin and lactulose are administered orally.

If the bleeding does not stop spontaneously vasopressin (20 units in 200 ml. of 5 per cent dextrose) is given intravenously. More than one dose may be necessary. If the bleeding continues a Sengstaken-Blakemore tube is passed through the mouth and the balloons are inflated to compress the varices. The tube must not be left in position for more than 24 hours, and if at the end of that time there is further bleeding a direct surgical approach is necessary.

At this hospital the operation of choice has been an oesophageal transection.

OPERATIVE TECHNIQUE

The anaesthetized patient is placed in the right lateral position and the chest is opened through the bed of the left eighth rib. The oesophagus is isolated immediately above the gastro-oesophageal junction.

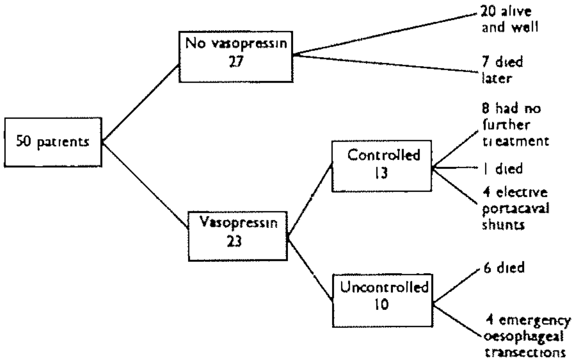

FIG. 1.—Summary of the progress of the last 50 patients admitted to the Royal Free Hospital, London, with bleeding oesophageal varices secondary to cirrhosis.

Table I.—AETIOLOGY OF BLEEDING OESOPHAGEAL VARICES IN 30 PATIENTS UNDERGOING OESOPHAGEAL TRANSECTION

AETIOLOGY	NO. OF CASES	AGE (yr.)		OPERATIVE MORTALITY
		Average	Range	
Alcoholic cirrhosis	7	40	42–66	4
Primary biliary cirrhosis	2	56	50–62	1
Active chronic hepatitis	2	30	21–39	1
Secondary biliary cirrhosis	1	60	—	0
Partial nodular transformation	1	60	—	1

Cryptogenic cirrhosis	15	55	40–68	8

Any varices on the surface of the oesophagus are ligated and divided. The vagus nerves are identified and avoided. The longitudinal muscle is opened for 4–5 cm. and the inner circular muscle and mucosa are cored out by blunt dissection. The inner core is transected and resutured with two continuous chromic catgut sutures. Bleeding from the cut varices is controlled by holding the distal part of the 'cored-out'

mucosa between the fingers and thumb of the left hand. Just before the suturing is completed a radio-opaque nasogastric tube is passed into the stomach. The longitudinal muscle is repaired with interrupted chromic catgut sutures.

The chest is closed in the usual manner using an underwater drain.

POSTOPERATIVE MANAGEMENT

Nothing is given orally until the fifth day, when a Gastrografin swallow is performed. If this shows no leak from the anastomotic site then oral feeding is commenced. The chest drain is removed if the chest radiograph is satisfactory after the Gastrografin swallow.

Protein is restricted initially and graduated amounts are given later on, dependent upon the liver function and satisfactory electro-encephalogram recordings.

If the general condition of the patient and hepatic function permit, then an elective portacaval shunt is performed approximately 6 weeks later.

RESULTS

Two groups of patients are considered separately: first, those with portal hypertension secondary to cirrhosis (*Cases* 1–30), and secondly those in whom the hypertension is secondary to an extrahepatic block (*Cases* 31–35).

1. **Intrahepatic Obstruction.**—In the majority of patients with haemorrhage from oesophageal varices control can be gained by medical means.

Fig. 1 summarizes the progress of the last 50 patients admitted to this hospital with bleeding varices secondary to cirrhosis (Parbhoo, Owens, and Sherlock, 1972).

In 10 cases the haemorrhage was not controlled medically and in 4 of these an emergency oesophageal transection was performed. The other 6 patients had terminal hepatic failure.

The aetiology of the disease in 30 patients undergoing oesophageal transection is shown in *Table I*, and the preoperative investigations and postoperative progress of these patients are summarized in *Table II*.

There were 16 postoperative deaths (death within 32 days of operation)—an operative mortality-rate of 53 per cent (*Table III*). Hepatic failure was the commonest cause of death.

Table III.—Cause of Postoperative Death

Cause of Death	*No. of Cases*
Hepatic failure	9
Oesophageal leak	3
Acute gastric ulcer and hepatic failure	1
Cardiac aneurysm	1
Respiratory failure	2

Two patients bled again during the postoperative period. *Case* 2 died of hepatic failure following a partial gastrectomy for an acute gastric ulcer. *Case* 25 bled terminally from a large gastric varix on the ninth postoperative day. Following transection his liver function rapidly deteriorated; his bilirubin had risen to 34 mg. per cent and his blood-urea to 190 mg. per cent.

Subsequent Progress.—Three patients (*Cases* 10, 14, and 29) had elective portacaval shunts performed 3 months, 1 month, and 6 months respectively after transection. *Case* 10 survived for 4 years and then died of hepatic failure. *Case* 29 survived for a further 6 years and died of complications following a fractured neck of the femur.

There was 1 other death in the first postoperative year (*Case* 1). This was a man who died 9 weeks postoperatively of hepatic failure and myocarditis. Post-mortem examination showed that he also had a hepatoma.

There are 9 patients on whom elective shunts have not been performed and to date 5 have re-bled. The haemorrhage was the cause of death in 3 of these 5 patients.

One patient (*Case* 18) bled 15 months following her transection. An emergency portacaval anastomosis was performed and she is alive 4 years later.

These results are summarized in *Table IV*.

Liver Function.—An attempt has been made to try to correlate liver function with survival or postoperative mortality. The preoperative measurements of serum albumin, bilirubin, and aspartate transaminase have not always been an accurate reflection of hepatic function since many patients had been transfused large volumes of blood prior to their transfer to this hospital.

There was no significant difference between the preoperative bilirubin and albumin levels in the two groups. However, there was only 1 survivor with a serum-albumin level of less than 3·0 g. per cent (*Case* 16).

Estimation of the aspartate transaminase level gave a slightly better correlation. The values for those surviving ranged from 7 to 65 units and for those dying postoperatively from 10 to 950 units.

The presence or absence of ascites did not vary significantly between the two groups.

A history of pre-coma or coma during the haemorrhage leading to the transection indicated a poor prognosis. Five out of 9 such patients died within a few days postoperatively of hepatic failure, 1 died 9 weeks later of hepatic failure and myocarditis (*Case* 1), and 1 case (*Case* 7) developed a leak at the line of transection. Of the 2 survivors, *Case* 16 is still alive 18 months later but has ascites and repeated episodes of portasystemic encephalopathy. *Case* 30 is alive and well 1 month postoperatively.

The average blood replacement prior to surgery in the patients who survived was 15 pints as compared with 22 pints in those who died in the postoperative period. Whether this difference is significant in itself is hard to judge because in the latter group liver function was worse and not unnaturally there was less desire to operate and medical treatment was more prolonged.

Oesophageal Complications.—All 3 patients (*Cases* 7, 23, and 28) who developed leaks at the site of the transection died. Two of these patients had pulled out their nasogastric tube and an attempt, wrongly, had been made to replace it!

One patient (*Case* 8) developed a stricture at the site of the transection which required dilatations. She also had a chronic duodenal ulcer with oesophageal reflux and she eventually died 2 years after transection from haemorrhage from her duodenal ulcer.

2. **Extrahepatic Obstructions.**—There were 5 patients in this group (*Table V*). In 2 cases there was a history of neonatal sepsis.

Case 32 had had osteomyelitis of her femur and spine complicated by hepatic abscesses. These had been drained at the age of 3 weeks and had grown *Staphylococcus aureus*. She was the only patient in this group to suffer any postoperative complication. She developed a left-sided empyema and lung abscess which required drainage—the causative organism was again *Staph. aureus*. She was also the only patient in this group to have further haemorrhages (two small bleeds almost 4 years after transection).

Table IV.—SUBSEQUENT PROGRESS OF THE OPERATIVE SURVIVORS

CASE	AGE (at the time of transection)	TIME OF HAEMORRHAGE AFTER TRANSECTION (mth.)	BLOOD-LOSS (pints)	CAUSE	OUTCOME
8	62	21 and 24	3 and 22	Duodenal ulcer	Died after second haemorrhage
16	62	10	10	Varices and healed duodenal ulcer	Alive and well at 14 mth.+. No further haemorrhage.
17	51	25	2	Varices	Alive and well at 7 yr.+. No further haemorrhage.
19	62	24	26	Varices	Died
20	58	18	29	Varices and duodenal ulcer	Died
3	66	No further haemorrhage			Alive and well at 4 yr.+
4	49				Alive and well at 2 yr.+
12	60				Alive and well at 3 mth.+
30	51				Alive and well at 1 mth.+

1 patient (*Case* 1) died 9 weeks postoperatively of liver failure and myocardial infarction Post-mortem examination showed a hepatoma

3 patients (*Cases* 10, 14, and 29) had an elective portacaval anastomosis.

1 patient (*Case* 18) had an emergency portacaval anastomosis following a haemorrhage 15 months after transection.

Table V.—DETAILS OF 5 PATIENTS WITH EXTRAHEPATIC OBSTRUCTION

CASE	AGE AND SEX	PREVIOUS HAEMORRHAGES		BLOOD-LOSS PRIOR TO OPERATION (pints)	POSTOPERATIVE PROGRESS	FURTHER HAEMORRHAGES
		No.	Blood-loss (pints)			
31	10 M.	2	6	19	No complications	None. Alive and well at 6 years
32*	9 F.	?	?	14	Empyema of left chest and lung abscess	2 at 45 and 48 mth. Blood-loss 3 and 4 pints respectively
33	20 M.	3	67	26	No complications	None. Alive and well at 3 years
34*	11 M.	5	19	30	No complications	None. Alive and well at 9 mth
35	15 M.	3	32	28	No complications	None Alive and well at 2 mth.

* History of neonatal sepsis.

Case 34 had required an exchange transfusion at birth for jaundice. This had been complicated by umbilical sepsis.

All 5 patients had normal pre- and postoperative liver-function tests. There was no operative mortality.

DISCUSSION

Ideally an attempt is made to control the haemorrhage by conservative means and then to proceed to an elective definitive operation, e.g., portacaval or splenorenal shunt. The 1-year survival of patients treated this way is 85 per cent (Hourigan, Sherlock, George, and Mindel, 1971; Rothwell-Jackson and Hunt, 1971).

The length of time that patients are treated conservatively varies markedly from hospital to hospital.

There have been few prospective studies, but Orloff (1967) attempted to compare medical and surgical therapy in the United States. The results of medical treatment were so bad, the survival rate being only 17 per cent, that this form of treatment was abandoned. The survival rates of patients submitted to early surgery were 54 per cent for varix ligation and 53 per cent for emergency portacaval shunt. In this country the survival figures with conservative management are considerably different, which in part reflects the difference in the aetiology of the cirrhosis.

In the period 1953–65 there were 245 admissions for bleeding oesophageal varices to one hospital (Rothwell-Jackson and Hunt, 1971). In 171 patients (70 per cent) the bleeding was controlled medically and an elective shunt was later performed.

The most useful drug in the medical management is vasopressin, which decreases splanchnic blood-flow and portal venous pressure (Schwartz, 1970). More than one dose may be necessary. Temporary (no blood-loss for 24 hours) or more permanent cessation of the haemorrhage will be obtained in the majority of cases (Shaldon and Sherlock, 1960; Merrigan, Plotkin, and Davidson, 1962).

If the bleeding is not controlled with intravenous Pitressin then a Sengstaken-Blakemore triple-lumen tube is passed orally (not through the nose) to compress the oesophageal varices. Conn (1970) described his results of using the tube in 90 patients. The bleeding was controlled in only 65 per cent of cases and furthermore in 20 per cent of the cases the death of the patient could be attributed directly to its use, the commonest complications being regurgitation and aspiration pneumonia. This is not our experience. Provided that the tube is correctly placed the haemorrhage is controlled, and the incidence of regurgitation and aspiration pneumonia can be reduced by using a quadruple-lumen tube, the extra lumen being used to aspirate saliva, etc., from the oesophagus.

Extrahepatic Obstruction.—In approximately 50 per cent of these patients the portal vein thrombosis is secondary to sepsis, umbilical sepsis and osteomyelitis being the commonest foci (Thompson and Sherlock, 1964).

The treatment is primarily medical in the hope that more portasystemic anastomoses will develop spontaneously (Stathers, Ma, and Blackburn, 1968). Cirrhosis is not a sequela (Hsia and Gellis, 1955). Certainly as the child becomes older the haemorrhages tend to become less frequent and severe. If definitive surgery has to be performed then a splenorenal anastomosis is the operation of choice, but for the procedure to stand a reasonable chance of success the diameter of the splenic vein should be at least 1 cm. (Hallenback and Adson, 1961). Alternatively, the superior mesenteric vein can be anastomosed to the inferior vena cava (Foster, Holcomb, and Kirtley, 1963).

Walker (1964) discussed the results of 24 patients with extrahepatic obstruction undergoing elective oesophageal transection. Eight re-bled seriously (33 per cent), the cases having been followed for periods of up to 11 years. Britton and Crile (1963) found that 4 of their 14 cases (29 per cent) had re-bled after 3–14 years.

One of our patients has so far re-bled (*Table V*) but longer follow-up is necessary, for it is not uncommon for these patients to have intervals of 5 years or more between bleeds.

There was no operative mortality in this group—a reflection of their normal liver function.

Intrahepatic Obstruction.—A variety of operative procedures has been described to control the haemorrhage when medical treatment has failed. The least traumatic of these is injection of the veins with sclerosants via an oesophagoscope (Macbeth, 1955; Hunt, Johnstone, and Rodgers, 1969). More extensive procedures include transoesophageal ligation of the varices via a thoracic approach (Boerema, 1949; Linton and Ellis, 1956; Crile, 1957; Rothwell-Jackson and Hunt, 1971). Welch (1956) described a similar operation through an abdominal approach. Walker (1960, 1964) reported an oesophageal transection which may be either mucosal or complete, while Tanner (1950, 1961) described a gastric transection (porta-azygos disconnexion).

Other surgeons have tried oesophagogastric resection either with an oesophagogastric anastomosis or using a loop of jejunum or colon to complete the anastomosis (Cooley and DeBakey, 1954; Koop and Roddy, 1958; Habif, 1959; Hallenback and Adson, 1961; Self, 1969). The latter operations are formidable and extensive procedures and certainly should not be used as emergency procedures.

At present in this country either an emergency portacaval shunt is performed or a direct approach is made to the bleeding varices by oesophageal transection or by the Boerema-Crile operation.

The operative mortality-rate for elective portacaval shunts is between 6 and 12 per cent (McDermott, Palazzi, Nardi, and Mondet, 1961; Brown and Walker, 1967; Panke, Rousselot, and Burchell, 1968; Hourigan and others, 1971). The mortality for emergency shunts, even when only 'good-risk' patients are operated upon, is higher at 20–50 per cent (Shaldon and Walker, 1962; Ekman and Sandblom, 1964; Rothwell-Jackson and Hunt, 1971).

The advantages of a transection operation are:—

1. It is relatively simple, and control of haemorrhage is obtained near the beginning of the operation.

2. Portal blood is not diverted away from the liver. Except in so far as any surgical procedure may adversely affect liver function, the effect on liver function of this operation is the beneficial one of stopping haemorrhage.

The disadvantages are:—

1. It involves doing a thoracotomy and oesophagotomy. As most of the patients have severe impairment of liver function it is perhaps not surprising that some patients have postoperative breakdown of the oesophageal anastomosis. This complication is a real disadvantage of the operation though the incidence in the present series (9 per cent) is less than in other reports, for example 17 per cent in the series of Rothwell-Jackson and Hunt (1971), and is due to the poor healing power of these patients which may in part be due to their hypo-albuminaemia. By doing a mucosal transection as opposed to a full-thickness transection one aims to minimize this complication.

2. It is not definitive. It does nothing to lower portal venous pressure, although it does not increase it, and thus unless further surgery is undertaken these patients are likely to have further haemorrhages (*Table IV*) as a result of the re-formation of varices across the suture line.

3. It does nothing to stop bleeding from gastric varices, though Walker (1964) stated that bleeding from submucous varices below the hiatus was rare.

Rothwell-Jackson and Hunt (1971) presented a series of 58 cases of patients with cirrhosis and uncontrollable haemorrhage. They were treated by the Boerema-Crile operation. Over a period of 5 years 31 patients were operated on with an operative mortality of 50 per cent, and only 3 patients who survived were considered subsequently for portacaval shunts. These figures for a similar group of patients are almost identical to our own.

The patients with cirrhosis and haemorrhage who do not respond to conservative measures may be divided into two main groups: (*a*) those who would have been considered for elective shunts had the bleeding been controlled medically; (*b*) those in whom a shunt would not be considered.

As regards the former group only a controlled prospective study will show whether an emergency portacaval shunt or a two-stage procedure (transection followed by a shunt) is the better treatment.

In the latter group the mortality-rate would be 100 per cent without surgical intervention.

LONG-TERM RESULTS OF SURGICAL TREATMENT FOR BLEEDING OESOPHAGEAL VARICES IN CHILDREN WITH PORTAL HYPERTENSION

BY M. R. B. KEIGHLEY, R. W. GIRDWOOD, G. H. WOOLER, AND M. I. IONESCU*
DEPARTMENT OF CARDIO-THORACIC SURGERY, THE GENERAL INFIRMARY, LEEDS, AND LEEDS UNIVERSITY

SUMMARY

The long-term results of surgical treatment for bleeding oesophageal varices in children with portal hypertension are reviewed. Twenty-four children below the age of 13 years who presented with gastro-intestinal bleeding over a 20-year period form the basis of this study. The importance of the aetiology of portal hypertension on the long-term follow-up has been studied. The results of surgical treatment in controlling haemorrhage are assessed.

Though extrahepatic obstruction is considered to be associated with a better long-term prognosis than intrahepatic disease the results of treatment in both groups were similar, with a 7-year survival rate of 75 per cent. Shunt surgery as a definitive procedure is advised in both groups, though the type of shunt used will depend on the age of the child and the site of obstruction.

PORTAL hypertension though uncommon in children is still one of the most important causes of major gastro-intestinal haemorrhage in this age-group. Most authors consider that surgical treatment for portal hypertension is justified only for the arrest of severe bleeding which cannot be controlled by other means or for the prevention of further haemorrhage in a patient who is at risk (Walker, Shaldon, and Vowles, 1961).

The long-term results of surgical treatment in the adult population leave much to be desired (Voorhees, Price, and Britton, 1970). The frequency of recurrent bleeding after direct ligation of the varices within the stomach and oesophagus is very high (Mikkelson and Pattison, 1959; Walker, 1960; Tanner, 1961), and the majority of surgeons consider that these procedures are justified solely in an attempt to control acute bleeding in a patient who is unfit for shunt surgery (Tanner, 1961; Rothwell-Jackson and Hunt, 1971). The hazards of shunt surgery, however, are not to be underestimated even when this is undertaken as an elective procedure (Riddell and Wilkinson, 1964; Hunt, 1965). Although the risk of encephalopathy may be reduced by side-to-side portacaval anastomosis or by a peripheral shunt (Burchell, Rousselott, and Panke, 1968; Lord, Rossi, Daliana, and Rosati, 1970), the danger of thrombosis in small-vessel anastomoses makes some of these procedures frequently unreliable (Hunt, 1965).

The results of surgical treatment in children, in terms of survival, appear to be more encouraging (Foster, Holcomb, and Kirtley, 1963). On the other hand, recurrent bleeding after surgery is a frequent event (Trusler, Morris, and Mustard, 1962). The principal factor in the more favourable natural history of these patients is a higher incidence of extrahepatic obstruction associated with normal liver function (Voorhees, Harris, Britton, Price, and Santulli, 1965). Although bleeding is better tolerated in these subjects, shunt surgery in early life involves the anastomosis of small-calibre vessels and the failure rate is higher (Foster and others, 1963). Some surgeons also consider that bleeding has a natural tendency to spontaneous remission (Hsia and Gellis, 1955), so that devascularizing procedures might therefore be justified. There are few reports in which the long-term results of surgery in children with cirrhosis have been studied (Trusler and others, 1962; Voorhees and others, 1965).

The present analysis is concerned with the long-term results of surgery for bleeding gastro-oesophageal varices in children. In over half of the children in this series cirrhosis was the prime cause of portal hypertension.

CLINICAL MATERIAL

During the 20-year period 1947–67, 142 patients have received surgical treatment for severe gastro-intestinal bleeding complicating portal hypertension in the Department of Cardio-thoracic Surgery, the General Infirmary, Leeds. Twenty-four of these patients (17 per cent) were under the age of 13 years and form the basis of this report.

For the purpose of this retrospective review the hospital records of all the patients have been examined and all the known survivors were interviewed. The details of the patients who have died or have been lost to follow-up were compiled by means of a questionnaire which was sent to the close relatives of these patients. Relevant radiographic and histological findings were reviewed. In all but one of the survivors (operated upon in 1964) the follow-up exceeds 10 years.

Age and Sex Distribution.—There was an even distribution from neonatal to the age of 13 years, with 50 per cent of the cases occurring before the age of 6 years. Four patients (17 per cent) presented within the first year of life and in 3 of these cases the obstruction was extrahepatic in origin. There was an equal number of male and female patients.

Clinical Features.—The initial presentation in 19 patients was the onset of severe unheralded gastro-intestinal bleeding. In all the cases bleeding occurred prior to surgery (*Table I*) and was therefore the principal indication for operation. In addition, 4 children presented with hepatosplenomegaly, 1 with ascites, and 2 with jaundice.

---

* Correspondence to: M. I. Ionescu, Department of Cardio-thoracic Surgery, The General Infirmary, Leeds 1.

The principal clinical findings are shown in *Table II*. Splenomegaly was found in all but 4 children; hepatomegaly and chronic anaemia were also frequent findings. It is interesting to note the occurrence of haemorrhoids in 3 children. Pancytopenia (W.B.C. 2000 and platelets 50,000) was found in 6 patients, although stigmata of liver disease were noted in only 5 cases.

Diagnosis.—Gastro-oesophageal varices were demonstrated by barium-swallow examination in all the subjects and the varices were invariably confirmed by oesophagoscopy when this was performed (15 cases). Although splenoportography was undertaken in only 7 cases this was of considerable value in distinguishing between prehepatic and intrahepatic obstruction.

Aetiology.—The aetiology of portal hypertension in this series is shown in *Table III*. Extrahepatic obstruction was present in 10 children (42 per cent). Of these cases, the obstruction was confined to the portal vein in 9. One patient had a splenic vein thrombosis and normal liver histology. Bleeding occurred in this case from gastric varices. Thrombus occlusion of the portal vein occurred in 6 children; 2 had had exchange transfusions performed within a week of birth for Rhesus incompatibility and 2 had neonatal staphylococcal infections, one in the umbilical stump and the other in the buttock. Congenital absence of the portal vein was found in 3 children. This was associated with a cavernous transformation in 1 of them.

Table III.—AETIOLOGY OF PORTAL HYPERTENSION

Total	24	20	6	4	3	5

* Clinical findings apart from bleeding.

Histological evidence of liver disease was demonstrated in half of the patients. In 5 children features of congenital hepatic fibrosis, with dense bands of collagen surrounding relatively normal hepatic lobules, were found. In 2 of these patients their siblings were also known to have had the same pathology. Liver biopsy revealed a disordered architecture with centrilobular necrosis, periportal inflammation and sinusoidal hyperplasia in 2 patients where previous hepatitis had been present. There were 5 cases in whom patchy areas of fibrosis with a non-specific infiltrate of lymphocytes and eosinophils amongst islands of regeneration were seen. These cases were classified as idiopathic juvenile portal cirrhosis. There remain 2 children in whom the cause of portal hypertension was never established; in both cases liver histology was unremarkable and no evidence of extrahepatic obstruction was found.

The clinical features were studied in each group and a high incidence of pancytopenia with signs of liver failure was found in the children with cirrhosis It was interesting to note the absence of features of hepatocellular failure in the children with congenital hepatic fibrosis, and the frequency of pancytopenia in the patients with post-necrotic scarring. In contrast, liver failure and pancytopenia were rarely found in the children with extrahepatic obstruction On the other hand, 3 of our cases had haemorrhoids before the age of 13 years.

Associated Pathology.—In addition to the stigmata of portal hypertension, 2 patients with congenital absence of the portal vein were found to have an atrial septal defect, 1 of which was associated with anomalous pulmonary venous drainage. Bronchiectasis occurred in 1 patient with cirrhosis, and polycystic disease of both kidneys was found in a child with congenital hepatic fibrosis.

Surgical Treatment.—Surgical treatment consisted of gastro-oesophageal devascularization in 7 patients, splenectomy in 9 patients, and shunt surgery in a further 8 cases. The frequent use of direct surgical measures and splenectomy reflects the incidence of extrahepatic obstruction. Because of this, recurrent bleeding frequently occurred, requiring a total of 15 further operations on 11 patients.

The remainder of this report is concerned with the results of surgical treatment with particular reference to the aetiology and clinical presentation of the patients under review.

RESULTS

Of the 24 children treated for severe gastrointestinal bleeding complicating portal hypertension, 12 (50 per cent) are known to be alive at the present time. In 11 of these at least 10 years have elapsed since surgery was first performed. Eight (33 per cent) patients have died and 4 are now lost to follow-up, though all of the latter group were alive at least 8 years after surgical treatment. The overall survival figures are shown in *Table IV*.

Analysis of Initial Surgical Treatment.—The results of the initial surgical treatment for bleeding are shown in *Tables V* and *VI*. Gastro-oesophageal devascularization by meticulously dividing all the veins draining the lower oesophagus and cardia was performed in 7 children. In all but 2 cases further devascularizing procedures were required for recurrent bleeding, either upon the oesophagus alone (3 cases) or on the stomach as well (2 cases) using a modified Tanner's transection with extensive porta-azygous disconnexion. The results were uniformly disappointing, with 4 deaths within a year of the operation and only 2 known survivors. These procedures were followed by gastric stasis in 2 patients, requiring subsequent pyloroplasty, and by temporary dysphagia, requiring dilatation only, in 2 other cases.

Splenectomy alone was performed in 9 cases. There was 1 hospital death, 3 patients are now lost to follow-up, and 5 patients are alive. Further surgery (9 devascularizing procedures) for recurrent bleeding was required in all except 3 children in whom splenectomy was performed for pancytopenia. In the latter cases the blood-count returned to normal in the weeks following surgery, re-bleeding did not occur, and all are alive and symptom-free. Two patients developed thrombotic episodes after splenectomy; a superior mesenteric thrombus occurred, requiring extensive bowel resection in 1 child in the early postoperative period; in the other case thrombus formation in the portal vein occurred associated with massive ascites and severe haemorrhage requiring three devascularizing procedures. Both these patients are alive, despite considerable morbidity, 8 and 19 years respectively after surgery.

Table VII.—RESULTS OF SURGERY IN RELATION TO AETIOLOGY

* Thrombectomy of portal vein prior to portacaval anastomosis.
Figures in parentheses refer to subsequent operations.

Shunt procedures were undertaken in 8 children. Splenorenal anastomosis was used in only 1 child, aged 8 years, with a thrombus occlusion of the portal vein. In the remainder of the cases portacaval anastomosis was performed using a side-to-side anastomosis in 5 patients and an end-to-side shunt in 2 cases. None of these patients required further surgery, and although re-bleeding did occur in 1 patient this was shown to be due to late thrombosis of the shunt associated with ascites and liver failure from which she died. The overall known survival following shunt surgery was 63 per cent, though with only 1 exception all were alive 7 years after surgical treatment. Transient encephalopathy occurred in 3 cases. Both patients with an end-to-side anastomosis developed episodic stupor. In each case symptoms were adequately controlled on dietary measures and oral neomycin alone. Portacaval anastomosis was performed after initial thrombectomy in 2 other patients with a portal vein thrombosis. Bleeding and thrombosis recurred within 3 months of both procedures, however, and interruption of the varices at the oesophagus was thereafter required.

Surgical Treatment in relation to Clinical Presentation.—The only long-term survivors among the patients with pancytopenia were those treated by splenectomy alone. Of the patients with ascites prior to surgery, none left hospital after the initial surgical treatment. The operative stigmata of liver failure were not invariably associated with a poor long-term survival since 60 per cent of the patients with these remain well at follow-up and all survived for at least 5 years.

Results with reference to the Aetiology of Portal Hypertension.—In 12 children with cirrhosis 7 were treated by portacaval anastomosis, 4 by splenectomy, and 1 by direct ligation of the varices (*Table VII*). Although the 7-year survival was 75 per cent, less than half of the patients in this group are now known to be alive. It is said that the prognosis of patients with congenital hepatic fibrosis is much better than for those with infantile portal cirrhosis. However, our figures do not substantiate this view. There were no major complications following operation in patients with portal cirrhosis. In contrast, hepatocellular failure and encephalopathy occurred frequently after operation in the children with congenital hepatic fibrosis.

Table VIII.—RESULTS OF EMERGENCY AND ELECTIVE SURGERY

OPERATION	NO.	ALIVE	DEAD	LOST TO FOLLOW-UP
Initial operation				
Category:—				
A (1 shunt)	4	2	1	1
B	5	2	2	1
C (7 shunts)	15	8	5	2
Total	24	12	8	4
Further operations				
Category:—				
A (1 shunt)	8	1	6	1
B	0	—	—	—
C (1 shunt)	7	5	0	2
Total	15	6	6	3

A, Emergency operation within 24 hours of uncontrollable haemorrhage. B, Operation within a week of severe bleeding. C, Elective operation.

The results of surgical treatment in the children with extrahepatic obstruction were disappointing. The majority of these patients required repeated devascularizing procedures and the high mortality was directly attributable to massive uncontrollable haemorrhage.

Results in relation to the Timing of Operation.—Despite the small number of patients in this study there was no evidence that emergency operations carried a higher mortality when performed as an initial procedure (*Table VIII*). On the other hand, when surgical treatment for recurrent bleeding was performed, a far higher mortality-rate was found when this was undertaken as an emergency measure.

Morbidity in the Long-term Survivors.—By reviewing the 16 survivors in the first 8-year period following surgery 9 were found to be asymptomatic and fully employed. Five patients have had recurrent bleeding which has required further hospital admissions, but nearly all have been back at work between these attacks. There are 2 patients with controlled encephalopathy, neither of whom has been regularly employed.

Cause of Death.—Eight patients died following surgery; in 5 this occurred as a direct result of uncontrollable gastro-intestinal haemorrhage and in the remaining 3 from hepatocellular failure. The high mortality in the children with extrahepatic obstruction was entirely due to massive haemorrhage which theoretically should have been avoidable. It is not surprising, however, that most of the deaths in the cirrhotic group were the direct result of hepatic failure.

DISCUSSION

The clinical features of the children with portal hypertension in this study are similar to those described elsewhere (Trusler and others, 1962; Foster and others, 1963). Other authors also point out the importance of excluding portal hypertension in the differential diagnosis of splenomegaly in this age-group. Although it is said that bleeding is uncommon in the first year of life (Voorhees and others, 1965), 4 of the patients in this review bled during this time. It has been suggested that transient ascites often precedes the onset of varices in patients with extrahepatic obstruction (Mikkelson, 1966). We found that bleeding and ascites often coexisted in these cases. Many authors are of the opinion that the incidence of haemorrhoids is no higher in patients with portal hypertension than in the rest of the population (Goligher, 1967). Nevertheless, 3 cases in this series of 24 patients represent a significant incidence, particularly in the infant population. We should also like to stress the frequent occurrence of pancytopenia associated with hypersplenism in children with cirrhosis.

Much discussion has centred on the importance of omphalitis and exchange transfusion in the aetiology of extrahepatic obstruction (Shaldon and Sherlock, 1962; Thompson and Sherlock, 1964; Mikkelson, 1966). Although portal hypertension is a rare complication of these incidents, 50 per cent of the cases in this series had a history of one of these occurrences. In at least 2 cases extrahepatic obstruction was considered to be due to congenital atresia of the portal vein and in both cases this was associated with an atrial septal defect. This association had not previously been recorded. On the other hand, the coexistence of portal hypertension and polycystic disease, which occurred in 1 of our patients, has recently been described (Gailsford and Bloor, 1968).

Congenital hepatic fibrosis is an uncommon cause of infantile portal hypertension (Sherlock, 1968b). These patients usually present with bleeding varices, and hepatocellular damage is considered uncommon. For this reason, therefore, shunt operations have been advocated. There were 5 children with this condition in the present series. However, the results of portacaval anastomosis were disappointing, with 2 deaths, 1 of which was due to hepatic failure. The majority of reports include a small number of patients in whom the aetiology of portal hypertension has never been explained (Hsia and Gellis, 1955; Sherlock, 1968a). Two patients in this study are considered to be in a similar category. These cases may be due to presinusoidal fibrosis associated with normal liver architecture (Mikkelson, Edmondson, Peters, Redeker, and Reynolds, 1965).

It is unrewarding to compare the long-term results from other centres, particularly because of the variation in the aetiology and the duration of follow-up. However, in series with a similar length of follow-up and incidence of cirrhosis, the results of surgery compare favourably with those of the present series (Trusler and others, 1962; Foster and others, 1963; Voorhees and others, 1965; Foukalstrud and Longmire, 1969).

All attempts to control bleeding by gastro-oesophageal surgery directed to the varices themselves can only be considered to be of temporary benefit (Mikkelson, 1966; Rothwell-Jackson and Hunt, 1970). Splenectomy is regarded as being inadequate and also jeopardizing the construction of splenorenal shunts in extrahepatic obstruction (Trusler and others, 1962; Foster and others, 1963). In addition, however, there is an increased risk of thrombosis following splenectomy which was a major cause of morbidity in 2 of our patients. On the other hand, splenectomy for pancytopenia with hypersplenism in 3 patients with cirrhosis was associated with excellent results.

The results of surgery in patients presenting with ascites was uniformly disappointing. When emergency devascularization was undertaken after a previous operation for bleeding a high mortality was noted, even though many of these patients had an extrahepatic obstruction, in which bleeding is said to be well tolerated (Voorhees and others, 1965).

The benefit obtained from portacaval anastomosis was encouraging, particularly as all these operations were performed in children with cirrhosis. However, most of the patients were at least 7 years of age at the time of operation. Shaldon and Sherlock (1962) point out that portacaval anastomosis for patients with liver disease should not be undertaken under the age of 8 years because of the dangers of thrombosis at the site of the shunt. A splenorenal anastomosis was only performed in 1 patient with prehepatic obstruction, largely because the ages of the remaining subjects precluded such a procedure. Attempts to clear the portal vein of thrombus prior to portacaval anastomosis for extrahepatic obstruction were so disappointing that this procedure has virtually been abandoned. Since patients with extrahepatic obstruction usually present at an early age where for reasons of vessel size splenorenal shunts may be complicated by thrombosis, the procedure is now usually reserved for children over the age of 8 years (King and Shumacker, 1958; Trusler and others, 1962). For this reason the mesenteric caval shunt is considered to be the treatment of choice in patients under 5 years of age with prehepatic obstruction (Lord and others, 1970; Rothwell-Jackson and Hunt, 1970).

CONCLUSIONS

Portal hypertension in children may be due to intra- or extrahepatic obstruction. Congenital hepatic fibrosis may account for a small number of patients in the former group in whom hepatocellular damage is clinically unrecognizable. Prehepatic obstruction may be either congenital, in which case other anomalies of development may coexist, or acquired following exchange transfusion or neonatal sepsis.

The majority of these patients present with major gastro-intestinal haemorrhage. Bleeding oesophageal varices must be considered to be an absolute indication for surgery since recurrent bleeding will invariably occur and the hazards of emergency surgery in such a situation are considerable.

Extrahepatic obstruction is best treated by splenorenal anastomosis in patients over the age of 8 years or by mesenteric-caval shunt before this age. Children with cirrhosis deserve definitive shunt surgery if further bleeding is to be prevented. Direct gastro-oesophageal surgery is of temporary benefit only, but is justified after failed protosystemic shunts or in patients where for reasons of age these procedures would be technically inadvisable.

TRANSECTION OF THE OESOPHAGUS FOR BLEEDING OESOPHAGEAL VARICES

BY R. N. H. PUGH, I. M. MURRAY-LYON, J. L. DAWSON, M. C. PIETRONI, AND ROGER WILLIAMS

THE LIVER UNIT AND DIVISION OF SURGERY, KING'S COLLEGE HOSPITAL AND MEDICAL SCHOOL, LONDON

SUMMARY

Emergency ligation of bleeding oesophageal varices using the Milnes Walker technique was performed in 38 patients. Haemorrhage continued or recurred in hospital in 11 patients, all of whom subsequently died. A further 10 patients died in hospital following operation from hepatic failure and a variety of other causes. Five patients were finally considered suitable for elective shunt surgery, but of 12 patients who were discharged without a further operation, only 2 have re-bled. Although the overall 6-month survival was 32 per cent, in patients with good preoperative liver function this rose to 71 per cent, and the simple scoring system for grading the severity of disturbance of liver function was found to be of value in predicting the outcome of surgery.

Since the results of emergency ligation of bleeding oesophageal varices in our hands have been so disappointing we are currently using it less and are trying the mesenteric caval jump graft as an emergency operation for the control of bleeding varices.

ABOUT half of the patients admitted to hospital with bleeding oesophageal varices die during their admission (Ratnoff and Patek, 1942; Hislop, Waters, Kellock, and Swynnerton, 1966; Orloff, 1966), and the first aim of treatment must be to stop the haemorrhage by the fastest and simplest means available. Although treatment with the Sengstaken-Blakemore tube and intravenous vasopressin is usually effective initially, the former can be used for only 24–48 hours and the latter may have serious cardiac side-effects (Beller, Trevino, and Urban, 1971). In many patients haemorrhage recurs after initial control (Shaldon and Sherlock, 1960; Hermann and Traul, 1970), and in those in whom there are features of terminal liver failure no further treatment is indicated, but in others some form of surgery is required. Our policy (Williams and Dawson, 1968) has been to carry out ligation of the oesophageal varices via the transthoracic approach (Walker, 1964) after controlling the haemorrhage for 24 hours by other means, as this is a simpler and more rapid procedure than emergency portacaval anastomosis and has a lower immediate postoperative mortality. The aim was to assess these patients during the ensuing 6–8 weeks for definitive portacaval anastomosis after the bleeding had been controlled.

In this paper we report the results of such an approach in the management of 38 patients admitted as an emergency with bleeding oesophageal varices, the results being considered in relation to the severity of liver failure present as assessed by a simple grading system.

PATIENTS, PREOPERATIVE ASSESSMENT, AND THERAPEUTIC RÉGIME

The series comprises 38 patients seen between January, 1966, and July, 1972. It is a consecutive series except for 18 patients who formed part of an evaluation of prolonged infusion of the superior mesenteric artery with vasopressin (Murray-Lyon, Pugh, Nunnerley, Laws, Dawson, and Williams, 1973) in the control of oesophageal bleeding. Four of these patients who later had ligation of their varices are included in this series. No patient had undergone previous surgery for variceal haemorrhage. The causes of portal hypertension were alcoholic cirrhosis (13), cryptogenic (13), active chronic hepatitis (6), primary biliary cirrhosis (3), Wilson's disease (1), partial nodular transformation of the liver (1), and extrahepatic portal vein block (1). Varices were demonstrated in every patient by barium-meal studies or endoscopy, and no other potential bleeding site was shown prior to operation.

Nineteen patients had hepatic encephalopathy, 19 had jaundice, and ascites was clinically detectable in 17 patients. The combination of jaundice, ascites, and encephalopathy was present in 13 patients. These clinical features formed part of our grading of the severity of liver disease which was based on that originally described by Child (1964), but in addition included prolongation of the prothrombin time and omitted the assessment of body nutrition (*Table I*).

Table I.—GRADING OF SEVERITY OF LIVER DISEASE

CLINICAL AND BIOCHEMICAL MEASUREMENTS	POINTS SCORED FOR INCREASING ABNORMALITY		
	1	2	3
Encephalopathy (grade)*	None	1 and 2	3 and 4
Ascites	Absent	Slight	Moderate
Bilirubin (mg. per 100 ml.)	1–2	2–3	>3
Albumin (g. per 100 ml.)	3·5	2·8–3·5	<2·8
Prothrombin time (sec. prolonged)	1–4	4–6	>6
For primary biliary cirrhosis:—			
Bilirubin (mg. per 100 ml.)	1–4	4–10	>10

* According to grading of Trey, Burns, and Saunders (1966).

This system makes use of weighting whereby 1, 2, or 3 points are scored for increasing abnormality of each of the five parameters measured. Thus, in patients with good hepatic function the total score is 5 points whereas patients with poorer hepatic reserve have scores of up to 15 points. Those patients whose score totalled 5 or 6 were considered to be good operative risks (grade A), 7, 8, or 9 moderate (grade B), and patients with 10–15 poor operative risks (grade C). Allowance is made in the grading for patients with primary biliary cirrhosis in whom the level of serum bilirubin is usually out of proportion to other evidence of hepatic failure. Of the complete series, 7 patients were placed in grade A, 13 in grade B, and 18 in grade C categories.

Details of Therapy.—All the patients were placed on an anti-hepatic coma régime and parenteral vitamin K was given routinely. Blood transfusion was required in each patient and in most patients an attempt was made to control the haemorrhage for 24–36 hours prior to carrying out the transection. For this, systemic vasopressin was used in 6 patients and in 3 of these a Sengstaken-Blakemore tube was also passed. The latter was used alone in 18 patients and in 4 other patients who had initially received vasopressin by selective infusion of the superior mesenteric artery.

The oesophagus was transected by the Milnes Walker technique via a left thoracotomy approach. Large peri-oesophageal veins were ligated, the lower oesophagus was exposed and mobilized, and an atrial clamp was placed across the oesophagogastric junction. The lower oesophageal muscle was split longitudinally, the mucosal tube containing the submucosal varices was dissected free, and the clamp was opened. The mucosal tube was then pulled up and the clamp was reapplied, thus allowing a lower mucosal transection. The mucosal tube was resutured with continuous catgut, the subsequent healing process occluding the varices. Oral fluids were avoided for the first 5 postoperative days and a Gastrografin swallow was then performed to confirm that there was no leakage from the oesophagus.

RESULTS

Following operation the bleeding continued or recurred in 11 patients (*Table II*), all of whom subsequently died in hospital from the bleeding (9) or following an emergency portacaval anastomosis (2) carried out in an attempt to control the bleeding. The sources of haemorrhage were shown to be a separated oesophageal anastomosis (1), the suture line (2), an oesophageal varix above the suture line (1), a tear in the stomach mucosa (1), and a large acute gastric ulcer (1). No certain bleeding site could be found in 4 cases and in the remaining case no autopsy was performed.

Table II.—RESULTS OF TRANSECTION OF THE OESOPHAGUS COMPARED WITH THE PREOPERATIVE CLINICAL GRADING

GRADE	NO OF PATIENTS	RE-BLED	DIED		SURVIVED FOR 1 YEAR
			In Hospital	Within 6 Months	
A	7	1	2	0	5
B	13	4	5	2	4*
C	18	6	14	3	0†

* Plus 2 patients who survived for less than 6 months

† Plus 1 patient who survived for less than 6 months.

Of the remaining 27 patients in whom bleeding was controlled, 10 died in hospital within 30 days of transection of the oesophagus from liver failure (4), chest complications (3), unexpected cardiac arrest (1), disseminated hepatoma (1), and meningitis (1). Thus 21 (55 per cent) of the total series of 38 patients did not survive to leave hospital.

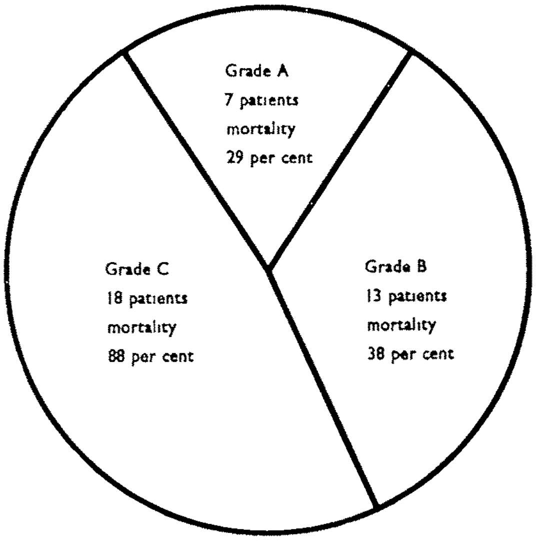

FIG 1.—Operative mortality in each grade of liver disease.

Of the 17 patients who were discharged from hospital, 5 had an elective portasystemic shunt and 3 of these are alive after 2 years and 2 have died of liver failure. The remaining 12 patients had no further treatment as their liver function was not considered adequate for a shunt procedure, and of these, 4 are alive at 2 years including the 2 patients without cirrhosis, and 3 are alive at less than 6 months after operation. Two other patients have died of liver failure and 1 of anorexia nervosa. Only 2 patients so far have re-bled, one dying at 6 months and the other at 1½ years.

For the complete series of 38 patients the overall 6-month survival was 32 per cent and the 2-year survival 20 per cent. When the results are considered in relation to the grading of severity of liver disease significant differences between the groups are observed (*Table II* and *Fig.* 1). Thus, of the grade A patients, 5 (71 per cent) left hospital and survived for at least 6 months, and 3 (43 per cent) survived for 2 years. Eight patients (62 per cent) of the grade B group left hospital and 4 (36 per cent) were alive at 6 months and also at 2 years. Only 4 (22 per cent) of the grade C patients left hospital, and none survived for 6 months.

DISCUSSION

The 55 per cent mortality in hospital in this series is similar to that reported by others for oesophageal variceal ligation. In Walker's (1964) series, 6 of the 16 cirrhotic patients died postoperatively. However, in most of the other reported series the Boerema-Crile operation has been employed (Orloff, 1966, 1967). In this procedure a longitudinal incision is made through both the muscular and mucosal layers and oesophageal closure is potentially less safe. Indeed, in the series of 58 patients reported by Rothwell-Jackson and Hunt (1971) there were 10 patients in whom the anastomosis leaked and all of these died. There was only one anastomotic leak in our series. It is difficult to compare the results of the various series because of differences in type and severity of liver disease, but comparison would be facilitated by the adoption of a grading system such as we have used. Both types of operation seem to control variceal haemorrhage in most patients and the high operative mortality is to a large extent a reflection of the severity of the underlying liver disease.

The outcome of operation in our series did not seem to be influenced by the age or sex of the patient, the presence of jaundice or encephalopathy, or individual liver-function tests considered separately. However, with one exception no patient with moderate or gross ascites or a combination of jaundice, ascites, and encephalopathy survived to leave hospital. Our method of grading the severity of liver disease is more flexible than that originally described by Child (1964), in which a low serum albumin alone was sufficient to place a patient who otherwise had good liver function into grade C. In the present series the operative mortality and long-term survival were closely related to the preoperative grade, and in grade C the results were so poor that operation on such patients does not seem justified unless there is a clear additional and reversible factor which may partially account for the poor liver function. For instance, in 1 patient the C grading on admission was partly due to a period of heavy drinking and her score improved by 5 points postoperatively whereas no other patient improved by more than 2 points. If all grade C patients are omitted from analysis the operative mortality in our series is reduced to 35 per cent.

It was disappointing that bleeding continued or recurred in hospital after operation in 11 of the 38 cases. Although the source of the haemorrhage was not always obvious, in most cases it seems likely to have been due to varices at or above the suture line, and a more extensive portasystemic disconnexion (Tanner's operation; Tanner, 1961) might have been more effective although this is a more major operation. Only 5 patients were considered suitable to follow the planned course and to undergo elective portacaval anastomosis, and this is an indication that most patients admitted as emergencies with bleeding varices have severe underlying liver disease. However, it is interesting that only 2 of the 12 patients who were discharged without a further procedure have re-bled and 7 of these patients are still alive.

Acknowledgements.—We are grateful to Sister Gladys and the nurses of Todd Ward for their expert care of the patients reported here.

INTERPOSITION TEFLON MESENTERIC CAVAL SHUNT FOR BLEEDING OESOPHAGEAL VARICES

BY G. R. GILES, T. G. BRENNAN, AND M. S. LOSOWSKY
UNIVERSITY DEPARTMENTS OF SURGERY AND MEDICINE, LEEDS (ST. JAMES'S) UNIVERSITY HOSPITAL, LEEDS

SUMMARY

A modified mesenteric caval shunt using a Teflon 'H' prosthesis has been performed in 4 poor-risk patients with cirrhosis and exsanguinating haemorrhage from oesophageal varices and a fifth patient with portal vein thrombosis. Although 2 patients ultimately died, the procedure was effective in arresting the haemorrhage and is technically simple to perform.

SIDE-TO-END mesenteric caval shunt is technically difficult to perform and the division of the inferior vena cava results in undesirable sequelae. Thus, this type of operation has hitherto been largely confined to patients with extrahepatic portal obstruction in whom neither the portal nor the splenic vein is available for anastomosis. However, the recent report of Lord, Rossi, Daliana, and Rosati (1970) suggests that a satisfactory mesenteric caval shunt can be readily constructed by using a Teflon prosthesis between the two veins in the form of an 'H'.

We have used this technique in 5 patients in whom bleeding from oesophageal varices continued despite protracted conservative therapy. Four of the 5 patients were considered to be poor risks because of age or liver failure and it was felt that this operation might prove to have a lower mortality than other types of shunt surgery in such subjects. In the fifth patient a mesenteric caval shunt seemed to be the only appropriate procedure available.

SURGICAL TECHNIQUE

Under general anaesthesia and with adequate means for rapid intravenous infusion, the abdomen is opened through a long midline incision. After a thorough inspection of the intra-abdominal viscera, the transverse colon is lifted upwards and forwards by an assistant and dissection is begun at the root of the mesocolon, having first palpated the position of the superior mesenteric artery. The superior mesenteric vein lies to the right of its companion artery, crossing the third part of the duodenum to pass behind the pancreas (*Fig.* 1). It was necessary on each occasion to carry the dissection over the duodenum to the lower edge of the pancreas in order to mobilize a sufficient length of vein of wide calibre for anastomosis. It has also proved necessary to sacrifice one or two jejunal, colonic, and duodenal branches of the vein in order to provide access.

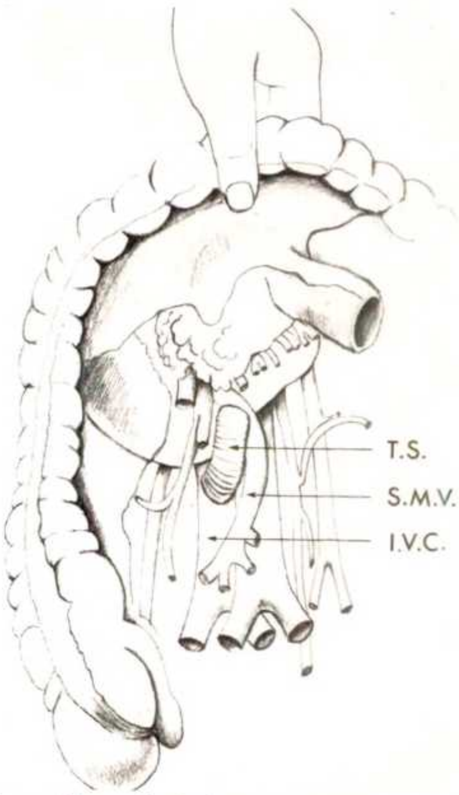

FIG. 1.—Diagram showing the position of the Teflon prosthesis (T.S.) between the superior mesenteric vein (S.M.V.) and the inferior vena cava (I.V.C.).

Having ensured that the superior mesenteric vein is patent and of sufficient calibre to accept the Teflon graft, the inferior vena cava is exposed by mobilizing the right colon and caecum towards the midline. The anterior and lateral surfaces of the vena cava are cleaned for about 5 cm. but it has not been necessary to complete the dissection around the vena cava.

The superior mesenteric vein is clamped and by rotating the clamps to expose its posterior surface a Teflon graft between 16 and 18 mm. in diameter is anastomosed to a suitably placed venotomy with a 00000 continuous Dacron suture. The graft is then passed through a hole in the right mesocolon so as to lie in a natural curve around the duodenum. The prosthesis is cut to a suitable length and the other end is anastomosed to the inferior vena cava which has been side-clamped with a large hexagonal clamp. Before completing this anastomosis the graft is first flushed by releasing the clamp on the superior mesenteric vein which is temporarily reclamped while placing the last one or two stitches (*Fig.* 1).

The right colon is replaced without fixation and the peritoneum over the superior mesenteric vessels is repaired with a continuous catgut suture. The abdomen is closed in layers with non-absorbable sutures.

CASE REPORTS

Case 1.—A female, aged 66 years, was admitted to another hospital in a coma, following a massive haematemesis. There was no previous history of liver disease, but jaundice, peripheral stigmata of liver disease, hepatomegaly, and ascites were present. Eighteen pints of blood were transfused, the coma was treated with neomycin and colonic wash-outs, and the patient underwent surgery 12 days later.

Immediately prior to operation the serum bilirubin was 3·6 mg. per cent, serum albumin 3·0 g. per cent, serum urea 30 mg. per cent, and the prothrombin time after massive vitamin-K administration was 16 seconds with a control of 12 seconds. The venous phase of a superior mesenteric arteriogram revealed a patent superior mesenteric vein and reversed flow down the portal vein from the liver.

The establishment of the Teflon shunt reduced the jejunal vein pressure from 37 to 25 cm. H_2O. Postoperatively there was an early recovery without signs of encephalopathy. Barium-swallow examination and oesophagoscopy 3 months after surgery revealed no evidence of oesophageal varices. There was no recurrent bleeding during the first postoperative year or evidence of encephalopathy, but the biochemical indices of liver function continued to deteriorate.

Case 2.—A female, aged 75 years, was first known to have cirrhosis when she underwent cholecystectomy in February, 1967. Over the next 4 years she suffered several severe haematemeses which required blood transfusions. She was again admitted to hospital in February, 1971, with a massive haemorrhage requiring the transfusion of 15 pints of blood. After the passage of a Sengstaken tube immediate control of bleeding was obtained, but there was recurrent bleeding after the tube was removed and the patient was transferred to St. James's Hospital. The Sengstaken tube was replaced, and after a further 4 pints of blood had been transfused the patient was operated upon and a Teflon shunt was inserted without technical difficulty. Four litres of ascitic fluid were removed at surgery.

Immediately prior to operation the serum bilirubin was 2·6 mg. per cent, serum albumin 2·5 g. per cent, serum urea 60 mg. per cent, and the prothrombin time had returned to normal after vitamin-K administration.

Postoperatively the patient remained well for 72 hours, after which she slipped into a Grade II hepatic coma which responded slowly to neomycin and colonic wash outs.

During the 12 months after operation the patient ha taken 2 g. of neomycin daily without further signs o encephalopathy. Barium-swallow examination shows n varices and there have been no further episodes of gastrointestinal bleeding. Although biochemical tests of live function continue to deteriorate, there has been n reaccumulation of ascites.

Case 3.—A female, aged 57 years, had 1 year previousl undergone a laparotomy at another hospital for wha appeared to be obstructive jaundice. However, a shrunke cirrhotic liver was found and the patient remaine jaundiced during the next 12 months. She next presente with continued haematemesis and hepatic precoma an was treated with intravenous Pitressin and a transfusion o 12 pints of blood. However, the bleeding continue unabated and the patient was transferred to St. James' Hospital where she was found to be severely jaundice (total bilirubin 24·8 mg. per cent) and disorientated and t have stigmata of chronic liver disease. The abdomen wa grossly distended with ascites and there was pitting oedem of the lower half of the body.

A barium-swallow examination showed oesophagea varices, the serum electrolytes and urea were markedl abnormal (sodium 122 mEq./l., chloride 81 mEq./l., ure 179 mg. per cent), and the serum albumin was low (2·4 g per cent).

Although the patient continued to vomit large amount of fresh blood, surgery was withheld for several days i order to try to improve her general condition. However, i became clear that the outlook was very poor withou surgery and, in the hope that portal decompression migh be life-saving, a Teflon mesenteric caval shunt wa established without further investigation. No technica difficulties were experienced.

Postoperatively the initial course was good for 48 hour but thereafter she rapidly became comatose and die 72 hours after surgery. Post-mortem examination reveale the Teflon graft to be partially obstructed by thrombosi with resultant venous congestion of the small intestine This failure was almost certainly due to narrowing of th inferior vena caval anastomosis by one stitch picking u the back wall about one-third of the distance along th suture-line.

Case 4.—A male, aged 57 years, was first diagnosed a suffering from alcoholic cirrhosis in 1959 but was relativel untroubled until 12 years later when he presented a another hospital with an uncontrollable haematemesi from oesophageal varices. After a trial of medical treatment and having received 10 pints of blood, the patien underwent a porto-azygous disconnexion and splenectom which were initially successful in averting bleeding However, 6 weeks later haemorrhage recurred, and durin the next 4 weeks a further 12 pints of blood were transfused and it was attempted to control the haemorrhag by a Sengstaken tube and intravenous Pitressin. Th patient was then transferred to St. James's Hospital wher he was found to be jaundiced (serum bilirubin, 8·9 mg per cent) and to have stigmata of chronic liver disease. pronounced liver flap was present with mild disorientation The abdomen was soft with evidence of ascites and th liver was enlarged three fingers' breadth below the costa margin. There was marked ankle oedema.

Investigations revealed a haemoglobin of 7·1 g. per cent platelet count of 67,000 per c.mm., serum albumin o 3 g. per cent, prothrombin time after vitamin-K administration of 19 seconds (control 15 seconds), and serum ure of 105 mg. per cent. A coeliac axis arteriogram demonstrated filling of the portal and superior mesenteric vein during the venous phase.

Vomiting of large quantities of bright-red bloo continued and surgery was carried out. No unusua technical problems were encountered and the post-shun pressure in a jejunal vein was reduced to 20 cm. H_2O from a pre-shunt pressure of 35 cm. H_2O.

Six hours after operation the patient collapsed and became comatose. Neomycin and colonic wash-out produced no improvement, and a tracheostomy was performed on the fourth postoperative day. Melaena occurred continuously for 1 week, necessitating repeated blood transfusions. The bleeding did not recur but bronchopneumonia and renal failure supervened and the patient died $2\frac{1}{2}$ weeks postoperatively.

Case 5.—A male, aged 32 years, had been operated on 6 years previously for bleeding oesophageal varices. At laparotomy an extrahepatic portal vein thrombosis had been found but an attempt at a definitive portacaval shunt had been made. However, the shunt had not effectively decompressed the portal system and bleeding had recurred 6 and 12 months later. Splenectomy had then been carried out but bleeding had recurred on several occasions, necessitating repeated blood transfusions.

After transfer to St. James's Hospital on the present admission a superior mesenteric arteriogram was carried out which, on subtraction films (*Fig.* 2), revealed a patent superior mesenteric vein although the portal vein appeared thrombosed. Liver-function tests showed no abnormalities.

A Teflon mesenteric caval shunt was constructed without technical difficulty, with reduction of the jejunal vein pressure from 35 to 22 cm. H_2O. The postoperative course was uneventful. Barium-swallow examination 3 months after operation revealed no trace of varices and there has been no recurrence of bleeding up to 9 months postoperatively.

DISCUSSION

Mesenteric caval shunts were introduced independently by Marion (1953) in France and by Clatworthy, Wall, and Watman (1955) in the United States of America. The operation was designed mainly to deal with patients with bleeding oesophageal varices in whom the portal and splenic veins were not available for anastomosis. Thus, the majority of patients selected for this procedure were children in whom the portal vein had thrombosed, or in whom the splenic vein was too small for shunting purposes, or who had already undergone splenectomy. The operation was also used in adult patients in whom a previously constructed portacaval shunt had thrombosed.

While the operation usually results in a wide shunt, certain technical difficulties are not unusual. In some patients the length of the vena cava is insufficient to curl easily around the lower border of the duodenum and difficulty is encountered in performing the anastomosis without distortion. Since the technique involves division of the vena cava there is venous stasis of the lower limbs and chronic oedema is to be expected. This has not proved a problem in younger patients, but adults have needed elastic support and diuretics in order to keep the oedema under control (Voorhees and Blakemore, 1962).

Possible advantages of a mesenteric caval shunt are that it is, in effect, a side-to-side shunt which in contrast to an end-to-side shunt could allow blood to drain from the liver if the haemodynamic situation requires it (Gliedman and Margulies, 1964). In other circumstances the shunt could allow continued portal flow to the liver and thus perhaps help to preserve residual hepatic function. As with splenorenal shunts, the mesenteric caval shunt is in a peripheral part of the portal system and postoperative encephalopathy should be relatively uncommon. However, mesenteric caval shunts have not found favour with the majority of surgeons. The largest series have been reported by Voorhees and Blakemore (1962) and Gliedman (1965). While the results in each study were satisfactory in the relief of variceal bleeding, there was no clear advantage over the portacaval shunt for the uncomplicated case of chronic liver disease.

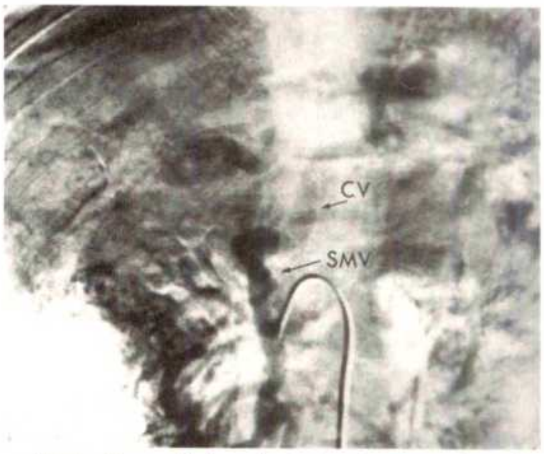

FIG. 2.—*Case* 5. Radiograph showing the venous phase of a superior mesenteric arteriogram outlining the superior mesenteric vein (S.M.V.) and a large collateral vein (C.V.) extending towards the cardio-oesophageal junction. No filling of the portal vein is demonstrated.

Interposed grafts of autogenous veins, homologous arteries, or synthetic materials such as Teflon and Dacron have been used in surgery of the portal venous system. Experimental studies suggest that autogenous veins and Teflon grafts give the most satisfactory results although routine anticoagulation may be necessary to ensure continued patency (Foster, Jolly, Symbas, and Dively, 1965). In the clinical situation vein-grafts have been used to bridge the gap between the portal vein and inferior vena cava in the hilum of the liver (Reynolds and Southwick, 1951; Foster and others, 1965). This technique may be advantageous where a side-to-side shunt is proposed and the portal vein is found to be short and the caudate lobe of the liver enlarged. Rousselot (1952) suggested that splenorenal shunts could be simplified if vein-grafts were used. However, while the early results in 4 patients were satisfactory, it has been reported that all of these grafts ultimately thrombosed.

Construction of mesenteric caval shunts by interposed grafts using a Teflon prosthesis has been reported by Lord and others (1970). Of the 7 patients studied by Lord and others (1970), in 1 case the shunt eventually thrombosed but the remaining patients were apparently in good health, although it is not clear whether these patients had been suffering from chronic liver disease originally. Read, Thompson, Wise, and Murphy (1970) reported 9 mesenteric caval shunts using vena caval homografts. In 2 of the patients the shunts ultimately thrombosed but 4 patients survived without further bleeding. Drapanas (1972) has reported the use of an interposition Dacron mesenteric caval shunt in 25 cirrhotic patients with an operative mortality of 8 per cent. Although the mean follow-up time of these patients is only

19 months, there has been an encouraging lack of re-bleeding and encephalopathic complications. Investigation of 15 of these patients has shown complete success with regard to long-term patency of the graft.

Our own experience with Teflon mesenteric caval shunts is limited to 5 patients with bleeding varices. One patient with extrahepatic portal vein thrombosis had undergone two unsuccessful attempts at portal decompression. A Teflon mesenteric caval shunt caused a considerable reduction in the portal hypertension with resolution of the varices without the need to divide the vena cava. The other 4 patients had exsanguinating haemorrhages from oesophageal varices and all had severe disturbance of liver function, with jaundice, ascites, and hypo-albuminaemia. It was hoped that a mesenteric caval shunt would decompress the portal system sufficiently to control the bleeding, and at the same time help to preserve liver function by not shunting all the portal blood away from the liver. It was also hoped that it would prove to be a simpler operation, but it must be admitted that at this stage of our experience this procedure had not reduced the operating time required or the degree of operative dissection in these very ill patients. The 2 patients with the severest degrees of liver decompensation died following the operation and in 1 there was clear evidence of further bleeding. The other 2 patients have made good recoveries and follow-up barium-meal and endoscopic studies have shown disappearance of the oesophageal varices. The mortality in these patients seems to be no greater than for the relatively simple Boerema-Crile operation, which requires a later definitive operation, or for emergency portacaval anastomosis with its attendant disadvantages (Wantz and Payne, 1961; Rothwell-Jackson and Hunt, 1971).

It seems possible that the Teflon mesenteric caval shunt might avoid the problems of lower-limb venous stasis in addition to having the other advantages of a mesenteric caval shunt. The experience of Lord and others (1970) would suggest that long-term patency of the graft can be achieved. It is also our impression that the procedure can be performed in the emergency situation without recourse to investigations to demonstrate patency of the portal and splenic veins. The main place for this type of operation will undoubtedly be in the management of patients with portal and splenic vein thrombosis, but the technique may also be useful when an emergency laparotomy has been carried out for gastro-intestinal bleeding and the surgeon is faced with unsuspected portal hypertension. In addition, we suggest that further assessment of its use as an emergency procedure in poor-risk patients is warranted.

CIRCULATORY PATTERNS IN THE NORMAL HAND

BY J. M. LITTLE, P. L. ZYLSTRA, J. WEST, AND J. MAY

DEPARTMENT OF SURGERY, THE UNIVERSITY OF SYDNEY AT THE ROYAL PRINCE ALFRED HOSPITAL, SYDNEY, AUSTRALIA

SUMMARY

Circulation in 100 apparently normal hands was studied clinically by the use of the Allen test and ultrasonically with a Doppler flowmeter. Circulatory dynamics in the hand were found to follow a very variable pattern, the ulnar artery being the dominant source of supply in most hands. It was concluded that collateral circulation in the hand would generally maintain viability of the fingers when either the radial or ulnar artery was occluded at the wrist. In 9 per cent of hands, however, there was evidence of more drastic disturbance of the circulation on occlusion of the ulnar artery, and in 6 per cent the same finding was made upon occlusion of the radial artery. The Allen test was positive in only 3 per cent of the hands, and in each case the ultrasonic examination confirmed the dependence of the digital circulation on a single artery at the wrist. It is suggested that these variations in collateral adequacy in the hand may explain ischaemic phenomena seen in some patients with the 'hammer-hand' syndrome, in a few patients after radial artery cannulation for monitoring purposes, and in a somewhat higher percentage of patients having arteriovenous fistulae constructed at the wrist for long-term haemodialysis. It is also suggested that patients undergoing procedures which will distort radial artery haemodynamics in the hand should be screened to test collateral adequacy.

THE radial artery at the wrist is a frequent site of surgical assault. It is convenient and relatively simple to cannulate the radial artery at this point when an indwelling arterial catheter is to be used for monitoring purposes. The radial artery is also readily accessible for the construction of arteriovenous fistulae in patients requiring long-term haemodialysis. It is assumed that the collateral circulation in the hand is generally adequate to cope with the haemodynamic disturbances thus created. Indeed, the hand is well supplied with arterial blood and communications between the radial and ulnar artery are provided through the dorsal arterial arch, the deep palmar arch, and, most important of all, the superficial palmar arch. The superficial palmar arch is completed on the radial side usually by junction with the radialis indicis or the princeps pollicis arteries and this communication is often small, measuring less than 2 mm. in diameter (McCormack, Cauldwell, and Anson, 1953).

There is increasing information to suggest that interruption of the radial artery flow may be less benign than has been assumed. Serious ischaemia of the hand with tissue loss has been reported in a relatively small percentage of cases following radial artery cannulation for monitoring purposes (Samaan, 1971), and in a somewhat larger number of cases following the construction of arteriovenous fistulae for maintenance haemodialysis (Storey, George, Stewart, Tiller, May, and Sheil, 1969; May, 1972). Although the percentage of patients who are prone to serious ischaemia may be low, tissue loss under such circumstances represents a major disaster.

The ulnar artery at the wrist is less prone to iatrogenic damage, but is particularly susceptible to trauma where it lies in relation to the hook of the hamate in the palm of the hand (Barker and Hines, 1944). The syndrome of digital ischaemia resulting from thrombosis of the superficial palmar branch of the ulnar artery at this site following prolonged use of the hand as a hammer has recently attracted considerable attention (Conn, Bergan, and Bell, 1970; Little and Grant, 1972; Millender, Nalebuff, and Kasdon, 1972). An industrial study has suggested that relatively asymptomatic examples of this 'hammer-hand' syndrome may be fairly common (Little and Ferguson, 1972), and that the development of symptomatic ischaemia may depend on individual variations in collateral adequacy between the radial and ulnar arteries.

In order to investigate possible means of predicting digital ischaemia after arterial damage at the wrist we have conducted a study of 100 hands, using clinical and ultrasonic methods of examination.

MATERIAL AND METHODS

Fifty randomly selected normal volunteers were used in this study. None of them had obvious clinical abnormalities affecting their hands, either on questioning or physical examination.

Clinical Examination.—All the hands were clinically examined by the Allen test (Allen, 1929), using strict criteria. The Allen test is carried out as follows. The patient is asked to clench his fist as tightly as possible so as to drive the blood out of his hand. The radial and ulnar arteries are then firmly compressed at the wrist. The fingers are partly straightened so that they are extended and relaxed. Hyper-extension of the fingers can produce a false-positive test. The hand appears bloodless and ischaemic while the two arteries are held compressed. When one artery is released there is a rapid return of pink coloration to the hand under normal circumstances. Return of this colour is complete in less than 5 seconds. The two arteries are individually examined in this way. A positive Allen test is said to occur when colour does not return to the hand within 5 seconds of release of one or other artery.

Ultrasonic Examination.—An E.M.I. Type 64 Ultrasonic Flow Velocity Detector, operating at 10 MHz. and delivering a 2-mm. beam, was used to identify pulsatile flow in each of the interdigital arteries in the three interdigital clefts of each hand. Once pulsatile flow had been located, first one artery, then the other was compressed at the wrist, and a record was kept showing whether pulsatile flow was abolished by compression of either artery. It was thus possible to determine the dependence of pulsatile flow in each interdigital cleft on radial or ulnar artery inflow.

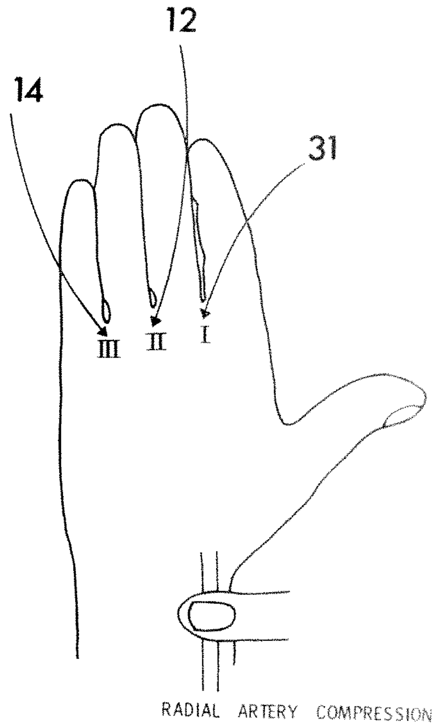

FIG. 1.—The number of times that interdigital pulsatile flow was abolished in each cleft by radial artery compression.

RESULTS

There were 19 men and 31 women in this survey. The mean age was 32 years, with an age range of 18–67 years. Thirty-four subjects were light or occasional smokers, 7 smoked between 10 and 20 cigarettes a day, and the remaining 9 subjects smoked 20 or more cigarettes each day. Smoking habits amongst these people without evidence of clinical arterial disease did not seem to have any bearing on the circulatory patterns in the hand.

Ultrasonic Examination.—The findings of the ultrasonic examination can be summarized as follows:—

1. Radial artery compression abolished pulsatile flow in 57 of the 300 interdigital arteries examined. The cleft between the index and middle fingers (cleft I) was affected in 31 cases, that between the

middle and ring fingers (cleft II) in 12 cases, and that between the ring and little fingers (cleft III) in 14 instances (*Fig.* 1).

2. Ulnar artery compression abolished pulsatile flow in 75 of 300 clefts. Cleft I was affected in 25 cases, cleft II in 28 cases, and cleft III in 22 cases (*Fig.* 2).

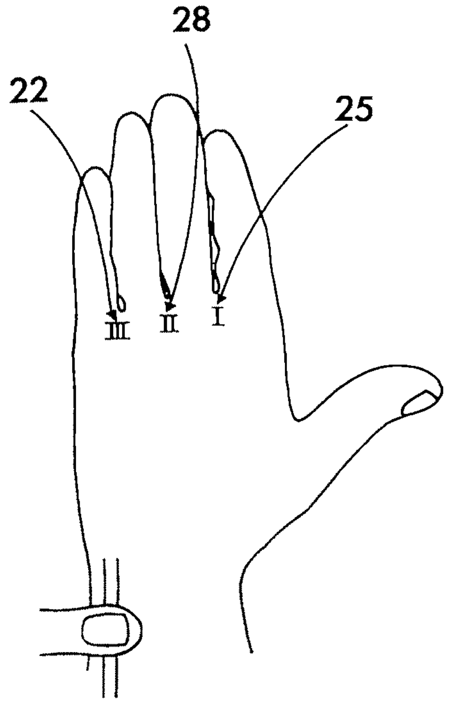

Fig. 2.—The number of times that interdigital pulsatile flow was abolished in each cleft by ulnar artery compression.

3. Radial artery compression abolished pulsatile flow in at least one cleft in 38 of 100 hands.

4. Ulnar artery compression abolished pulsatile flow in at least one cleft in 46 of 100 hands.

5. Ulnar artery compression abolished pulsatile flow in all three clefts in 9 of 100 hands.

6. Radial artery compression abolished pulsatile flow in all three clefts in 6 of 100 hands.

Allen Test.—Using the strict criterion of return of colour within 5 seconds, there were 3 positive Allen tests. In 2 instances the Allen test suggested that the radial artery supply to the hand was deficient, in that revascularization did not occur within 5 seconds after release of the radial artery while ulnar artery compression was sustained. In the remaining case release of the ulnar artery did not produce revascularization while compression of the radial artery was sustained. In the 2 hands in which the radial artery supply was thought to be deficient on the basis of the Allen test, compression of the radial artery made no difference to the ultrasonically detected pulsatile flow in the interdigital clefts, but pulsatile flow disappeared on compression of the ulnar artery, confirming circulatory dependence on the ulnar artery. In the 1 remaining hand in which the ulnar artery supply was felt to be deficient, compression of the radial artery abolished pulsatile flow in all three interdigital clefts.

DISCUSSION

The collateral circulation in the hand is important in three situations. Direct trauma to the arteries at the wrist is fortunately fairly rare except in suicidal attempts. When one or other artery is divided at this point, surgeons generally ligate with equanimity. Damage to the superficial palmar branch of the ulnar artery where it crosses the hook of the hamate (the 'hammer-hand' syndrome) may, however, be a potent cause of disability (Conn and others, 1970). Since it has been shown that some individuals with this injury have relatively few symptoms (Little and Ferguson, 1972), it is necessary to seek an explanation for the variation from individual to individual. While propagation of thrombus and micro-embolism to the digital arteries may account for more extreme forms of digital ischaemia, variations in the collateral supply may equally well explain some of the variation encountered.

Samaan (1971) reported 3 cases of digital ischaemia after the insertion of a radial artery catheter for pressure monitoring in patients undergoing cardiac surgery. In 2 cases frank gangrene of the fingers occurred, and in 1 case amputation above the wrist became necessary. These 3 cases were noted in a series of 'about 800 cases of open-heart surgery'.

The haemodynamic situation created by an arteriovenous fistula at the wrist for long-term dialysis is much more complicated. Diversion of radial artery flow will obviously be important, but a situation can develop in which reverse flow occurs in the radial artery distal to the fistula to such an extent that a 'steal' situation is created (Bussell, Abbott, and Lim, 1971). Gangrene of the fingers developing some time after the fashioning of such an arteriovenous fistula is being reported with increasing frequency (May, 1972). Once again, the circulatory pattern in the hand is likely to be an important determinant of this form of ischaemia.

Preoperative assessment of the circulatory dynamics in the hand is obviously difficult. It would be hard to justify routine arteriography, with its attendant risks, and an arteriogram has the shortcoming of producing a static picture which may well conceal the dynamics of the circulation. The Allen test seems to provide some useful information, but it is probably a relatively crude test. It is too early to say how useful ultrasonic examination will prove to be, but a prospective study has been set up to see whether any prediction can be made concerning the development of ischaemia in patients undergoing arteriovenous fistula formation at the wrist. Clearly, ultrasonic examination can only provide indirect information, but it has the theoretical advantage of testing the dynamics of the collateral circulation in the hand.

It would be unwise to base anything more than tentative conclusions on the data so far accumulated. It seems that circulatory dynamics in the hand follow a very variable pattern, and that ischaemia following occlusion of either artery may manifest itself in any finger. The ulnar artery seems to be the dominant source for digital arterial blood, as judged by abolition of the interdigital artery pulses on compression of the ulnar artery in 75 of the 300 clefts examined, compared with the 57 interdigital arteries affected by compression of the radial artery. The loss of pulsatile flow in at least one of the interdigital vessels, which occurred in 38 hands on compression of the radial artery and in 46 cases on compression of the ulnar artery, was of patchy distribution and did not follow any particular pattern. This suggests that collateral circulation will generally maintain viability of the fingers following occlusion of the radial or ulnar arteries, since abolition of pulsatile flow in all three interdigital arteries was relatively uncommon. In 9 per cent of the hands, however, ulnar artery compression did abolish pulsatile flow in all three interdigital clefts. Interruption of the ulnar artery flow under these circumstances could possibly lead to ischaemia in any finger. In 6 per cent of the hands radial artery interruption similarly produced abolition of pulsatile flow in all the interdigital clefts, and might likewise be expected to produce digital ischaemia. In only 3 of these 15 hands was the Allen test positive.

It is suggested that modes of investigation as mentioned in this paper should become part of the routine examination of patients who are likely to undergo procedures which may compromise the blood-flow in the radial artery. It is particularly important to bear in mind the frequency with which damage occurs to the superficial palmar branch of the ulnar artery over the hook of the hamate amongst subjects in heavy labouring jobs. Loss of flow in this vessel may lead to serious ischaemia if the radial artery flow is interrupted at the wrist.

THERMOGRAPHY IN THE DIAGNOSIS OF OCCLUSIVE VASCULAR DISEASE OF THE LOWER LIMB

BY G. A. McLOUGHLIN AND G. B. RAWSTHORNE
DEPARTMENT OF SURGERY, UNIVERSITY OF LIVERPOOL, AND THE ROYAL INFIRMARY, LIVERPOOL

SUMMARY

An assessment of the diagnostic accuracy of thermography in arterial disease of the lower limb is reported. By comparing the arteriographic and thermographic appearances of 52 patients, three independent observers had overall agreement of interpretation in approximately 50 per cent of cases. Factors found to limit accuracy were increasing subcutaneous fat thickness and localized disease with good collateral circulation.

FEMORAL arteriography as a diagnostic procedure is not without risk. Local haemorrhage, arterial thrombosis, peripheral embolism, plaque dislodgement, subintimal dissection, aneurysm formation, and guide-wire fracture are among its well-described sequelae (Grainger, 1965; Ansell, 1968). Lang (1963), in a review of 11,402 Seldinger procedures, reported 7 deaths and 81 serious complications. The hypothesis that thermography could be used as an alternative less hazardous method for locating the site of arterial blockage and assessing 'peripheral run-off' has been evaluated in this study.

MATERIAL AND METHODS

Sixty patients (58 males and 2 females) were subjected to thermographic studies of lower-limb blood-flow. Fifty-two of these patients had, in addition, femoral arteriography performed.

Each patient was warmed in a confined draught-free space by a source of radiant heat. A toe-knee temperature as near as possible to 28° C. in the ischaemic limb(s) was achieved. The patient was then moved into a specially constructed room at a constant ambient temperature of 16° C. Scanning was by Pyroscan Mark II with a scanning time of 35 seconds, which gave at a distance of exactly 2 ft. (60·96 cm.) a spatial resolution of 3 mm. Thermograms and toe-knee temperatures were recorded at 2-minute intervals over 40 minutes or until the ischaemic toe temperature fell to 21° C. Comparison of the thermographic and arteriographic appearances was then made by three independent observers who had no access to the clinical records of the case. The suspected site of the arterial blockage and assessment of the collateral circulation and peripheral run-off were recorded.

In addition, certain parameters possibly affecting the diagnostic accuracy of thermography were recorded; subcutaneous fat content expressed as skin-fold thickness using Harpenden callipers (Edwards, Hammond, Healy, Tanner, and Whitehouse, 1955) was estimated at the level of the adductor hiatus in each limb. This point was chosen as it is most frequently involved in occlusive disease (Watt, 1966) and therefore at this site subcutaneous fat insulation could be expected to have its greatest diagnostic impact in the majority of cases. Estimate of the extent of the disease on arteriography was made and recorded as the 'occlusive vascular score' according to the following scale:—

Grade I: Local segmental (either upper or lower segments involved) with good collateral circulation, score 1.

Grade II: Segmental disease with poor collateral circulation, score 2.

Grade III: Extensive (both upper and lower segments involved) disease with poor collateral circulation, score 3.

Grade IV: Extensive disease with no collateral circulation, score 4.

RESULTS

Of the 52 patients undergoing both arteriography and thermography, approximately 8 per cent of the thermograms were of such poor technical quality that no interpretation of the arterial pattern could be made. On comparing the arteriograms and thermograms of the remaining cases, observer agreement with accurate localization of the arterial block was achieved in 50 per cent of cases. Similarly, in 58 per cent of the cases observer agreement was found between the state of the collateral circulation and peripheral run-off on arteriography and thermography.

Table I.—CORRELATION BETWEEN SKIN-FOLD THICKNESS AND ACCURACY OF THERMOGRAPHY

SKIN-FOLD THICKNESS (mm.)	NO. OF CASES	NO. IN WHICH THERMOGRAPHY WAS SUCCESSFUL	PERCENTAGE ACCURACY
8·3	6	6	100
8·5	7	6	85·71
9·0	7	6	85·71
9·5	3	2	66·66
10·0	2	1	50·00
10·5	3	1	33·33
12·0	7	1	14·28
13·0	9	1	11·11
13·3	4	0	

$r = -0·974$, $P < 0·001$.

Table II.—CORRELATION BETWEEN SEVERITY OF ARTERIAL DISEASE AND ACCURACY OF THERMOGRAPHY

GRADE OF DISEASE	NO. OF CASES	TOTAL SCORE*	NO. IN WHICH THERMOGRAPHY WAS SUCCESSFUL	PERCENTAGE ACCURACY
I	6	6	0	0
II	7	14	1	14·28
III	9	27	3	33·30
IV	26	104	20	77·00

* *See* text for full description.
$r = 0·971$, $P < 0·001$.

Subcutaneous fat thickness varied from 8·3 to 13·3 mm., with a mean of 10·46 mm. (S.D., 1·89). A negative correlation was found between the percentage diagnostic accuracy and the subcutaneous fat thickness of the adductor hiatus (*Table I*; $r = 0·974$, $P < 0·001$), the percentage accuracy of thermography falling from 100 to 0 per cent with increasing subcutaneous fat thickness.

When the diagnostic accuracy of thermography was correlated with the extent of the disease expressed as the 'occlusive vascular score' (*Table II*) the accuracy rose from 0 to 77 per cent with increasing score, i.e., increasing severity of disease ($r = 0·971$; $P < 0·001$).

DISCUSSION

Many claims have been made as to the value and diagnostic accuracy of thermography in widely disparate clinical situations. Accuracy in diagnosis of 85–95 per cent has been claimed in thyroid disease (Samuels, 1972a); 90 per cent in parathyroid disease (Samuels, 1972b); 94·5 per cent in the localization of perforating veins (Patil, Williams, and Lloyd Williams, 1970), and 88·6 per cent in carotid artery occlusion (Capistrait, 1971). Claims as to the place of thermography in the diagnosis of breast carcinoma have ranged from the enthusiastic (accuracies of 100 per cent (Swearingen, 1965) and 87 per cent (Wallace and Dodd, 1968)) to the guarded (accuracy of 53 per cent (Furnival, Stewart, Weddell, Dovey, Granville, Evans, and Forrest, 1970)). It is significant that diagnostic accuracy has been found to be always greatest in situations where difference in infra-red emission could not be obscured by variable subcutaneous fat insulation. The wide observer variance in accuracy of thermographic diagnosis in breast carcinoma could be accounted for by the variable fat density of the breasts studied in different series.

The results of our study show that in general thermography is a poor diagnostic substitute for femoral arteriography. It would appear that this is because in lower-limb occlusive disease accuracy is limited by the insulating capacity of the subcutaneous fat and the higher thermal background provided by segmental disease with good collateral circulation.

Acknowledgements.—We wish to thank Mr. C. R. Helsby, under whose care the patients were admitted, Mr. A. Cuscheri, and Mr. D. Annis for their encouragement and advice in preparing this paper.

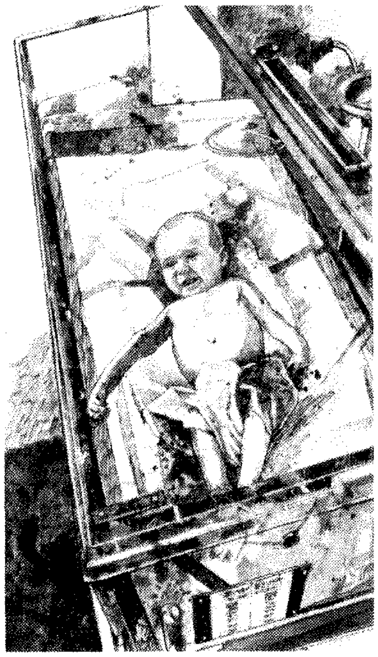
First and for all.



In severe neo-natal infections

In septicaemias

In serious post-operative situations

G-DAY-those first vital 24 hours in serious bacterial infections:

- when effective therapy must be initiated to prevent rapid deterioration in the patient's condition
- when the causative organism is unknown or uncertain
- when there is no time for trial and error

When these situations occur in acute or acute on chronic infections, Genticin Injectable, the antibiotic with the broadest bactericidal spectrum of all, has proved eminently successful as first-line therapy in a wide range of conditions.

"It therefore follows that on sensitivity testing alone, gentamicin (Genticin) would be the best single antibiotic for blind chemotherapy."[1]

[1] Reference: J Irish med Ass, 65, No 20, 514, 1972.

Genticin Injectable is available in 2 ml multidose vials and snap-off ampoules. Each 2 ml contains 80 mg gentamicin base as gentamicin sulphate.

Further details are available on request from:

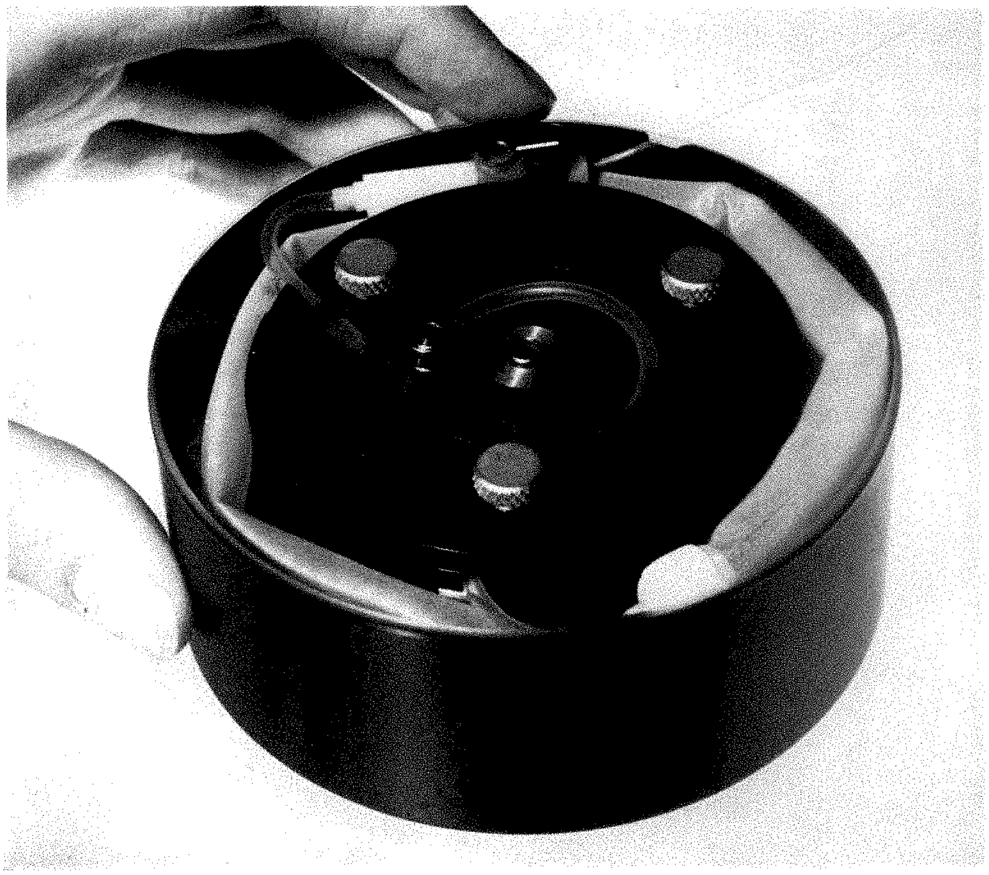
LUCAS
MEDICAL EQUIPMENT

THE BURN CHEMOFUSOR



A portable infusor to enable continuous Intra-Arterial Infusion Chemotherapy to be carried out safely in ambulatory patients.

The Chemofusor is lightweight and compact and can be worn with the carrying holster provided. Pumping pressure is by the peristaltic method and a single roller is used instead of the usual two or three rollers. Power is supplied for the Chemofusor motor by miniature mercury cell batteries which give a continuous running time of six weeks. The motor unit has an important fail safe factor which ensures that under no circumstances can the pump head increase its speed.

The drug sac and pumping tube, incorporating a miniature non-return valve, is supplied complete as a disposable item.

The pump will deliver 5 ml. per 24 hours and the capacity of the drug sac is 50 ml.

Enquiries should be addressed to:
Lucas Medical Equipment,
Electral House, Neasden Lane,
London, N.W.10

BLUNT ABDOMINAL INJURY: A REVIEW OF 59 CONSECUTIVE CASES UNDERGOING SURGERY

BY P. M. BOLTON, C. B. WOOD, J. B. QUARTEY-PAPAFIO, AND L. H. BLUMGART*
DEPARTMENT OF SURGERY, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

SUMMARY

1. A consecutive series of 59 patients undergoing laparotomy as a result of blunt abdominal trauma is reported.

2. Road-traffic accidents were the most common cause of blunt abdominal trauma and frequently produced a complex pattern of associated injuries.

3. There were 8 deaths, giving a mortality-rate of 14 per cent.

4. The number of associated injuries was the most important single factor influencing the mortality-rate.

5. Delay in diagnosis occurred in 14 patients, and this may contribute to the high mortality-rate of blunt abdominal injury.

6. A high index of suspicion, thorough and repeated clinical assessment, and willingness to resort to laparotomy are the main principles in the diagnosis of blunt abdominal injury.

OVER the past 15 years greater understanding of the physiopathology of shock has resulted in improvement in the resuscitation and management of severely injured patients. These advances have been responsible for the relatively recent decline in the mortality-rate of penetrating abdominal injury (McLeod and Brown, 1966). Nevertheless, the mortality-rate of blunt abdominal trauma has remained in the region of 6–23 per cent (Aho and Rastima, 1971). The failure to achieve a significant reduction in the mortality of non-penetrating abdominal injury is probably related to the progressive increase in high-speed road-traffic accidents producing major abdominal visceral injury in association with multiple other injuries (Macbeth, 1966). In addition, the difficulty in early diagnosis of the visceral injury, particularly in patients with multiple injuries, may lead to delay in the institution of appropriate treatment. In some cases symptoms and signs of visceral injury only become apparent hours or days after the initiating trauma. This delay in presentation also contributes to the higher mortality-rate of non-penetrating abdominal trauma.

In this paper we report a consecutive series of 59 patients who underwent surgery for blunt abdominal injury. The importance of early diagnosis is emphasized and the reasons for delay are discussed.

CLINICAL MATERIAL

Patients.—The 59 patients reviewed were treated between December, 1966, and June, 1972. Forty-two of the patients (71 per cent) were male. The age incidence is shown in *Fig.* 1. Two-thirds of the patients were in their second or third decade.

Aetiology.—The types of accident producing the abdominal injuries are listed in *Table I.* Road-traffic accidents were responsible for the injuries to 76 per cent of the patients in this series. Only 3 of the 45 victims of traffic accidents were pedestrians. The remaining 14 patients (24 per cent) were involved in domestic, sporting, or industrial accidents.

* Present address: University Department of Surgery, Royal Infirmary, Glasgow.

Abdominal Injuries.—The incidence of injury to the different abdominal organs is listed in *Table II*. In many patients more than one viscus was damaged. The liver, spleen, and kidney were the organs most frequently involved, accounting for 58 (62 per cent) of the 94 visceral injuries recorded, although virtually every abdominal organ appears on the list.

All but 3 of the 28 cases of liver injury had associated major damage to at least one other organ. Crushing injury sustained in the front seat of a motor vehicle was the usual aetiology. A detailed analysis of 20 of these patients has been recorded elsewhere (Blumgart and Vajrabukka, 1972).

In general, rupture of the spleen appeared to be associated with a lesser or more localized trauma and a smaller proportion of these injuries was due to traffic accidents. Hepatic injury coexisted in 5 cases and renal injury in 4 of the patients with rupture of the spleen.

Table III.—ASSOCIATED INJURIES AND MORTALITY

SITES OF INJURY	NO OF PATIENTS	NO OF DEATHS	MORTALITY-RATE (per cent)

Total	59	8	14

Orthopaedic injury. Fracture of one or more long bones or the pelvis.

Craniocerebral injury: includes facial fracture and scalp and facial lacerations. One case had cerebral injury

Ten of the 11 patients with a ruptured kidney had associated injuries to other abdominal organs. In the remaining patient minor trauma had led to the rupture of a hydronephrotic kidney. The renal damage itself was not severe in the majority of cases and surgical intervention was usually necessitated by the associated injuries. Nephrectomy was performed in only 2 patients, both of whom had gross renal disruption. Rupture of the membranous urethra in association with a fractured pelvis occurred in 4 cases and intraperitoneal rupture of the bladder in 2 cases. One of the latter patients had also sustained a rupture of the gall-bladder and has been reported previously (Blumgart, 1969).

Diaphragmatic injury was always due to major crushing trauma. All 6 patients with diaphragmatic injury had severe multiple injuries to the thoracic and upper abdominal viscera.

The small intestinal injuries were associated with high-speed traffic accidents. Three patients were found to have a laceration of the second part of the duodenum at laparotomy. In each of these patients there were associated abdominal visceral injuries. The ileum was the site of rupture in 2 patients and the jejunum in 1. Large-bowel injury also occurred in 6 patients and in 3 it was associated with fracture of the pelvis. Mesenteric injury usually accompanied intestinal injury, but in 1 case an isolated mesenteric tear was the sole lesion found at laparotomy.

Pancreatic injury occurred twice in the series. One of these 2 patients had severe multiple injuries elsewhere including damage to the stomach and duodenum, while the other had sustained an isolated pancreatic injury following local trauma to the left side of the abdomen (*Case* 5). Evidence of pancreatitis was found at post-mortem examination in 2 fatal cases (one with liver injury and the other with multiple injuries to the chest and abdomen). In neither of these cases was there direct evidence of pancreatic rupture.

One patient had ruptured a pre-existing abdominal aortic aneurysm when he had fallen on to his abdomen (Bolton and Blumgart, 1972).

Associated Injuries (*Table III*).—Only 12 (20 per cent) of the patients in this series did not have extra-abdominal injuries.

Fractures of long bones or pelvis were the most common of the associated injuries, occurring in 32 patients (54 per cent). A common combination was fracture of an upper limb bone and rupture of an upper abdominal viscus. In particular, 5 of 9 patients with severe injury of the right lobe of the liver had sustained fractures of the right upper limb. Fracture of the pelvis occurred in 10 patients. In 4 cases this was associated with rupture of the membranous urethra and in another 3 with rupture of the colon.

Twenty-nine patients (49 per cent) had associated head injuries. The majority of these injuries were relatively minor, comprising concussion and/or facial and scalp lacerations. Only 3 patients had fractures of the skull, and in only 1 case was there evidence of significant cerebral injury when contused occipital lobes were found at post-mortem examination.

Thoracic injuries occurred in 21 patients (36 per cent) and 9 of these required tracheostomy and assisted respiration. Fractures of the ribs were present in nearly all of these cases, but only 5 patients had significant flail segments. In 9 of the 21 patients there was a pneumothorax and 7 had sustained contusions or lacerations of the lung(s). Two patients sustained damage to the thoracic aorta. One of these died as a result of rupture of a traumatic aneurysm of the aorta sited just distal to the ligamentum arteriosum. The other patient was found to have an intimal tear of the thoracic aorta at post-mortem examination.

Diagnosis.—In general, diagnosis was based on clinical features similar to those outlined by Mathieson (1962), supplemented at times by radiological findings. Only rarely was abdominal paracentesis used, and in 1 such patient a ruptured spleen was found following a negative four-quadrant tap. In cases of doubt, repeated examinations and review of the findings usually resolved the problem. In the few patients where doubt still remained, laparotomy was performed.

Only one negative laparotomy was performed. This patient was under the influence of alcohol and had upper abdominal tenderness in association with multiple fractured ribs.

A clinical diagnosis of intra-abdominal injury requiring surgery was made within 8 hours of admission in 45 of the 59 patients in this series. In

14 cases the diagnosis was delayed for more than 8 hours following admission to hospital (*Table IV*).

RESULTS

Eight of the 59 patients died, a mortality-rate of 14 per cent (*Table III*). All the fatal cases were the result of road accidents. The mortality-rate appeared to be directly related to the number and severity of the injuries sustained. It is significant that all 12 patients with abdominal injury alone survived. Where there was a combination of abdominal visceral damage and injuries to the thorax, head, and limbs, 5 patients out of 11 died, a mortality-rate of 45 per cent. Two of the 14 cases where there was delay in diagnosis and treatment died. The mortality-rate of this small group is 14 per cent and does not differ significantly from that of the whole series.

During the 5½-year period of the series 20 cases of penetrating abdominal injury were also treated with no deaths.

DIFFICULTIES IN DIAGNOSIS

Analysis of the injuries sustained by the 14 patients whose diagnosis was delayed for longer than 8 hours (*Table IV*) reveals two groups of clinical situation responsible for the delay. In the first group abdominal signs were initially absent or insignificant after injury. However, with persistence of fluid leak into the peritoneal cavity, signs of shock or peritonitis became manifest usually 12–48 hours after injury. This type of 'slow-leak' picture was associated with the diagnostic delay in 3 of the patients with ruptured liver, in 1 with ruptured spleen, in 1 with ruptured duodenum, and in 1 patient with combined rupture of the gall-bladder and urinary bladder.

Table IV.—TYPE OF INJURY IN PATIENTS IN WHOM THERE WAS DELAY IN DIAGNOSIS

Type of Injury	*No. of Patients*
Ruptured liver	4
Ruptured spleen	4
Ruptured colon	3
Ruptured pancreas	1
Ruptured gall-bladder	1
Ruptured duodenum	1
Total	14

The second type of clinical picture resulted when either there was no initial leak or the leak became temporarily sealed off. Delayed rupture then followed days or weeks later and produced rapid development of generalized peritonitis or led to a faecal fistula. Delayed visceral rupture of this type was seen in 3 of the cases of ruptured spleen, 3 cases of ruptured colon, and 1 case of ruptured liver.

The following case histories are illustrative of the difficulties encountered in the diagnosis of such cases.

CASE REPORTS

Case 1.—A 58-year-old woman was involved in a road-traffic accident. She was concussed initially but complained of pain in the right hypochondrium when seen in the casualty department of another hospital. On examination at this time her pulse and blood-pressure were within normal limits. No abdominal signs were noted and she was admitted for observation. Sixteen hours later she became hypotensive, developed generalized abdominal pain and tenderness, and was transferred to our care. At laparotomy there was a rupture of the second part of the duodenum, a contused segment of ileum, and a small haematoma of the liver. The pancreas did not appear to be damaged. Repair of the duodenum was performed but she died on the fifth postoperative day in a state of refractory hypotension associated with bacteriaemic shock and acute renal failure. It seems likely that the initial delay associated with continued leakage of intestinal contents contributed to the ultimate fatal outcome.

Case 2.—A 13-year-old boy fell from a milk van. On admission he was fully conscious and complained of pain in the right hypochondrium. His general condition was good, with a pulse-rate of 64 per minute and a systolic blood-pressure of 105 mm. Hg. There was local tenderness in the right hypochondrium but no rigidity. The diagnosis of ruptured liver was considered but in view of the minimal symptoms and signs he was treated conservatively and laparotomy was not performed. Sixteen hours later he developed a tachycardia and the abdomen became more tender with rigidity in the right upper quadrant. At laparotomy there was a large haemoperitoneum resulting from an extensive injury to the right lobe of the liver which necessitated right hepatic lobectomy. There was also a right perirenal haematoma. Postoperatively there was some transient respiratory difficulty followed by an uneventful recovery.

COMMENT.—Despite the very extensive liver injury in this patient, 16 hours elapsed before sufficient blood had accumulated in the peritoneal cavity to give definite signs of peritoneal irritation and hypovolaemia.

Case 3.—A 67-year-old man complained of pain in the right iliac fossa following a road-traffic accident. On examination he was dyspnoeic, drowsy, and hypotensive (blood-pressure, 80/50 mm. Hg). There was bruising in both flanks and some tenderness on palpation in the right iliac fossa. Rhonchi and coarse crepitations were audible in both lungs. Radiographs confirmed the clinical diagnosis of fractured pelvis and fractured left humerus. The chest film showed increased basal markings bilaterally and emphysema. No rib fractures were visible.

As a major problem appeared to be acute respiratory distress, the patient was admitted to a respiratory unit and treated with oxygen, antibiotics, bronchodilators, and physiotherapy. There was some persistent lower abdominal tenderness which was attributed to the fractured pelvis. On the fifth day after admission he suddenly developed severe generalized abdominal pain, accompanied by distension and diarrhoea. On examination there was generalized abdominal tenderness and rigidity. Laparotomy revealed a perforation of the anterior wall of the caecum. The perforation was exteriorized. His recovery was slow owing to his chronic pulmonary disease. Three months later the caecostomy was closed surgically and the patient is now mobile and well.

Case 4.—A 31-year-old man fell 5½ m. while bricklaying, landing on his hands and left side. On admission he complained of pain in both wrists and clinically there were bilateral Colles's fractures. Examination of his abdomen revealed tenderness in the left hypochondrium but no other abnormality was found. Radiographs confirmed the clinical diagnosis of bilateral Colles's fractures. These were reduced and he was observed for 48 hours prior to discharge from hospital when his abdominal tenderness had subsided. Nine days later he was readmitted complaining of pain in the left hypochondrium and left shoulder tip. On examination he was pale. His pulse was 90 per minute and blood-pressure 100/60 mm. Hg. There were tenderness and guarding in the left upper quadrant. Delayed rupture of the spleen was suspected and a splenic arteriogram performed via coeliac axis catheterization confirmed the clinical diagnosis (*Fig.* 2). Splenectomy was performed and he made an uneventful recovery.

COMMENT.—In this patient symptoms and signs of visceral injury were absent 2 days after rupture of the spleen. The well-known potential dangers of such cases leading to diagnostic delay and increased morbidity and mortality are apparent.

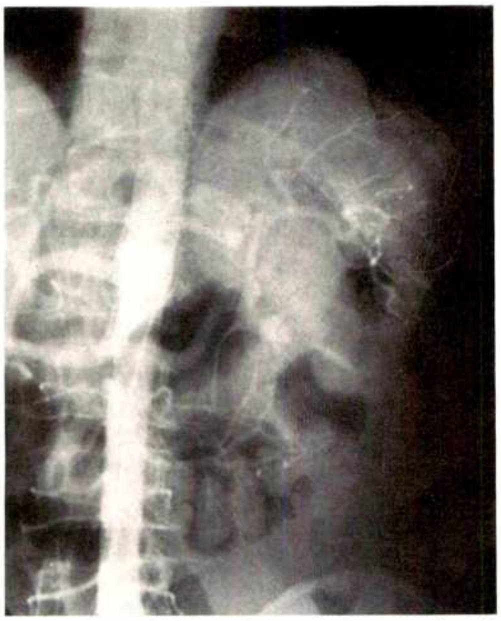

FIG. 2.—*Case* 4. Splenic arteriogram showing separation of the lateral splenic vessels from the diaphragm with loss of a clear-cut splenic margin.

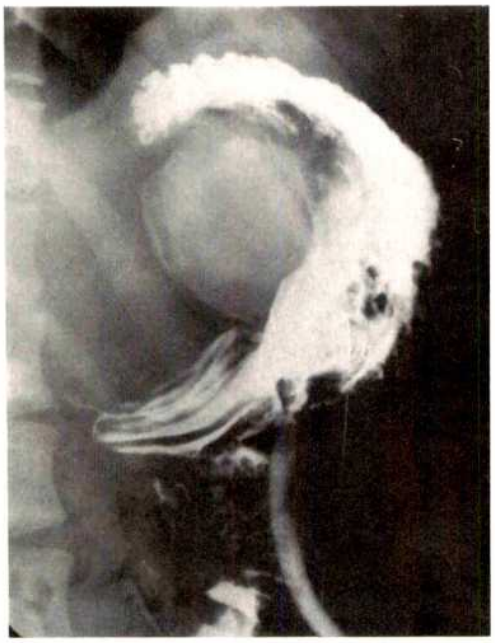

FIG. 4.—*Case* 5. Barium-meal film showing the relationship of the contrast-filled pancreatic pseudocyst to the stomach.

Case 5.—A 21-year-old man was kicked in his left side during a rugby match. On admission he complained of pain in the left upper quadrant and left shoulder tip. His pulse was 72 per minute and blood-pressure 140/80 mm. Hg. There was mild tenderness in the left upper abdomen. Radiographs of the chest and abdomen were within normal limits. He was considered to have a bruised abdominal wall and was admitted for observation. Over the next 12 hours he vomited four times and his tenderness increased. A clinical diagnosis of ruptured spleen was made. At laparotomy there was bruising in the splenic hilum and a retroperitoneal exudate about the tail of the pancreas. The spleen was mobilized to inspect the tail of the pancreas and then removed. A diagnosis of pancreatic contusion producing traumatic pancreatitis was made. A large tube drain was laid beside the tail of the pancreas and the wound was closed. Postoperatively he remained unwell with persistent upper abdominal tenderness, a left pleural effusion, and elevated serum-amylase levels. Large volumes of amylase-rich fluid passed through the drainage tube. A sinogram (*Fig.* 3) and barium-meal film (*Fig.* 4) confirmed the presence of a pseudocyst of the pancreas. Posterior cystogastrostomy was carried out 24 days after the original laparotomy. The patient then made an uninterrupted recovery.

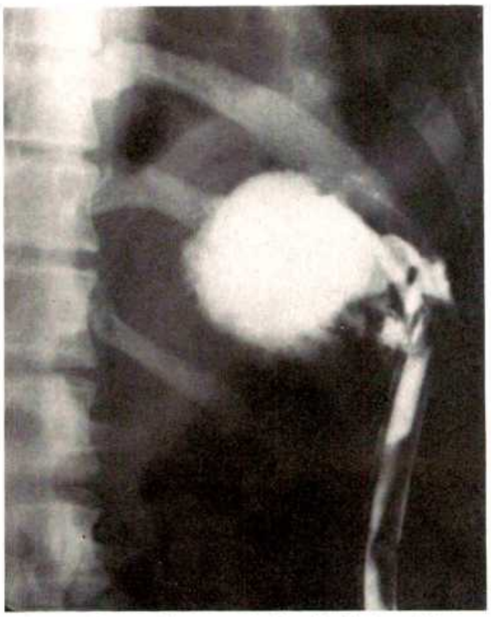

FIG. 3.—*Case* 5. Sinogram via the tube drain outlining a pancreatic pseudocyst.

Case 6.—A 23-year-old man was run over by a tractor. On admission he was shocked with a blood-pressure of 70/50 mm. Hg. There was tenderness in the left loin, haematuria, and absent bowel-sounds. Plain radiographs revealed fractures of the right transverse processes of the upper four lumbar vertebrae. An intravenous pyelogram showed no excretion of dye by the left kidney. His condition improved after resuscitation, but 36 hours later he again became hypotensive and developed generalized abdominal tenderness. At laparotomy the lower pole of the left kidney was found to be avulsed and a nephrectomy was performed. There was also an extensive retroperitoneal haematoma which had ruptured through the posterior peritoneum just medial to the descending colon. There was no apparent damage to the descending colon or any of the other viscera. Twenty days after the operation he was readmitted with faeces discharging through his left loin incision, the fistula presumably resulting from delayed rupture of the descending colon. The fistula was treated conservatively and closed spontaneously 10 weeks after the injury.

COMMENT.—This case, the full details of which have been reported elsewhere (Wightman, 1967), did not have any macroscopic abnormality of the colon at laparotomy, although there was an adjacent mesenteric tear. Presumably the fistula was related to focal ischaemia of the colonic wall.

DISCUSSION

The sex ratio, age incidence, and mortality-rate in this series are similar to those of recent reports (Macbeth, 1966; Divincenti, Rives, Laborde, Fleming, and Cohn, 1968). Massive blood-loss and refractory hypotension were prominent features in 7 of the 8 deaths. The other patient (*Case* 1) did not have major blood-loss but developed persistent hypotension and terminal renal failure.

A particularly high mortality-rate of 45 per cent was found in our series among patients with combined injuries to the abdomen, head, chest, and limbs. McLeod and Brown (1966) also recorded a high mortality-rate of 57 per cent in a small group of patients with major injuries to the abdomen, head, and chest.

Williams and Zollinger (1959) found that in half of their fatal cases of non-penetrating abdominal injury there was significant delay in diagnosis and treatment. In this series we have suggested two patterns of injury associated with delay in diagnosis. Our numbers are too few to permit meaningful statistical analysis of the effects of such diagnostic delay. However, there were 2 deaths in the group where diagnosis was made more than 8 hours after admission, and in both the fatal outcome was related to the diagnostic delay. In *Case* 1 surgery was not performed until 16 hours after admission. The second death in this group occurred in a man who was referred 48 hours after admission. He was anuric following hypotension as a result of severe hepatic injury. Right hepatic lobectomy was performed but he died 14 days postoperatively with unresponsive renal failure and gastro-intestinal haemorrhage. There appears to be little doubt that earlier recognition and diagnosis of intra-abdominal injury will result in an improvement in the mortality-rate.

Sometimes extra-abdominal injury may mask the abdominal visceral damage. In particular, a diminished level of consciousness in association with craniocerebral injury may obscure the signs of peritoneal irritation. Although 29 of our patients had sustained varying degrees of head injury, many of these were relatively minor and only 6 patients were unable to give some details of history on admission. Thus, in our series the presence of concomitant head injury did not appear to contribute significantly to the difficulties of diagnosis. The low incidence of major head injury is surprising. A likely explanation is that the association of major cerebral and abdominal injury is the result of very severe trauma and often leads to a rapidly fatal outcome. Also, major cerebral injury is frequently due to acceleration/deceleration forces rather than crushing trauma and the abdomen may be spared significant injury in these circumstances, where the upper part of the body absorbs the major forces of impact.

Many patients had ingested alcohol before injury, but it is of interest that this only contributed to delay in diagnosis in 1 case.

The main problem for the clinician in the diagnosis of blunt abdominal injury is to make a decision as to laparotomy in the presence of minimal abdominal symptoms or signs.

A detailed accurate history from the patient or a witness may provide valuable clues as to the likely patterns of injury. If this is not available, examination of the body wall may reveal contusions or abrasions overlying the site of visceral injury.

Determinations of haemoglobin, haematocrit, and leucocyte count are of little value in the first 4 hours after injury. However, they do provide a useful baseline for comparison with subsequent values. Serum-amylase levels are raised in patients with traumatic pancreatitis and this estimation should be performed when there has been blunt trauma to the upper abdomen (Northrup and Simmons, 1972).

Blood-pressure on admission was frequently within normal limits, possibly because the majority of road-accident victims are young and rapidly compensate for a hypovolaemic state. However, pallor, sweating, restlessness, and tachycardia were usually present. Patients admitted in a state of hypotension usually had major blood-loss or serious multiple injuries as a result of road-traffic accidents.

Persistent pain and signs of peritoneal irritation were the most reliable clinical features and occurred in the majority of patients in this series. However, physical signs may be minimal or absent. In cases where there is real doubt, repeated clinical examinations are probably of more value than ancillary investigations (Williams and Zollinger, 1959; Mathieson, 1962). Increase in pain or tenderness or development of tachycardia indicates the need for laparotomy. Although anaesthesia and laparotomy in a patient with multiple injuries are not without side-effects, we consider a negative laparotomy to be preferable to the dangers of an unrecognized visceral injury.

Some authors (Morris, 1966; Stephens and Conolly, 1967) have reported that abdominal paracentesis by the method of a four-quadrant tap can give valuable diagnostic aid. Using this technique in a study of 304 patients with blunt abdominal injuries, Perry, DeMeules, and Root (1970) found the incidence of false-negative and false-positive taps to be only 4 per cent. In our experience false-negative taps have occurred and we do not routinely use the technique for this reason. Root, Hauser, McKinley, LaFave, and Mendiola (1965) used peritoneal lavage as an aid to the diagnosis of abdominal visceral injury and found no false negatives in a series of 28 patients. Peritoneal lavage was not performed in our series although it is possible that it might have been of use in some patients.

Plain radiographs of the chest or abdomen are sometimes of value, particularly in the diagnosis of ruptured diaphragm (*Fig.* 5). They may also be useful in demonstrating the presence of free gas in the peritoneal cavity. However, perforation of a hollow viscus can be present without free gas in the peritoneal cavity and in addition the necessary views may be difficult to obtain in an ill patient. A ground-glass appearance on supine films is seen in only a small proportion of cases with free fluid in the peritoneal cavity. Loss of the psoas shadow is indicative of a retroperitoneal fluid collection. Fractures of the lower ribs may be associated with injuries to the upper abdominal viscera. However, ruptures of the liver and spleen frequently occur without rib fractures. In a review of 153 patients with fractures of the left lower ribs, Bollinger and Fowler (1956) found the incidence of splenic injury to be only 3·9 per cent. They also found that only 6 of 24 cases of ruptured spleen had associated left lower-rib fractures. Arteriography has been recommended in the severely injured patient (Freeark, Love, and Baker, 1968) to delineate the site(s) of bleeding. In the acute case this procedure should not delay laparotomy which is therapeutic as well as diagnostic. However, in 2 patients with suspected delayed rupture of the spleen we found splenic arteriography by coeliac axis catheterization (Nusbaum, Baum, Blakemore, and Finkelstein, 1965; Redman, Reuter, and Bookstein, 1969) to provide confirmatory diagnostic evidence of the splenic injury. A third patient not in this series with left upper quadrant pain and tenderness was spared a laparotomy by a normal splenic arteriogram.

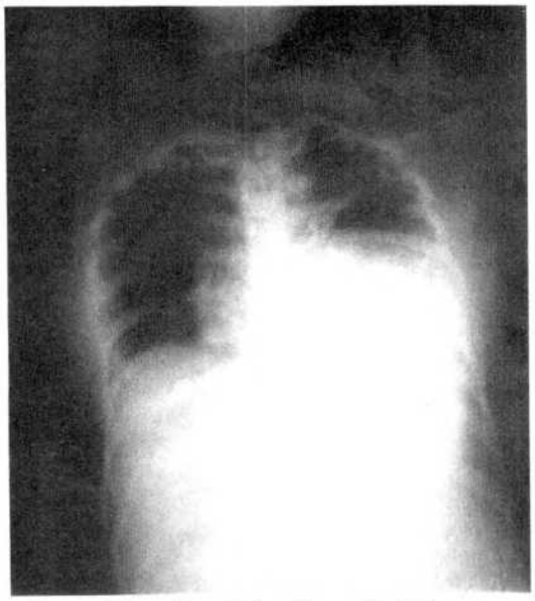

FIG. 5.—Chest radiograph of an 18-year-old girl illustrating rupture of the left leaf of the diaphragm.

Delayed rupture of a subcapsular haematoma is a common complication of splenic injury (Bollinger and Fowler, 1965; Watkins, 1960). These reports suggest that delayed rupture occurs in between 14 and 33 per cent of patients with splenic injury and may occur at any time up to several months following the initial trauma. In our series the longest interval between trauma and delayed rupture was 12 weeks and the shortest was 48 hours. Terry, Self, and Howard (1956) have reported that the latent period is less than 7 days in 50 per cent of patients and less than 2 weeks in 75 per cent. Thus, it has been suggested that patients who have sustained left upper abdominal trauma should be observed in hospital for 2 weeks after the injury. We would recommend splenic arteriography in such patients. Sizer, Wayne, and Frederick (1966) reported an increased mortality in patients with delayed rupture of the spleen. This underlines the importance of early diagnosis. In our small group of patients with delayed rupture of the spleen there was no mortality.

We found an unexpectedly high incidence of delayed rupture of the large bowel. This condition is unusual, although there have been previous reports in the literature (Hicken and Carlquist, 1944; Wightman, 1967). It is possible that some cases may represent misdiagnosis rather than late perforation. Nevertheless, delayed perforation of the colon does occur. It may be caused by the formation and rupture of an intramural haematoma, by crushing of the bowel wall with subsequent necrosis, or by local interruption of the arterial supply or venous drainage resulting in ischaemic necrosis. The initiating force is usually considerable, and rupture of the colon is often associated with fractures of the pelvis and/or vertebral column. The possibility of delayed rupture of the colon should be considered in all cases of crushing injury to the abdomen.

Pancreatic injury is uncommon. Symptoms and signs are often absent initially. The damage is frequently more extensive than the surgeon suspects. A recent comprehensive review (Northrup and Simmons, 1972) has emphasized the problems of early diagnosis, recognition at laparotomy, and treatment of pancreatic injury. Possibly our *Case* 5 might have been saved a second operation by the recognition of the major duct injury and the performance of a distal pancreatectomy at the initial laparotomy.

The high mortality-rate of blunt abdominal injury is largely due to severe multiple associated injuries. Some reduction may be possible through the prompt and energetic treatment of shock, and the improved co-ordination of management and early diagnosis, using repeated and thorough clinical assessment of the abdominal signs coupled with a willingness to resort to laparotomy.

Acknowledgements.—The patients reviewed were all treated at the Sheffield Royal Infirmary, Nottingham General Hospital, and Cardiff Royal Infirmary. One of us (L. H. B.) was associated with the treatment of all the cases but many were admitted under the care of the following surgeons to whom we record our thanks: Mr. C. P. D. Jones, Mr. J. F. Sheehan, Mr. T. Field, Mr. J. Swan, Mr. H. N. Renyard, Mr. J. Wightman, Mr. D. L. Crosby, and Mr. J. L. Craven. Mr. J. Wightman of Chesterfield Royal Infirmary gave permission to quote details of *Case* 6.

COMMON ILIAC VEIN COMPRESSION SYNDROME OCCURRING IN SIBLINGS

BY W. M. JONES, I. TAYLOR, AND C. J. STODDARD
ROYAL INFIRMARY, SHEFFIELD

SUMMARY

Two sisters displaying the common iliac vein compression syndrome are reported. It is suggested that this syndrome may be congenitally determined, which would explain the increased familial incidence of deep-vein thrombosis.

CASE REPORTS

Case 1.—K. B., a 40-year-old woman, was admitted with a 1-month history of cramp-like pains occurring in the left leg associated with moderate ankle swelling. She had also noted occasional episodes of chest pain with dyspnoea which was unrelated to exercise. There was no haemoptysis. She was not taking an oral contraceptive and there was no history of recent inactivity. Her mother had died suddenly in 1961, following an episode of severe chest pain which had been preceded by 1 week's history of left calf pain.

On examination the patient had a markedly swollen left leg, calf tenderness, and a positive Homan's sign. All the peripheral pulses were palpable and the remainder of the examination was unremarkable. An initial diagnosis of deep-vein thrombosis was made and she was anticoagulated with heparin and maintained on Warfarin. A venogram performed through the left femoral vein showed left iliac vein compression (*Fig.* 1). At the completion of this investigation the patient complained of severe left chest pain and dyspnoea. A lung scan was performed, and poor perfusion of the left posterior base, consistent with a pulmonary embolus, was demonstrated.

It was decided to examine the iliac veins to determine the local pathology. At operation a triangular fibrous band was seen to be constricting the left common iliac vein where it was crossed by the right common iliac artery. This band was divided and a segment was excised. A venotomy was performed and an intraluminal band crossing the vessel obliquely was divided. In an attempt to widen the lumen the vein was closed using a vein-patch graft. The immediate postoperative period was uneventful and the patient was discharged home on the thirteenth postoperative day.

Case 2.—A. N. (sister of *Case* 1), aged 56 years, presented with an 8-month history of intermittent pain and swelling in the left leg. During this time she had had three separate episodes of haemoptysis. On two occasions, once in 1949 following an operation and once in 1958 following a period of bed-rest, she had developed a left deep-vein thrombosis.

On examination the left leg was swollen and the calf was tender to palpation. An intra-osseous venogram performed

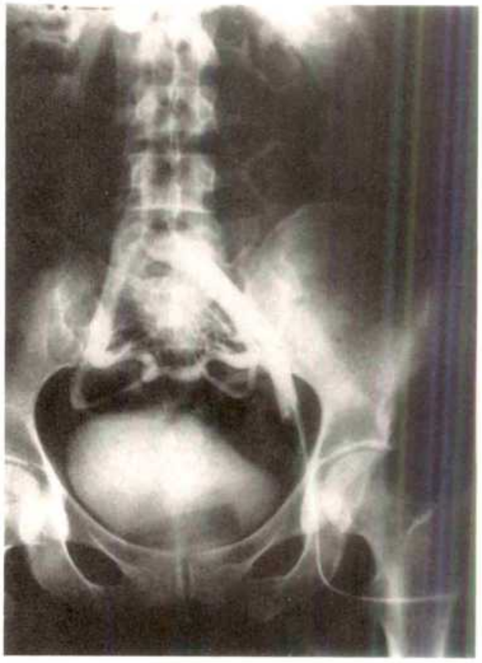

FIG. 1.—*Case* 1. Transfemoral venogram showing the left common iliac vein compression syndrome. Note the large pelvic collateral vein.

through the greater trochanter showed a noticeable obstruction of the left common iliac vein with a large pelvic collateral vessel (*Fig*. 2).

At operation the left common iliac vein was occluded across its junction with the inferior vena cava by a distinct fibrous band. The left common iliac vein appeared to be replaced by a mass of small tributaries as far as the left internal iliac vein. No further surgery was feasible and the abdomen was closed.

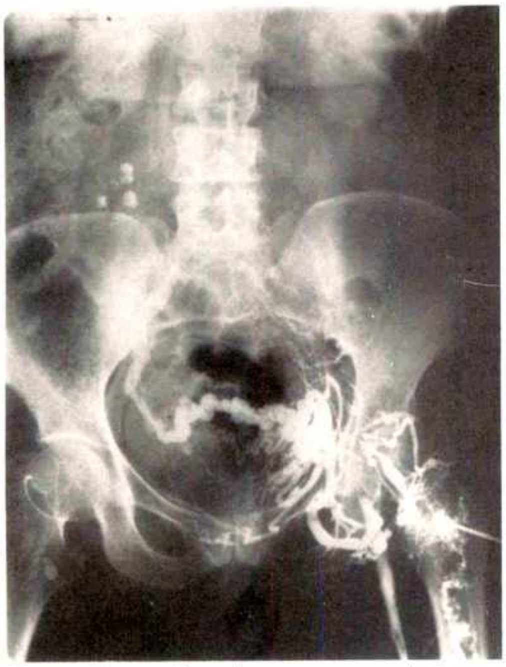

FIG. 2.—*Case* 2. Pertrochanteric venogram showing non-filling of the left common iliac vein. A large pelvic collateral vein is present which communicates with the right common iliac vein.

DISCUSSION

Compression of the left common iliac vein by the right common iliac artery has been recognized for many years (McMurrich, 1906; Erhlich and Krumbhaar, 1943). This flattening and widening of the lumen of the common iliac vein combined with an intraluminal band determine the predominance of left-sided iliofemoral thrombosis (May and Thurner, 1957; Cockett, Lea Thomas, and Negus, 1967; Mavor and Galloway, 1967).

The aetiology of the intraluminal bands is a subject of dispute. McMurrich (1906) suggested that they were a persistence of an embryological condition. Veins develop as multiple venous channels most of which later disappear, but fragments remain and manifest themselves as intraluminal bands. Other workers believe them to be of acquired origin, arising by local pressure resulting in the organization of thrombus and fibrosis. Their constant position, always lying immediately behind the artery, makes an acquired origin a possibility (Negus, Fletcher, Cockett, and Lea Thomas, 1968).

The reported cases, however, suggest that hereditary factors may be responsible for the presence of the bands and so play a part in the development of iliofemoral thrombosis. Histologically they resemble congenital bands since they consist of smooth muscle and fibrous tissue (Negus and others, 1968). Cockett and others (1967) found a family history in 13 out of 57 patients with iliofemoral thrombosis. Erhlich and Krumbhaar (1943), in a study of unselected autopsies, found a 4·7 per cent incidence of bands in 127 children and babies.

It is suggested that the added insult of an intraluminal congenitally determined band in the presence of an extrinsic compression is the factor which precipitates iliofemoral venous thrombosis.

In Memoriam

Sir Clement Price Thomas, K.C.V.O., F.R.C.S., F.R.C.P.

(1893–1973)

SIR CLEMENT PRICE THOMAS, a pioneer of thoracic surgery, called the 'King's Surgeon' because of his successful operation on King George VI in 1951, is remembered and loved by a host of people, not only by medical men and women, nurses, and patients, but by the members of many national institutions who elected him to high office. To have attained presidencies, such as those of the British Medical Association, the Royal Society of Medicine, the Association of Thoracic Surgeons, the Welsh National School of Medicine, the Medical Protection Society, and the Association of Surgeons of Great Britain and Ireland, amongst others, demands a man of great qualities, of exceptional stamina and leadership, and of loyalty to the particular institution that had asked him for devotion and guidance. His international and national achievements in thoracic surgery are widely acknowledged.

Although he died at the age of 79, he never appeared to be an elderly man; he underwent a serious operation many years ago with courage and with cheerfulness, having characteristically chosen as his surgeon a man junior to himself. Then, as more recently following an eye operation, he was determined to return to work in the committee room, and in his beloved garden.

He was always genial, humorous, and welcoming, maintaining to the end of his life a vivacious interest in the establishments with which he had been associated. After his school-days at Caterham, he spent a short period at the University College of South Wales before joining the Army to serve as a private in the R.A.M.C. in the First World War from 1914 to 1918. As an active consultant in thoracic surgery to the Army and Royal Air Force in the Second World War he was deeply involved in the treatment of Forces personnel who had suffered wounds or injuries to the chest.

He entered the Westminster Hospital Medical School with an Entrance Scholarship. He qualified in 1921 and gained the Fellowship of the Royal College of Surgeons in 1923. Elected to the staff of his hospital, he formed a valuable partnership with Tudor Edwards, which flourished also at the Brompton Hospital and at Midhurst. Both were 'general surgeons' but found the time and energy to develop thoracic surgery, ultimately becoming 'specialized'. Price Thomas was a fine teacher of students, both undergraduate and postgraduate; he played an important role in the training of younger men who have become thoracic surgeons and who owe much of their success to the stimulating effect that he provided; his devotion to Wales was exemplified by his many visits to Sully Hospital, which was then in the charge of the Welsh National Memorial Hospital.

In the thirties and forties Clement Price Thomas provided a most valuable link between leading thoracic surgeons, such as Tudor Edwards and J. E. H. Roberts, and the group of younger men who were always the object of his encouraging affection and whom he instructed by word and precept.

In the 1930–60 period when surgery played a large role in the treatment of pulmonary tuberculosis he was accepted throughout the world as a leader both in the field of thoracoplasty and of resection procedures. At the Brompton Hospital, Midhurst, and at Sully he established centres of excellence and encouraged many surgeons, now no longer young, to overcome the difficult days that faced them before the discovery of streptomycin. His success in the surgical treatment of lung cancer and other tumours and of bronchiectasis was remarkable. The advancement of cardiac surgery was not actively possible for him to achieve as he was nearing the time of retirement from clinical surgery. However, in addition to being the first surgeon in Great Britain to operate on coarctation of the aorta, he was wise and generous in providing every opportunity for his younger colleagues to develop this field, particularly at the Westminster Hospital, thus laying the foundations of the fine cardiovascular department which has been so successful.

Sir Clement's large experience of general surgery before becoming 'specialized' made him valuable to the Royal College of Surgeons, where he was happy, gaining respect and affection as a Member of Council and subsequently Vice-President.

The surgical world has been enriched by the late Sir Clement; an optimistic outlook on life, nurtured by a strong religious belief, and a capacity for surgical work of an exhausting nature were sustained by a splendid sense of humour and of loyalty. He was helped by a wonderful wife, who, by her gentleness and affection for his friends and patients, shared his love for mankind at all times.

The Service of Thanksgiving for his life and work, held in Westminster Abbey on 30 May, 1973, was a moving ceremony, attended by a large congregation.

SHORT NOTES OF RARE OR OBSCURE CASES

'SPONTANEOUS' RUPTURE OF THE DIAPHRAGM DURING DELIVERY

BY K. S. DAVE, S. M. BEKASSY, G. H. WOOLER, AND M. I. IONESCU*
DEPARTMENT OF CARDIO-THORACIC SURGERY, THE GENERAL INFIRMARY, LEEDS, AND LEEDS UNIVERSITY

SUMMARY

A case of 'spontaneous' diaphragmatic rupture occurring during a normal delivery and resulting in herniation, incarceration, and gangrene of the stomach and omentum is described. Resection of incarcerated viscera was followed by complete recovery. To the best of our knowledge this is the first report of such a complication of a 'normal' delivery.

TRAUMATIC rupture of the diaphragm may occur as a result of blunt or penetrating injury to the chest or abdomen. The condition is well documented in the medical literature (Bekassy, Dave, Wooler, and Ionescu, 1973).

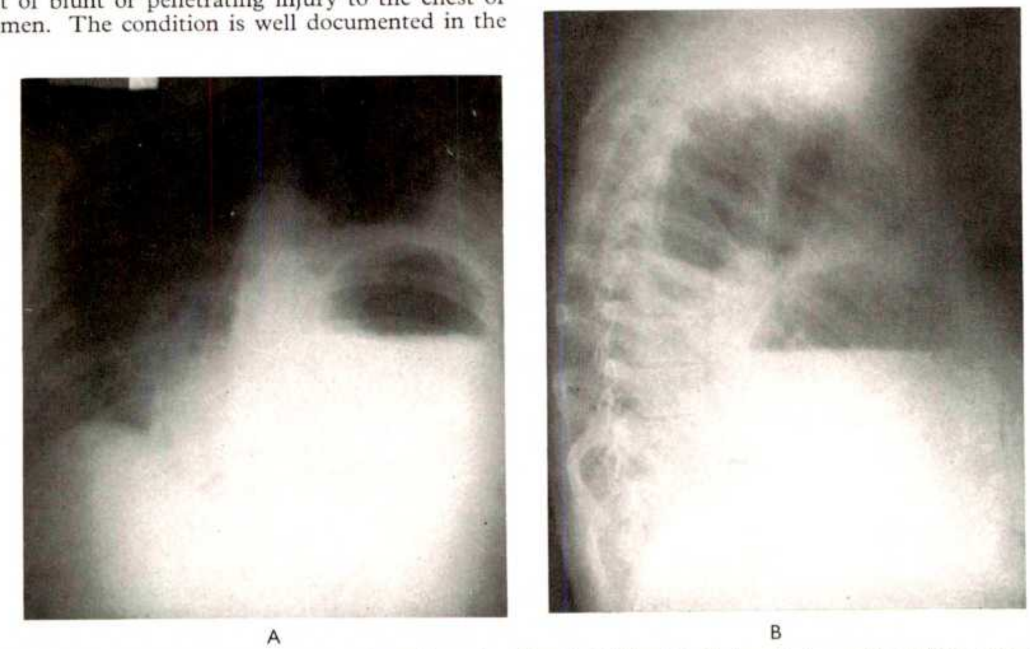

FIG. 1.—Postero-anterior (A) and lateral (B) chest radiographs. Note the fluid level in the herniated stomach and displacement of the oesophagus to the right (nasogastric tube in situ). The lateral view shows two fluid levels, one in the stomach and the other at a lower level which is due to free fluid in the left pleural cavity.

A congenital or traumatic defect in the diaphragm may become symptomatic during pregnancy or in the postpartum period. There have been only 14 such cases reported since 1916 (Granzow, 1927; Fishbeck, 1928; Delee and Gilson, 1941; Diddle and Tidrick, 1941; Salgado, 1944; Thompson and LeBlanc, 1945; Yenen, 1946; Bourgeois and Hood, 1949; Pearson, Pillsbury, and McCallum, 1950; Osborne and Foster, 1953; Grage, MacLean, and Campbell, 1959).

'Spontaneous' rupture of the diaphragm may occur as a result of severe instantaneous effort. Except for 5 cases reported from this department (Bekassy and others, 1973), there has been only 1 other published case of 'spontaneous' rupture of the diaphragm (Salomon, Feller, and Levy, 1969).

The present case is unique as it occurred during an otherwise normal delivery. To our knowledge this is the first such case reported.

CASE REPORT

A 25-year-old primipara was admitted to hospital 38 hours after a 'normal' full-term delivery. She had had a normal antenatal course and denied any previous trauma or symptoms referable to gastro-intestinal, respiratory, or cardiac disease. During the labour she had felt nauseated and immediately thereafter she had developed continuous vomiting, dyspnoea, and constant pain in the left interscapular area which increased on inspiration.

---

* Requests for reprints to M. I. Ionescu.

On examination the patient looked ill and was apyrexial and the conjunctivae were pale. Her heart-rate was 200 per minute and regular. The respiration was shallow and the rate was 40 per minute. Examination of the chest revealed signs of collapse of the left lower lobe. There was generalized tenderness in the abdomen. The uterus was small and firm. Intestinal sounds were present. Her haemoglobin was 13·6 g. per cent and the white-cell count 36,500 per c.mm. with 80 per cent polymorphonuclear leucocytes. The serum sodium was 142 mEq./l. and potassium 4 mEq./l. Analysis of the blood-gases showed P_{CO_2} 24 mm. Hg, P_{O_2} 55 mm. Hg, *p*H 7·45, standard bicarbonate 20·0 mEq./l., and base deficit 5·5 mEq./l. A postero-anterior chest radiograph showed a fluid level in the left hemithorax, and the oesophagus was displaced to the opposite side (*Fig.* 1). A diagnosis of rupture of the diaphragm with herniation of the stomach causing high intestinal obstruction was made and the patient was taken immediately to the operating theatre.

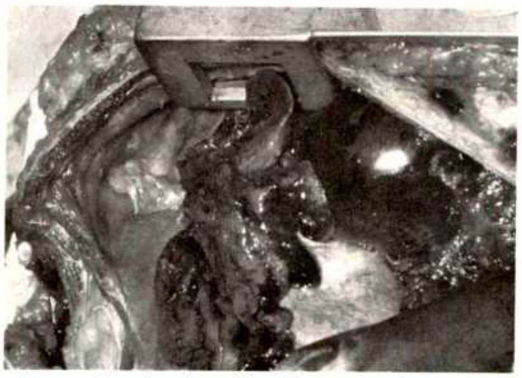

FIG. 2.—Operative view of the left pleural cavity showing the herniated gangrenous stomach and omentum through a fresh tear in the central part of the left diaphragm.

The left chest was opened at the upper border of the seventh rib. About 800 ml. of foetid sanguineous fluid were aspirated from the pleural cavity. The left lower lobe was collapsed. The herniated three-quarters of the stomach together with a large portion of the greater omentum were found to be gangrenous and incarcerated through a rupture of about 3 cm. in diameter situated in the tendinous part of the diaphragm (*Fig.* 2). The chest incision was extended into the abdomen and the diaphragm was incised radially up to the site of rupture, releasing the incarcerated viscera. Three-quarters of the body of the stomach together with the greater omentum were resected. The only healthy parts of the stomach were the cardia with a small segment of the fundus and the pyloric antrum. They were anastomosed with a double layer of continuous sutures. The reconstructed remnant of the stomach was reattached to the transverse mesocolon and the diaphragm was repaired with a double layer of interrupted and continuous silk sutures. Intravenous fluids were given for 7 days postoperatively. The patient made an uneventful recovery and left the hospital on the seventeenth day.

DISCUSSION

'Spontaneous' rupture of the diaphragm is very rare. Five such cases in a group of 19 patients with rupture of the diaphragm seen in this hospital since 1940 have been reported (Bekassy and others, 1973). To the best of our knowledge only 1 other case of 'spontaneous' rupture has been described (Salomon and others, 1969) and none has been reported complicating a 'normal' delivery. Silent diaphragmatic rupture due to previous injuries and congenital defects of the diaphragm have been known to become symptomatic during pregnancy or in the immediate postpartum period. Fourteen such cases have been reported in the literature.

In the present case there was no history of previous injury and the location and appearance of the rupture were such as to exclude a congenital abnormality. Furthermore, a chest radiograph performed 3½ years previously showed no abnormalities of the diaphragm and lungs (*Fig.* 3).

The 'spontaneous' rupture of the diaphragm probably results from a sudden sharp rise in the intra-abdominal pressure, pushing the diaphragm up and tearing its fibres at the least supported part. During the later months of pregnancy the diaphragm is considerably stretched, rendering it more vulnerable to sudden pressure changes. Asynchronous diaphragmatic contractions during labour may create areas of unequal tension, contributing to its rupture.

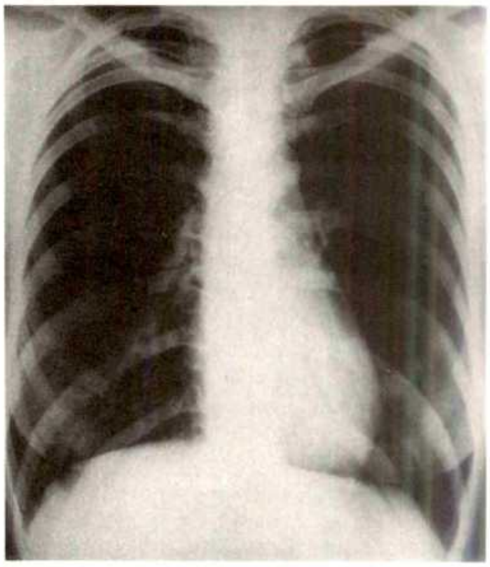

FIG. 3.—Postero-anterior chest radiograph performed 3½ years prior to admission to hospital.

The liver probably protects the right hemidiaphragm by even distribution of the pressure over its entire surface. The peripheral fibres of the diaphragm are supported by the thoracic cage especially when they are more intimately apposed to the chest wall when the diaphragm is suddenly pushed up. The highest part of the left hemidiaphragm is least supported. This possibly accounts for the spontaneous rupture occurring at the centre of the dome. It has been suggested that the site of the rupture in the left leaflet of the diaphragm correlates well with the embryological area of weakness in the posterior and lateral leaflets (Salomon and others, 1969). This, however, does not explain rupture at the centre of the dome in an apparently normal diaphragm.

The diagnosis of 'spontaneous' rupture of the diaphragm is difficult and it should be suspected in patients with uncertain abdominal or respiratory symptoms following instantaneous effort. Radiological examination of the chest and abdomen seems to be the most useful investigation in such cases. Any unusual abnormality on plain radiographs calls for a barium-swallow or barium-enema examination to elucidate the diagnosis further.

Diagnostic pleural aspiration is a hazardous procedure if a diaphragmatic rupture is suspected. Inadvertent injury to the herniated spleen during a diagnostic pleural aspiration, necessitating its subsequent removal, has been reported (Salomon and others, 1969).

In the patient reported here the rupture occurred during a normal delivery and it was followed by chest pain, dyspnoea, and symptoms of high intestinal obstruction. The correct diagnosis was established when chest radiographs showed the herniated stomach and displacement of the oesophagus to the opposite side.

Once the diagnosis is made immediate operation should be performed as there is danger of incarceration and gangrene of the herniated viscera. A mortality of 58·3 per cent has been reported in diaphragmatic hernia complicating pregnancy or the postpartum period (Osborne and Foster, 1953). In doubtful cases an exploratory thoracotomy would seem to be preferable to a laparotomy especially when there is no trauma and no associated abdominal visceral lesions. It is easier to deal with the incarcerated viscera through the thoracic cavity and the incision can be extended into the abdomen if necessary. The repair of the diaphragm is best achieved by a double layer of non-absorbable sutures.

ACUTE TUBERCULOUS ABSCESS OF THE THYROID GLAND

By A. G. JOHNSON, M. E. PHILLIPS, and R. J. S. THOMAS
DEPARTMENTS OF SURGERY AND MEDICINE, CHARING CROSS HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

A case is reported of acute tuberculous abscess of the thyroid gland in a young woman. The rarity of this presentation is discussed in the context of the other forms of tuberculous thyroiditis.

Tuberculosis of the thyroid gland is a rare condition and presentation of the disease as an acute abscess is even more uncommon. The case of a young woman with primary tuberculosis of a congenitally malformed thyroid gland in whom an acute abscess destroyed much of the existing thyroid tissue is reported.

CASE REPORT

A 25-year-old married Scots woman was referred to Charing Cross Hospital on 1 Sept., 1972, with a history of pain and swelling in the right side of the neck for 1 week, associated with a fever, general malaise, and a little loss of weight. She had not been abroad recently and there had been no known contact with tuberculosis. On examination there was a tender swelling, the size of a hen's egg, that did did not move freely on swallowing, in the right anterior triangle of the neck. There were no signs of thyrotoxicosis and the provisional diagnosis was haemorrhage into a thyroid cyst.

A chest radiograph was normal but a radiograph of the neck showed tracheal deviation to the left. The white-cell count was normal but the erythrocyte-sedimentation rate was 50 mm. per hour (Westergren) and electrophoresis of the plasma proteins showed an increase in α_2- and γ-globulins. The Paul-Bunnell test was negative. A thyroid scan showed a 'cold' mass in the right lobe and no accumulation of radioactivity in the left lobe, which raised the suspicion of a generalized thyroid disorder.

On 15 Sept. the lump in the neck was explored by a standard thyroid approach. The isthmus and left lobe were absent except for a small nodule of tissue at the lower pole. The right lobe was adherent to the strap muscles and mostly replaced by an abscess containing creamy pus. The abscess was deroofed and drained and pus continued to discharge for several weeks.

Microscopy of the wall of the abscess showed partial destruction of thyroid follicles by tuberculoid granulomas and the pus gave no growth on routine culture. A Mantoux test at this time was just positive at a 1 in 10,000 dilution. Six weeks later acid- and alcohol-fast bacilli were grown from the pus and treatment with streptomycin and Pasinah was started.

DISCUSSION

Tuberculosis of the thyroid gland has been recognized for more than a century, but although the first diagnosis in a living patient was made in 1893 (Bruns, 1893), the majority of cases have been discovered at post-mortem examinations. It is a very rare condition; of 20,758 partial thyroidectomies performed between 1920 and 1931, tuberculous infection was found in 21 cases, an incidence of 0·1 per cent (Rankin and Graham, 1932). In 1952, out of 2114 partial thyroidectomy specimens, only 2 cases were reported (Levitt, 1952), and only 2 cases were discovered among 74,393 patients who underwent thyroid biopsies at an Italian centre between 1941 and 1970 (Bolis, 1970). Most of the patients have been middle-aged females.

The infection of the thyroid may be primary or in association with tuberculosis elsewhere in the body and there is disagreement about which is the more common condition. There are at least five pathological varieties:—

1. Multiple lesions throughout the gland in association with miliary tuberculosis (Rankin and Graham, 1932).
2. A goitre, often with much caseation (Andretta, 1968).
3. Cold-abscess formation sometimes presenting on the surface (Rankin and Graham, 1932).
4. Chronic fibrosing tuberculosis which is difficult to distinguish from De Quervain's thyroiditis (Andretta, 1968);
5. Acute abscess formation is the rarest form (Goldfarb, Schifrin, and Graig, 1965) and the danger of making the wrong diagnosis of carcinoma has been stressed (Crompton and Cameron, 1969).

Disorders of thyroid function are not common but hyperthyroidism does occur and hypothyroidism has been reported (Rankin and Graham, 1932).

The case presented here is an unusual variety of a rare disease. The patient was a young woman with no known contact with tuberculosis and no evidence of tuberculosis involvement of the respiratory or urinary tracts. The onset was sudden and was associated with fever and a painful swelling in the neck. The operative findings suggested acute infection with an organism such as *Staphylococcus*. The correct diagnosis was suggested by the histopathology and was confirmed bacteriologically, but the Mantoux test was only weakly positive, suggesting recent conversion. The patient was euthyroid, but the destruction of the right lobe by the infection combined with the virtual absence of the other lobe (also a rare condition) make it likely that she will become hypothyroid.

We suggest that, with the persistence of tuberculosis in this country, unusual forms and presentations of the disease should not be forgotten.

Acknowledgements.—We are grateful to Dr. R. Jewkes for the thyroid scan, to Dr. K. C. Chong for the histopathology report, and to Dr. H. Andrews for the bacteriological studies.

REVIEWS AND NOTICES OF BOOKS

Maladie de Dupuytren. Edited by R. TUBIANA and J. T. HUESTON. 10½ × 8¼ in. Pp. 185. Illustrated. 1972. Paris: Expansion Scientifique Française. 85F.

As the results of the treatment of Dupuytren's disease are rather disappointing it is interesting to read the lectures given at a symposium in Paris by outstanding hand surgeons from several countries.

There is a difference of opinion about the necessity of partial or radical removal of the palmar fascia, but the extension on the fingers is the main cause for recurrences. The operation is anatomically difficult particularly because of the closeness of the neurovascular bundle.

The incision in the distal palmar crease is no longer used, longitudinal incisions offering better primary healing.

Grafting of the skin, especially of the fingers, is advocated by many, as necrosis of the skin is not an exception, while the disease sometimes involves the cutaneous tissue.

The extrapalmar symptoms such as contracture of the plantar fascia and Peyroni's disease draw attention to the theory of a congenital disposition.

Non-surgical therapy, using enzymes (trypsine-hyaluronidase) in the case of the hand, and drugs (the cytostatic agent methylhydrazine in Peyroni's disease), offers alternative therapeutic possibilities.

No doubt the surgical treatment should only be undertaken by experienced hand surgeons.

Abraham Colles 1772–1843 Surgeon of Ireland. By MARTIN FALLON, O.B.E. (Mil.), M.A., M.Ch., F.R.C.S.I., F.A.C.S., Perth. 8¼ × 5½ in. Pp. 238 + xii, with 19 illustrations. 1972. London: William Heinemann. £2·25.

EPONYMS are unfashionable, but it is unthinkable that a fracture of the lower end of the radius could ever become dissociated with the name of Abraham Colles.

In this sensitive biography by Martin Fallon, which in fact is the life and times of Abraham Colles, the author portrays vividly a remarkable man, not only as a surgeon with an extraordinary versatility but also as a great leader and teacher who brought honour and distinction to the Dublin School of Medicine in the early nineteenth century. He was twice elected President of the Royal College of Surgeons of Ireland and he also held the Chair of Anatomy, Physiology, and Surgery of the college. Those were the days when Robert Graves, William Stokes, Robert Adams, and John Cheyne made their great contributions to medicine. They were golden years. It is salutary to be reminded in this age of the computer that many of the great advances in medicine can be attributed to the thoughtful interpretation of accurate clinical observation.

This book is much more than a biography. The author has taken great pains to make it so and has succeeded admirably. Around the life of Abraham Colles he has woven a tapestry of events and personalities which provides a background for this astonishing man. It is a most enjoyable book and one that will appeal not only to the orthopaedic surgeon but also to all those interested in the history of medicine.

Die rückenmarksnahen Anästhesien. Edited by H. NOLTE and J. MEYER, Minden. 9 × 6 in. Pp. 105 + vii. Illustrated. 1972. Stuttgart: Georg Thieme Verlag. DM.26.

THIS German work records the proceedings of an international symposium in Minden in 1972. The problems associated with spinal and epidural anaesthesia are discussed in relation to anatomy, physiology, and indications and contra-indications. The approach is somewhat didactic and the text in many places reminds one of a synopsis type of book relieved only in its rather dull presentation by two cartoons. It may be of interest to the anaesthetist with special interest in this field.

Spezielle Chirurgie für die Praxis. Volume II, Part 3. Edited by F. BAUMGARTL, Augsburg, K. KREMER, Dusseldorf, and H. W. SCHREIBER, Hamburg. 10¼ × 7¼ in. Pp. 528 + xii. Illustrated. 1972. Stuttgart. Georg Thieme Verlag. DM. 270.

THIS book is one of a series of beautifully illustrated works on surgery. This volume includes abdominal surgery in children and sections on urology and gynaecology. The text is in German, but the illustrations are self-explanatory and well worth looking at. The text follows the conventional style and deals with indications for surgery and operative technique. It is a practical manual but with good references. The presentation makes for ease in reading, and it will find favour with surgeons in training.

Surgical Treatment of Developmental Jaw Deformities. By EDWARD C. HINDS, B.A., D.D.S., M.D., F.A.C.S., F.A.C.D., Houston, and JOHN N. KENT, B.A., D.D.S., Houston. 10 × 8 in. Pp. 258 + xi. Illustrated. 1972. London: Henry Kimpton. £14·60.

THE indications for skeletal surgery in the treatment of facial deformity are becoming more widely recognized and an extensive literature dealing mainly with techniques already exists. Coincident with this, the demand for this type of surgery is increasing.

The various facets of the subject are brought together by Hinds and Kent in such a way that this book presents itself as a comprehensive review of much value both to the student as well as to the surgeon practising in this difficult and exacting field.

The early chapters spell out the importance of an exact knowledge of the anatomy, both normal and pathological, and the various interests of the surgeon and dentist are very well presented.

Considerable emphasis is put upon the importance of case 'work up' where the problems of skeletal growth and dental function are found to be parameters requiring minute attention. Cephalometry, photography, and dental study models are the techniques required in diagnosis.

The standard surgical procedures which are carried out on the maxilla and the mandible are well described and clearly illustrated. There is sufficient technical information for any surgeon suitably trained and equipped or working with a dental colleague to embark on corrective skeletal procedures although he will find that the more exotic Le Fort osteotomies are not really convincingly described.

The section on splintage is short and anyone unaccustomed to arch bar or cast metal caps would find himself in difficulties. This, however, indicates the importance of teamwork in this field.

The bibliography is comprehensive and offers access to any aspect of the subject, and the book can certainly be recommended for inclusion in the library of anyone interested in facial surgery.

Gastro-intestinal Pathology. By BASIL C. MORSON, V.R.D., M.A., D.M., F.R.C.S., F.R.C.Path., St. Mark's Hospital, London, and I. M. P. DAWSON, M.A., M.D., F.R.C.P., F.R.C.Path., Westminster Medical School, London. 10 × 7 in. Pp. 676 + xii. Illustrated. 1972. Oxford: Blackwell Scientific Publications. £12.

THIS is a book for both the pathologist and the clinician. There has been a need for a concise textbook of the pathology of the alimentary tract, and the authors have done a great service by setting their experience in clinical perspective. Each section of the book is devoted to an organ, and deals first with the normal situation, then common pathology, followed by a consideration of developmental anomalies and disease. It has liberal references, providing an up-to-date starting point for the young clinician or research worker; yet these do not obtrude into the text for the general reader. There are valuable sections on the assessment of biopsies of the alimentary tract, particularly orientated to their clinical significance.

Among the many excellent sections, those on gastritis, the sections on polyps and neoplasms of the colon, as well as the chapter on inflammatory bowel disease reflect the unique contribution of the authors who help to guide us in the significance of pathological findings in these conditions which pose so many problems in management for the clinician. There are carefully selected and beautifully produced illustrations, and the presentation of the book is without criticism.

The task of presenting a textbook is arduous and the tendency is to reproduce the standard model. The authors have rejected this temptation and have given their views of the significance of pathological contribution to the clinical problem. We need more books of this type. This book is essential reading for all gastroenterologists. It should become the standard reference book for pathology of the alimentary tract. All clinicians will find it helpful in the management of patients with alimentary disorders, and the cost should not detract from the need for the clinician to include this as an essential part of his personal library.

Manual of Surgical Therapeutics. Second edition. Edited by ROBERT E. CONDON, M.D., M.S., Iowa, and LLOYD M. NYHUS, M.D., Chicago. 8½ × 5¼ in. Pp. 385 + xii. Illustrated. 1972. Edinburgh: Churchill Livingstone. £3·25.

THIS is an excellent book; being a mere 385 pages long, it starts with the advantage that undergraduate students, junior hospital staff, and others can hope to find time to read it. There are seventeen chapters, some of which contain several sections by different authors. For example, Chapter 1 is on the evaluation and management of trauma and comprises 66 pages divided into eight sections, all by different authors. Other chapters are shorter, for instance, massive upper gastro-intestinal haemorrhage is disposed of in 4½ pages by Professor Nyhus. Despite the multiple authorship there is a remarkable uniformity in style and presentation with succinct sentences, short, numbered paragraphs, and free use of italics and heavy type; no doubt this is the work of the editors. They are to be congratulated for producing a concise book which promotes clear thought and logical, effective action.

Drug therapy in surgical patients is a notable feature of the book; British readers will have to translate the names of some drugs. They will note some absences: 'parenteral fat emulsions are not currently available in U.S.A.', but readers will be rewarded by finding that even in Chicago pills and injections are not everything: 'Cranberry juice, 240 ml., twice daily will keep the urine *p*H acidic.'

Progress in Pediatric Surgery. Volume 4. Edited by P. P. RICKHAM, Zürich, W. CH. HECKER, Munich, and J. PRÉVOT, Nancy. 8¾ × 6 in. Pp. 164. Illustrated. 1972. Munich: Urban & Schwarzenberg. DM.45.

THIS is the fourth volume of a series. It begins with C. E. Koop's 1971 Simpson Smith Lecture on neuroblastoma; an interesting and stimulating account of the author's experience and views on the treatment of this baffling and lethal tumour. In it he emphasizes the poor results of present methods of treatment and the lack of improvement in the past 15 years and the importance of removing, even by crude surgical means, the bulk of the tumour. He cites evidence for the importance of the immune response of the individual host against the tumour and suggests that all that much of conventional treatment by radiotherapy and chemotherapy achieves is an impairment of the host's natural resistance and some prolongation of survival at the expense of increased illness.

Pleuropulmonary circulation in neonates and infants is a different process to that found in adults and is discussed by Geley and Hartl from Linz, Austria. They discuss the aetiology of empyema of the pleura in the neonate, particularly staphylococcal pneumonia, and how they have reduced the mortality by suction drainage of the abscess at a much earlier stage than had been attempted previously, with an associated reduction in the need for thoracotomy from 30 per cent to 5 per cent and the improvement in subsequent expansion of the lungs by positive-pressure inflation with decortication if this form of treatment fails. The long-term results were also much improved by early suction drainage.

J. Prévot and his colleagues from Nancy, France, deal with the treatment of very-long-segment Hirschsprung's disease in which the whole of the colon and distal ileum are aganglionic. They discuss the diagnostic problems of this form of Hirschsprung's disease and their own experience with it in 7 patients and 1 in whom they used the technique of Lester Martin, in which a long length of normally innervated distal ileum is pulled down to the anus and then is anastomosed side to side to the rectum and colon from the splenic flexure of the pelvic floor. This operation was designed in the hope that it would reduce the morbidity and mortality resulting from excision of the whole colon in the neonate.

In his 1971 Forshall Lecture in Genoa Soave described his experience with the use of the transverse colon to bridge the gap between the two ends of the oesophagus in oesophageal atresia when this was too wide for a primary anastomosis. Soave describes his experience with the use of the transverse colon in 27 patients, with a 19 per cent mortality-rate, the colon being anastomosed to the distal end of the upper pouch and the proximal end of the distal pouch.

Moosa, in describing 16 patients with acute pancreatitis seen at the Alder Hey Hospital, Liverpool, between 1954 and 1970, has stated that he believes that now that this condition is known to occur in children many more patients are being recognized than in the earlier part of the period covered by his series. He points out that the clinical features, the complications, and the way in which the disease should be treated in children are similar to those in adults although the aetiological factors are different. So also is the prognosis in children which is usually good. Only 1 of their patients had recurrent pancreatitis and only 1 died.

Finally, Lawson discusses the results of treatment of obstruction due to the resection of too little of the aganglionic segment of Hirschsprung's disease in 28 patients and suggests that forcible dilatation of the anal canal and the distal residual segment should be tried and that if this treatment fails a vertical internal sphincterotomy may be necessary to produce relief.

The papers in this volume are of most interest to paediatric surgeons who are directly concerned with the problems which are described, but in the sense that the number of survivors from the successful treatment of these various anomalies and diseases is steadily increasing, they have some general interest for all surgeons who have to deal with children later in life, either for the late complications of neonatal operations or for other conditions which are not associated with their original anomalies.

Symposium on Aesthetic Surgery of the Face, Eyelid, and Breast. Edited by FRANK W. MASTERS, M.D., Kansas, and JOHN R. LEWIS, jun., M.D., Atlanta. 11 × 8½ in. Pp. 222 + xii. Illustrated. 1972. London: Henry Kimpton. £16.

THIS is the fourth volume in a series on plastic and reconstructive surgery. The previous volumes reported symposia on head and neck cancer, maxillofacial injuries, and the hand. This volume documents a symposium held at Phoenix, Arizona, in November, 1970, organized by the Educational Foundation of the American Society of Plastic and Reconstructive Surgeons. There are thirty-eight contributors.

Of the two introductory chapters, the first, on the psychological aspects of aesthetic surgery, is helpful but too short; however, there is further coverage of this topic in later chapters. The second chapter gives some hints on how to run a cosmetic surgery practice.

Surgery of the ageing face is covered in thirteen chapters. The section commences with a brief review of the anatomy and physiology of ageing skin; following this the indications and contra-indications for rhytidectomy are discussed and a standard operative technique is described. There is a comprehensive list of complications and how to avoid them. Completing this section there are two detailed chapters on the 'chemical peel'.

The five chapters on blepharoplasty include a clear description of a standard technique and an account of several useful modifications.

The aesthetic surgery of the breast is dealt with in the final fourteen chapters. This part starts with a short history and comprehensive bibliography of cosmetic and reconstructive breast surgery and continues with a brief account of the anatomy and a rather lengthy description of the thermographic and radiographic appearances of the breast. There follows a description of the types of breast prosthesis available and the techniques of breast augmentation. The complications of this procedure are mentioned. Breast reconstruction following subcutaneous mastectomy for fibrocystic disease is fully discussed and methods of nipple reconstruction are described. Breast reduction by the methods of nipple transplantation and transposition is detailed and suggestions for how to tailor the surgery to the type of deformity are given. The chapter on the complications of breast reduction is too brief.

The presentation of this book is good but there is wasted space and repetition. Illustrations are plentiful although many of the 'before' and 'after' photographs are not strictly comparable and in one diagram (*Fig.* 24-9) the titles are transposed.

It is a book that should be read by all who are engaged in the aesthetic surgery of the face and breast.

Perfusion Techniques in Biochemistry. A Laboratory Manual. By B. D. Ross. 9½ × 6½ in. Pp. 479 + xv. Illustrated. 1972. London: Oxford University Press. £11·50.

THIS book is for the specialist and might usefully be available in all laboratories carrying out work on organ-perfusion systems. There is an immense amount of detail about technique with many hints to the worker who is new to this field. More valuable, however, is the consideration of the advantages and limitations of techniques which is so necessary to the novitiate, yet often so hard to find.

It is a closely packed volume which should act as a standard reference for this type of work. It is carefully illustrated and has excellent references. The general principles section deals with the characteristics of perfusion media and even includes a part on items such as cannulae. The sections on perfusion of individual organs frequently itemize more than one technique, so that the experimental research worker can choose the one which is most suited to his needs.

It is not a book for general reading. The research worker in this field will find it a most excellent guide and reference book.

Immunization in Tuberculosis. Forgarty International Center Proceedings No. 14. Edited by Dr. CARL C. CHAMBERLAYNE. 9 × 6 in. Pp. 252 + v. Illustrated. 1972. Bethesda: U.S. Department of Health, Education, and Welfare. $3.

THIS book reflects the use of anti-tuberculous vaccines by the United States Public Health Service. It reviews

SEPTRIN TACTICS

first

SEPTRIN ensures coverage against all likely bacterial pathogens.

fast

SEPTRIN rapidly obtains effective blood levels with simple twice daily dosage.

decisive

SEPTRIN crushes bacterial resistance with a bactericidal action which differs essentially from that of the antibiotics

Superior to either ampicillin or tetracycline as judged by reduction in sputum purulence or sputum volume.[1,2]

"...not only are the two primary pathogens, *Strep pneumoniae* and *H influenzae*, sensitive, but so are the secondary invaders such as klebsiella which often replace them after antibiotic treatment."[3]

"...can only be considered excellent on the criteria originally specified, namely the elimination of the infecting micro-organism."[4]

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House,* 159 *Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

Dexon* sutures can save a small fortune!

Dexon* alone can replace 75% of the various sutures used in most procedures.

When a Dexon* suture replaces a suture combination (catgut, silk, nylon) the overall cost is less.

Using Dexon* sutures can eliminate most post-operative care obligatory with other suture materials with obvious cost savings.

You can prove these savings for yourself.
Ask your Theatre Superintendent to get full details from your Dexon* representative, or write to Mr. D.G.Codrai.

Dexon*–the everyday suture.

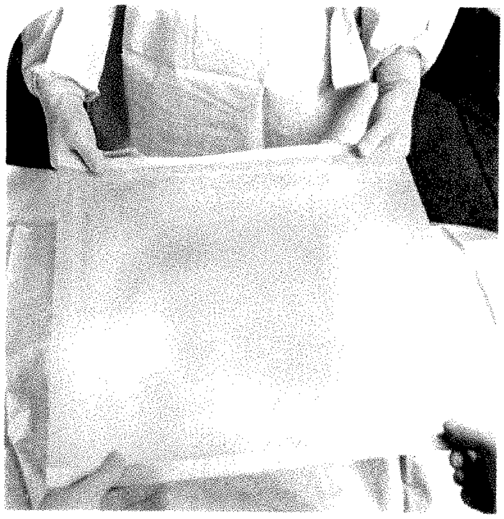
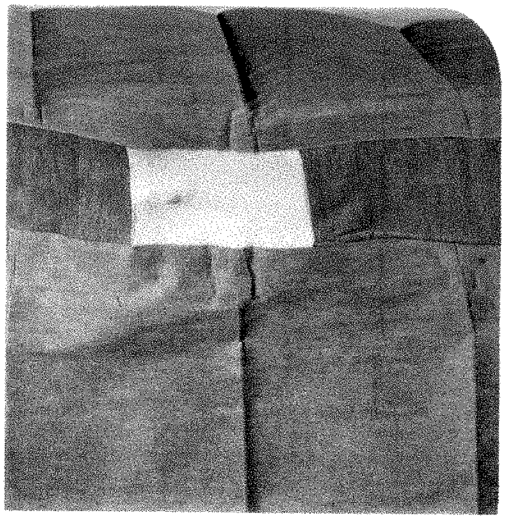
The new BARRIER* Incise Drape



BARRIER* Incise Drapes used with disposable or traditional drapes.



BARRIER* Incise Drapes in use with the BARRIER* Theatre Drape System.

The transparent drape with clear advantages

BARRIER* Incise Drapes are effective – film elasticity and the specially developed High Tack adhesive ensure adhesion at the edge of the incision even during heavy retraction and manipulation.

BARRIER* Incise Drapes are supplied sterile – the pack's heavy board reinforcement protects the sterile drape from puncture damage, and its Fibre Tear seal gives immediate visual proof of seal integrity and improves aseptic handling.

BARRIER* Incise Drapes give greater control – wide control tabs that give positive control of the drape and help prevent 'self-adhesion'.

BARRIER* Incise Drapes emphasise safety – they are glare free and inherently static safe while providing a smooth surface for organs temporarily displaced during a procedure.

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND

1974 MOYNIHAN FELLOWSHIP

The Association of Surgeons of Great Britain and Ireland invite applications for the Moynihan Fellowship up to the value of £1,000.

The object of the Fellowship is to enable the holder (usually of the status of a young consultant or senior registrar) to broaden his surgical education by visiting clinics at home and abroad.

Candidates, who must be resident in the United Kingdom or Eire, but who need not be either Fellows or Associate Fellows of the Association, should state clearly in their application their programme and what they hope to achieve. If they intend holding the Fellowship in conjunction with any similar grant they should give details. They should also give short accounts of their past careers and present appointments. The names of two sponsors should be given. The Council will expect a report of the visit at its conclusion.

Applications (twenty-five copies) must be submitted to the Honorary Secretary, Association of Surgeons of Great Britain and Ireland, at The Royal College of Surgeons, 35/43 Lincoln's Inn Fields, London WC2A 3PN, *by* 31 *October*, 1973. Applicants should be prepared to attend for interview if they are requested to do so.

July, 1973.

SEAT-BELT INJURIES OF THE LEFT COLON

By JOHN SHENNAN

SENIOR REGISTRAR IN GENERAL SURGERY, THE UNITED LIVERPOOL HOSPITALS

SUMMARY

Two patients with a particular type of isolated injury to the left colon produced by the lapstrap of a seat belt are described. The literature on this subject is reviewed and the features and management of these injuries are discussed, with particular reference to the delay in presentation often seen in such patients and to the frequent association with ischaemic damage which makes proximal colostomy advisable where primary repair is undertaken.

Of 4 patients presenting at a major accident centre with closed injuries of the left colon, there were 2 in whom a seat belt appeared to have been responsible for the injury. These 2 patients are reported and the features of seat-belt injuries of the colon are described together with a review of the literature and a discussion of the management of this type of injury.

CASE REPORTS

Case 1.—A 42-year-old lorry driver was admitted to the Accident Centre at Walton Hospital, Liverpool, on 18 March, 1970. He had been driving a car which had been in collision with another car 14 hours earlier. He had been wearing a lapstrap and diagonal belt type of seat belt.

He had sustained a head injury and after regaining consciousness he had noticed some discomfort in his left lower abdomen which he had attributed to the tightening of his seat belt at the time of impact. This sensation had rapidly passed off and he had felt well enough to return home without attending hospital.

Twelve hours later (2 hours prior to admission) the discomfort had returned and had slowly increased in severity, being latterly aggravated by movement and by coughing. He had therefore attended the Accident Centre.

He stated that he had passed both flatus and faeces per rectum since the accident and at the initial examination the only positive finding was of localized moderate tenderness without guarding in the left lower quadrant of his abdomen. Straight radiographs of his abdomen showed no abnormality. It was felt that he had suffered a contusion of his abdominal wall from his seat belt but nevertheless he was detained in hospital under observation.

His condition did not change for 6 hours but then he developed a pyrexia associated with a tachycardia, and further examination disclosed a slight but definite increase in his still-localized abdominal tenderness with, more significantly, the appearance of associated guarding.

With this evidence of intraperitoneal injury laparotomy was undertaken, being commenced 9½ hours after admission and 23½ hours after the injury.

At operation, apart from an area of minor contusion of the lower ileum, the only finding was that the lower descending colon was gangrenous over a length of 7 cm. The colon was intact although perforation was imminent, and the damaged segment was exteriorized by the method of Paul and Mikulicz through a separate incision in the left lower quadrant, and resected at skin level after closure of the main wound.

The postoperative course was uneventful and the colostomy was closed on the twentieth day. The patient was allowed home 13 days later and when seen subsequently he was found to have made an excellent recovery.

Histological examination of the excised colon showed nothing other than ischaemic changes due to trauma.

Case 2.—A 39-year-old engineer was admitted to the Accident Centre on 20 March, 1970. He had been driving a car which had collided with another vehicle 3 hours earlier. He had been wearing a lapstrap and diagonal belt type of seat belt.

Following the accident he had walked away unaided, and although he had noticed some left-sided abdominal discomfort he had returned home immediately. During the next 3 hours the discomfort had steadily increased and in the hour prior to admission he had vomited and had felt pain at the tip of his left shoulder. There was no other injury, but he stated that he had been treated with a steroid preparation for ulcerative colitis in the past, although he had been well and had not required any such treatment for the previous 5 years.

Examination showed that he was moderately shocked with evidence of peritoneal irritation in the left half of his abdomen. A transverse band of bruising was noted on the left side of his abdomen caused by the seat-belt lapstrap.

A diagnosis of intraperitoneal injury and bleeding was made and laparotomy was undertaken 4 hours after the accident.

At operation a haemoperitoneum of 1 litre was aspirated and free faecal material was removed from the left side of the abdominal cavity. The descending colon was almost completely severed in its upper third and multiple minor contusions of the small bowel were also noted. The bleeding had come from torn paracolic vessels. There was no evidence of active ulcerative colitis. The damaged ends of the colon were resected and these were then exteriorized as a double colostomy on the left side of the abdomen.

The postoperative course was normal and the patient was allowed home on the fourteenth day. Histological examination of the excised colon showed no evidence of ulcerative colitis and full investigation during the recovery period was normal. His colostomy was closed 3 months later and he has subsequently made a full recovery.

REVIEW OF THE LITERATURE

In 1952 DuBois, discussing the Viking aeroplane crash of 1950, described, in addition to other major injuries, severe intra-abdominal damage to the solid viscera and the great vessels owing to acute flexion of the victim over the lapstrap safety harness in use.

During the past decade considerable interest has been shown in the United States of America in what has become popularly known as the 'seat-belt syndrome', where a variety of injuries may be produced by the sudden tightening of a seat belt in road accidents, including intra-abdominal damage (Shennan, 1973). This latter type of injury is particularly likely to occur when such belts are worn improperly (Sube, Ziperman, and McIver, 1967).

The first description of this type of abdominal injury is credited to Kulowski and Rost (1956), who reported 1 case of traumatic contusion of the terminal ileum due to a seat-belt lapstrap which was followed by adhesion formation and repeated bouts of intestinal obstruction. Subsequently, a number of similar reports have been published and it is clear from these that the jejunum and ileum with their mesentery are the most frequently damaged structures (Garrett and Braunstein, 1962, 1 case; Sube and others, 1967, 2 cases; Shamblin, 1968, 2 cases; Witte, 1968, 5 cases). Other viscera have been injured by seat belts including the bladder and kidney (Garrett and Braunstein, 1962), the gravid uterus (Rubovits, 1964), common bile-duct (Spitz, 1971), pylorus (Shamblin, 1968), and duodenum (McLeod and Nicholson, 1969).

Seat-belt injuries of the colon are most uncommon and the first case of isolated colon injury by this mechanism was recorded by Tolins (1964). Williams, Lies, and Hale (1966) reported 1 patient with sigmoid mesocolon damage where the colon itself was intact, and Blumenberg (1967) described a patient with delayed ischaemic perforation of the sigmoid colon occurring 72 hours after injury. Witte (1968) reported that 1 of his 5 patients with seat-belt injury of the jejuno-ileum had also sustained multiple lacerations of the sigmoid colon and mesocolon. Towne and Coe (1971) reported 4 patients with seat-belt injuries of the left colon and in 2 of these patients associated major damage to the small bowel was present. Sube and others (1967) described a unique injury to the sigmoid colon where the serosa and muscularis layers are torn away leaving an intact mucosal tube and which they termed the 'sleeve-stripping injury'.

DISCUSSION

Both the patients reported in this paper were the drivers of cars and were wearing seat belts of the lapstrap and diagonal belt type. Both were involved in a head-on collision with another vehicle and their seat belts probably prevented multiple injuries being sustained by them. Each patient was able to walk away from the accident apparently without serious harm but were later seen to have sustained isolated severe damage to the descending colon caused by the seat-belt lapstrap on impact.

The features of interest demonstrated by these 2 patients were:—

1. Initial discomfort at the site of the injury experienced immediately after the accident but attributed by both patients to the seat belt and therefore causing them no early concern. This was followed by a variable latent period, of 12 hours in the patient with ischaemic damage and of 3 hours in the patient with actual colon rupture.
2. A consequent delay in seeking advice even in the patient with faecal soiling.
3. The importance of close observation in doubtful cases with a suggestive history is illustrated by *Case* 1, as without doubt ischaemic perforation of the colon would have ensued had he been merely reassured and allowed to leave hospital.
4. A progressive increase in the clinical picture, the rapidity being clearly related to the type of lesion present. Maximal signs occurred over the site of the colon injury in both patients but the clinical evidence of intraperitoneal injury took considerably longer to develop in the patient with traumatic ischaemia of the colon.
5. Bruising along the line of the seat-belt lapstrap was present in *Case* 2.
6. The isolated nature of the injury which involved the fixed part of the descending colon in both patients. Minor small-bowel contusion was present in both patients but in neither was this severe enough to have necessitated exploration itself.
7. The Paul-Mikulicz operation was particularly satisfactory in the patient with traumatic ischaemia as the basic lesion.
8. The favourable prognosis when the correct diagnosis is made without delay and treatment is instituted immediately.

Most reports of the 'seat-belt syndrome' where injury to either the large or the small bowel has occurred have stressed that delay in presentation is commonly seen (Williams and others, 1966). Sube and others (1967) described a delay in presentation of from 2 to 13 days in 4 of the patients whom they reviewed. Blumenberg's (1967) patient with traumatic ischaemia of the sigmoid colon presented 72 hours after injury. Towne and Coe (1971) reported a delay in the presentation of 3 of their 4 patients. These authors have emphasized the importance of close observation in this group of patients and recommended diagnostic abdominal paracentesis as being helpful (Williams and others, 1966; Sube and others, 1967; Towne and Coe, 1971).

There can be no doubt that delayed rupture of the colon following traumatic ischaemia is a definite entity, and although usually occurring before the fourth day it has been described considerably later (Gogler, 1962). With the more frequent use of car seat belts the possibility of colon damage existing in patients with seat-belt injuries should certainly be kept in mind.

MANAGEMENT

In *Case* 1 resection and anastomosis with proximal colostomy carried no advantage over the Paul-Mikulicz procedure which was used. The risk of further extension of the ischaemic process with breakdown of an anastomosis was an important consideration here and the Paul-Mikulicz operation was the method of choice with a highly satisfactory outcome.

Case 2 had significant faecal soiling at operation and there was the additional possibility of a severe exacerbation of his ulcerative colitis occurring and the risk of anastomosing colon involved by this disease to consider. Exteriorization was therefore the procedure of choice in this patient.

Witte (1968) performed simple primary repair in his patient with lacerations of the sigmoid colon, with a satisfactory outcome. Blumenberg (1967) performed a Paul-Mikulicz operation on his patient with delayed ischaemic perforation of the sigmoid colon and survival ensued. The experience of Towne and Coe (1971) is instructive. They described 4 patients with seat-belt injuries of the left colon of whom 2 had seromuscular tears of the sigmoid colon without penetration of the lumen. One of these patients had no other injury and simple oversewing was successful. The other patient also had severe damage to the ileum and its mesentery but the apparently minor superficial colon injury was treated by simple oversewing; postoperatively the colon repair broke down and the patient died. The 2 other patients in this series had perforating injuries of the left colon and both were treated by exteriorization; one of these patients, who had multiple associated injuries, died of renal failure on the tenth day, while the other patient recovered. These authors concluded that patients with seat-belt injuries of the left colon should have a proximal colostomy when primary repair is undertaken, even for seemingly trivial seromuscular tears.

It would seem that injuries of the left colon produced by seat belts might appear minor in extent and amenable to simple repair. However, there is a high incidence of associated ischaemic damage which may not be immediately obvious and which might be responsible for delayed breakdown of such a repair in the postoperative period. In view of this, proximal colostomy in addition to repair might be the treatment of choice even in the most minor injuries. For the same reasons the author would agree with Towne and Coe (1971) in suggesting that all transecting injuries produced by this mechanism should probably be exteriorized as a double colostomy and would add that for traumatic ischaemia of the left colon the Paul-Mikulicz procedure is particularly suitable.

CLASSIFICATION AND MECHANISM OF SEAT-BELT INJURIES

Sube and others (1967) classified seat-belt injuries of the abdomen according to the structure damaged and suggested three groups of injury which might occur alone or in combination:—

1. Superficial injury to the abdominal wall comprising cutaneous abrasions and bruising as well as muscular damage.
2. Intra-abdominal vascular injuries comprising tears of the mesentery or mesocolon with bleeding and including adjacent bowel ischaemia and possible delayed perforation.
3. Hollow visceral injury, usually the small bowel but less commonly the colon, stomach, bladder, and gravid uterus being damaged.

Towne and Coe (1971) described two types of bowel injury due to seat belts:—

1. Discrete perforations, usually at the anti-mesenteric border and often multiple, occurring at any level of the gastro-intestinal tract.
2. Complete or almost complete transections occurring particularly at or near points of fixation in the small and large bowels and due largely to shearing forces impinging against the vertebral column.

Discussing the way in which seat belts cause injury to the abdominal contents, Sube and others (1967) pointed out that a loosely worn belt was particularly concerned, and Towne and Coe (1971) emphasized that if the belt was worn at all loosely there was a tendency to slide forwards and under the lapstrap at impact, so-called 'submarining', so that instead of the force of impact being taken on the bony pelvic girdle it is exerted on the soft tissues of the abdomen and flank. Indeed such a shearing force applied to the flank may well be the major factor in transecting and ischaemic injuries of the fixed parts of the left colon.

It is certainly not the purpose of this paper to suggest that seat belts, properly worn, are dangerous. There is no doubt that the incidence of serious injury and death in road accidents has been dramatically reduced by their use. Garrett and Braunstein (1962) in America cited a reduction of 35 per cent, Lister and Milsom in Britain (1963) quoted a reduction of 51 per cent, and Shamblin (1968) stated that 5000 lives per year are saved by seat belts being employed.

Acknowledgements.—I am most grateful to Mr. G. J. Santer and Mr. D. Sykes for allowing me to publish these reports of their patients, and I would also like to express my thanks to Mrs. A. O. Mansfield and to Mr. David Annis for their interest and invaluable assistance.

REVERSED AUTOGENOUS SAPHENOUS VEIN BY-PASS FROM THE COMMON TO THE DEEP FEMORAL (PROFUNDA FEMORIS) ARTERY

BY R. BERGUER AND L. T. COTTON
DEPARTMENT OF BIOMEDICAL ENGINEERING, KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

Extended deep femoral angioplasty is an invaluable method of saving a limb especially where a femoropopliteal vein by-pass is not possible because of a poor run-off. Atherosclerosis in the deep femoral artery often extends for more than 10 cm. In such cases we have preferred to perform a short vein by-pass than an extensive endarterectomy and patch graft. Our experience is described of 6 such cases, in 5 of whom amputation was avoided.

EXPERIENCE with revascularization of the ischaemic leg by extended deep femoral (profunda femoris) angioplasty has proved that such an operation is a simple and effective method of increasing the blood-supply and an indispensable technique where femoropopliteal by-pass grafting is either undesirable or impossible (Martin, Frawley, Barabas, and Rosengarten, 1972, Berguer, Cotton, and Sabri, 1973). In our continuing experience with reconstruction of the deep femoral artery we have met 6 instances in which our standard technique—endarterectomy and patching—did not seem an adequate solution, and therefore a vein by-pass was used instead. The discussion of this technique is the concern of the present report.

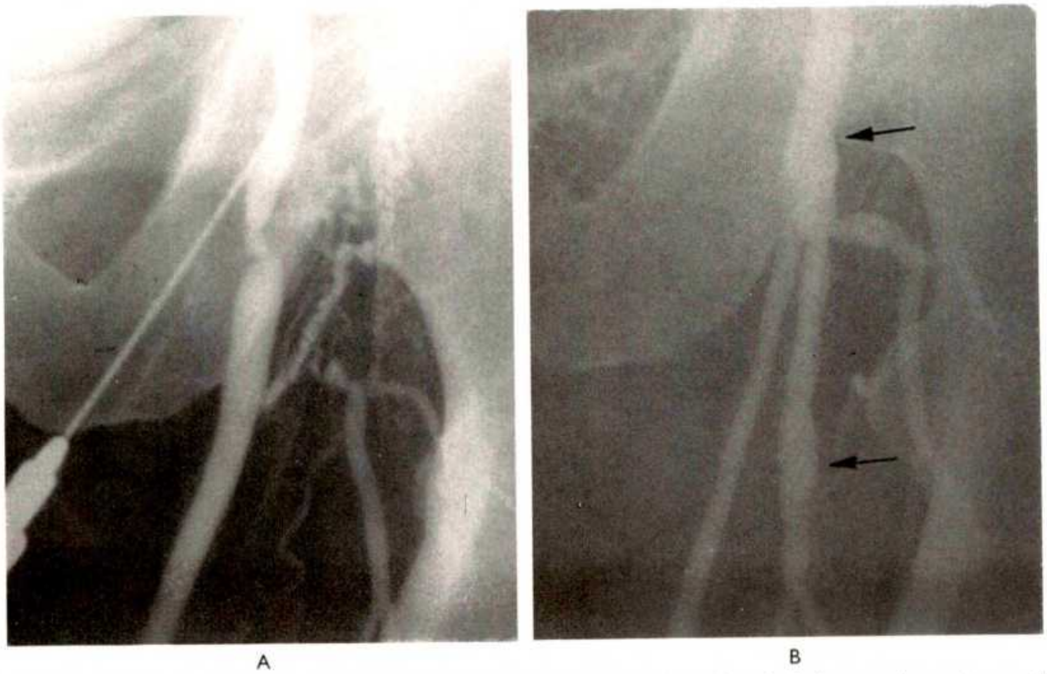

FIG. 1.—*Case* 1. A, Preoperative arteriogram showing complete occlusion of the deep femoral trunk. B, Postoperative arteriogram. The by-pass is between the arrows.

INDICATIONS

Four patients presented with rest pain, 1 of whom had ischaemic ulceration as well. Because of severe distal disease below the level of the knee they were not candidates for a femoropopliteal by-pass operation and were therefore facing amputation. The fifth patient had severe intermittent claudication (20 yards). The sixth patient underwent an aortofemoral endarterectomy to the level of the deep femoral artery on both sides. In spite of a good pulsation being produced in both the common and proximal deep femoral arteries, electromagnetic flow readings in the right common femoral artery were very low (45 ml. per minute). This figure represented the total outflow to the leg through the deep femoral artery since the superficial femoral artery was occluded. In this patient the right deep femoral artery was further exposed and a vein by-pass to the distal part of the deep femoral artery was carried out.

Frontal and oblique angiograms in these patients were of little help in determining the actual extent of the disease beyond the origin of the deep femoral artery. In 1 case the trunk was occluded (*Fig.* 1). In arteries of small calibre (3–5 mm. diameter) atherosclerotic plaques often cause drastic reductions in the cross-section area although angiograms fail to reveal their presence.

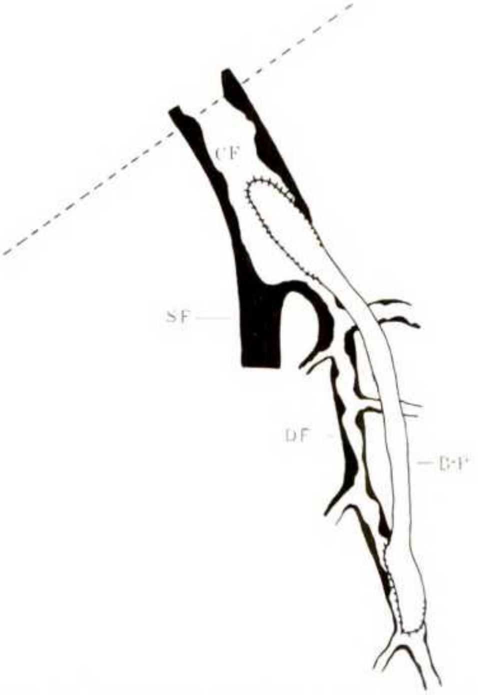

FIG. 2.—Schematic drawing of the common to deep femoral artery by-pass operation.

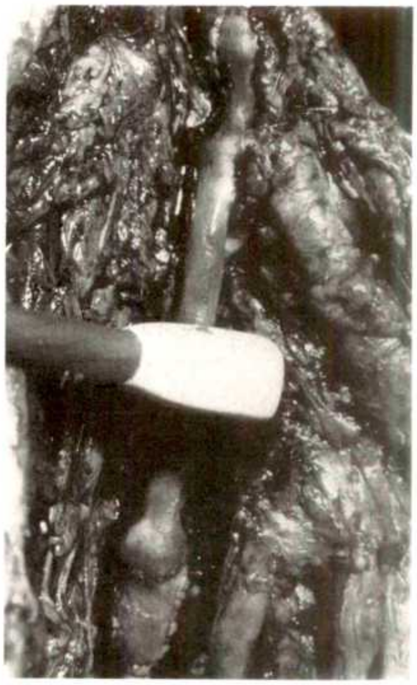

FIG. 3.—A completed by-pass with the flow transducer in place.

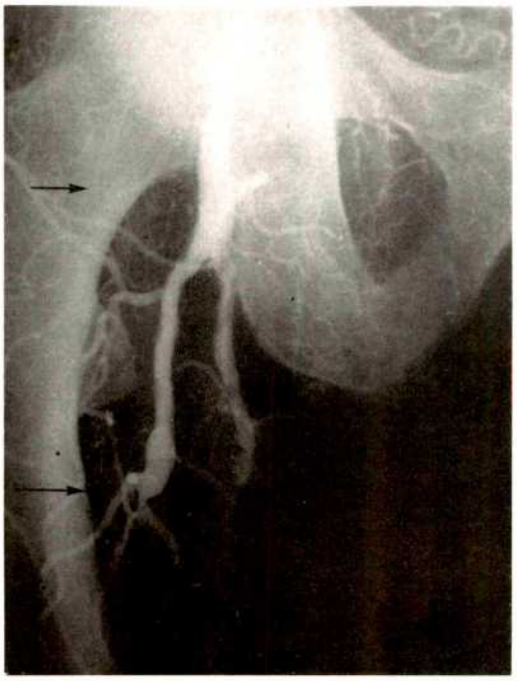

FIG. 4.—*Case* 2. Postoperative anteroposterior arteriogram showing the deep femoral by-pass (between the arrow levels).

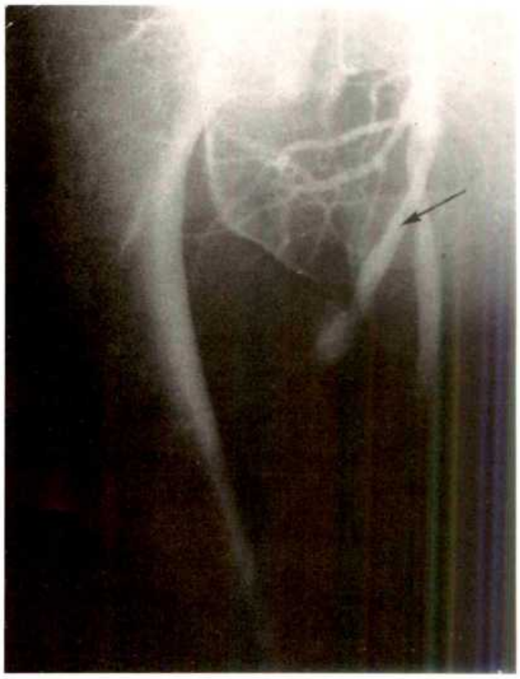

FIG. 5.—*Case* 4. Postoperative oblique arteriogram showing the functioning by-pass. The deep femoral trunk has occluded.

TECHNIQUE

Five operations were performed under general anaesthesia; one was done under local anaesthesia because the patient represented a high cardiopulmonary risk (*Case* 3). The approach was the same as that used for an extended deep femoral angioplasty (Berguer and others, 1973). The dissection of the deep femoral artery was pursued until a soft, clear segment was met. This meant dissecting as much as 14 cm. of the deep femoral artery in some cases. The branches of the deep femoral vein that cross the trunk of the parent artery were divided between ligatures. A segment of the proximal part of the saphenous vein was excised from its bed at the edge of the operative wound and reversed. The proximal arteriotomy was made over the common femoral artery, sometimes including the origin of the deep femoral artery (*Fig.* 2). The proximal end of the reversed vein was so fashioned as to provide a patch effect at the proximal anastomosis. The distal arteriotomy was made at the selected place in the non-involved distal deep femoral artery; no endarterectomy was done at this level. The graft was sutured end to side at both ends with 000000 Dacron material. Electro-magnetic volume-flow readings and qualitative flow-wave analysis were done before and after the procedure (*Fig.* 3).

Table I.—SUMMARY OF THE DETAILS OF THE PRESENT SERIES*

CASE	AGE (yr)	CONCOMITANT DISEASE	INDICATIONS	POSTOPERATIVE FLOW VOLUME (ml. per min)		RESULT
				By-pass Alone	By-pass + Deep Femoral Artery	
1. J. M.	53	Thrombo-angiitis obliterans, coronary artery disease†	Rest pain	—	170	Good
2. M. M.	72	Diabetes, coronary artery disease	Rest pain	70	—	Amputation‡
3. J. O.	62	Diabetes, coronary artery disease	Rest pain	28	128	Good
4. M. R.	71	Coronary artery disease	Rest pain and ulceration	72	—	Good
5 H. B.	67	Coronary artery disease	Intermittent claudication	96	128	Good
6. J. K.	59	—	Inadequate deep femoral outflow§	96	—	Good

* Preoperative flow data are not included because intravascular pressure variations and changing arterial wall thickness at the measuring point introduce substantial errors which invalidate comparative conclusions. Flow measurements have been made in the by-pass itself or in the common femoral artery, the superficial femoral artery being occluded Technical problems related to arterial wall thickness or inclusion of the anastomotic line in the flow transducer prevented simultaneous flow measurement in both sites in 4 patients.

† Previous history included bilateral cervical and bilateral lumbar sympathectomies, below-knee amputation (opposite leg) with poor healing and breakdown of the stump, and myocardial infarction.

‡ Patency of the graft, which was demonstrated by arteriogram, failed to relieve distal foot pain.

§ This patient underwent aorto-femoral endarterectomy on both sides for intermittent claudication. The indication for reconstruction of the right deep femoral was a post-endarterectomy volume-flow reading of 45 ml. per minute in the right common femoral artery (superficial femoral artery was occluded). Claudication was relieved postoperatively

RESULTS

The follow-up period extends from 1 to 10 months (mean, 4·1 months). The postoperative patency rate has been 100 per cent. The results are shown in *Table I*. We have not had any postoperative complications related to this technique except that *Case* 2 continued to have rest pain, necessitating a below-knee amputation. This man had diabetes and extensive infrapopliteal disease. The angiograms taken before the amputation (*Fig.* 4) show a patent graft; this might have helped in obtaining rapid healing of the stump.

The proximal end-to-side anastomosis preserves the flow through the proximal segments of the deep femoral to the femoral circumflex branches. Only in 1 case (*Case* 4) did the postoperative angiograms show the proximal part of the deep femoral trunk to have occluded (*Fig.* 5). In cases of occlusion of the origin of the deep femoral artery, flow to the circumflex branches may be re-established in a retrograde fashion via the by-pass.

DISCUSSION

In these 6 cases with extensive atheromatous disease along the deep femoral artery we have been reluctant to perform extensive endarterectomies and patching because: (*a*) the endarterectomy has to be done by the open method since the multiple branch orifices need to be cleared with precision, and (*b*) the resulting channel is haemodynamically unsound with its unavoidable patch dilatation and two long suture lines. Furthermore, it is difficult to find a suitable end-point to the endarterectomy if there is widespread atherosclerosis of the deep femoral artery. The expedient of placing tacking sutures at the end-point of an endarterectomy is not devoid of difficulty and risk in a vessel with a 2·5–3·5-mm. internal diameter such as the distal deep femoral artery.

The experience accumulated in surgical reconstruction of the superficial femoral artery has shown that the patency results of long endarterectomy with a patch are inferior to those obtained with autogenous vein by-pass (Darling, 1969). It is generally agreed that an autogenous vein by-pass provides a better arterial blood conduit in a medium-sized vessel than an endarterectomized wall covered with a patch attached by two long suture lines.

Reviewing the material published on surgery of the deep femoral artery, we have found only one report of a case, in a young man, of common to deep femoral artery by-pass (Billig, Callow, and Deterling, 1970), while two other papers mention this technique (Sproul, 1968; Youmans, Hopkins, and Derrick, 1969). Our short experience with this procedure inclines us to think that it deserves more attention. The question posed by this paper is whether a vein by-pass is preferable to endarterectomy when faced with extensive disease in the deep femoral artery. We have preferred the by-pass technique in such advanced cases in the light of previous experience with reconstruction of the superficial femoral artery and because of the technical difficulties and dangers inherent to endarterectomy in these circumstances.

CLOSED INJURY OF THE EXTERNAL ILIAC AND COMMON FEMORAL ARTERIES*

BY M. P. BRADY, T. V. KEAVENY, AND P. A. FITZGERALD

DEPARTMENTS OF SURGERY, UNIVERSITY COLLEGES, CORK AND DUBLIN

SUMMARY

Two cases of traumatic closed injury of the iliofemoral arterial segment incurred while working at sea are reported. These cases share many similarities which are discussed together with general observations on the management of such injuries. The need for repair utilizing the by-pass principle rather than direct procedures on the involved segment is stressed.

WOUNDS and injuries of arteries have been grouped into two categories (Kinmonth, Rob, and Simeone, 1962). These categories are summarized in *Table I*.

The type of lesion has a bearing on the prognosis. In acute lesions of major vessels there is a high probability that gangrene will occur. Chronic lesions lead to malfunction of the limb but gangrene is a more remote possibility.

Table I.—CLASSIFICATION OF WOUNDS OF ARTERIES

A. Acute arterial lesions
  1. Spasm: segmental or diffuse
  2. Contusion, involving one or more arterial coats
  3. Perforation and penetration
  4. Laceration, with partial or complete transection
  5. Thrombosis, occurring alone or, more usually, in association with the above

B. Chronic arterial lesions
  1. Traumatic aneurysm: true or false
  2. Arteriovenous fistula

The anatomical site of the injury must be taken into account. The iliofemoral arterial segment has a generous collateral potential, making closed injuries in this region less dramatic in their effects on the circulation of the distal ipsilateral limb.

The effect of such lesions is illustrated in the following case reports.

CASE REPORTS

Case 1.—M. M., a 27-year-old ship's purser, was admitted to hospital in November, 1971. Eight weeks previously he had been caught in a closing automatic door on his ship. His left lower chest, left hip, and thigh had been crushed. He had been admitted to hospital for immediate treatment where he had been kept for 2 weeks and then had been referred for vascular consultation because of suspected damage to his lower-limb vessels.

On admission he complained of weakness and dragging of the left lower limb but no pain. On examination he had diffuse swelling of the left groin and, to a lesser extent, of the thigh. There was no obvious wasting of the lower-limb muscles. The left femoral and popliteal pulses were absent but he had a palpable posterior tibial pulse and dorsal pulse in his left foot. The right-limb pulses were normal.

A clinical diagnosis of traumatic thrombosis of the left external iliac artery was made and the patient underwent translumbar aortography. This revealed complete occlusion of the left external iliac artery from its origin down to and including the common femoral artery. The superficial and deep femoral vessels were patent and filled through diffuse anastomotic channels from an enlarged internal iliac artery (*Fig.* 1).

At operation the iliac vessels were exposed through an oblique supra-inguinal approach. A vertical incision was made over the common femoral artery. The occluded vessels were found to be thrombosed and the walls were a dusky blue in colour. The proximal long saphenous vein on the left side was removed, prepared, and reversed. It was used as a by-pass graft from the common iliac to the distal common femoral artery which was patent opposite the profunda orifice.

The patient's postoperative progress was satisfactory, with restoration of the popliteal pulse and increase in pedal pulsation. A repeat aortogram was done a month later and showed the functioning graft. The internal iliac artery was diminished in size while the previously noted rich collateral circulation had greatly decreased (*Fig.* 2).

The patient's subsequent course has been satisfactory with no symptoms or signs of vascular deficit.

Case 2.—F. M., a 27-year-old captain of a fishing boat, was admitted in December, 1971, following an accident sustained the previous day at sea. He had been crushed between the cable of a fishing net and the side of the boat. Following this injury he had lost the use of his right lower limb and felt diminished sensation over the lower two-thirds of the leg and foot.

---

* Based on a communication to the Vascular Society of Great Britain and Ireland in November, 1972.

On examination he was not shocked. The blood-pressure was 110/70 and the pulse-rate was 60 per minute and regular. A haematoma measuring 3 × 2 cm. was present over the anterior superior iliac spine and another haematoma measuring 6 × 3 cm. lay over the right inguinal canal. All the lower-limb pulses were absent on the right side including the femoral pulse. The right foot was slightly colder than the left but he had full movements of the ankle-joint and toes. There was impaired sensation to light touch and pin-prick from the middle third of the leg to the toes.

The patient was operated upon on the day of admission, preoperative angiography being omitted. The iliofemoral area was exposed by two incisions: (*a*) an oblique extraperitoneal approach to the iliac vessels, and (b) a hockey-stick-shaped incision over the right common femoral artery. The soft tissues of the right iliac fossa were stained by blood but no active haemorrhage was present. The artery from the common iliac bifurcation to the common femoral bifurcation was pulseless and stained a dark-red colour. The common femoral artery was opened opposite the profunda orifice. A Fogarty catheter passed easily to the ankle without evidence of distal thrombus. On passing the catheter proximally it met with an obstruction at the level of the inguinal ligament. A crimped 8-mm. Dacron tube was used as a by-pass. This was placed from the lower end of the common iliac artery to the femoral arteriotomy. Local heparin was used distally in the limb. On removal of the arterial clamps the graft functioned normally and pulses reappeared in the popliteal fossa and

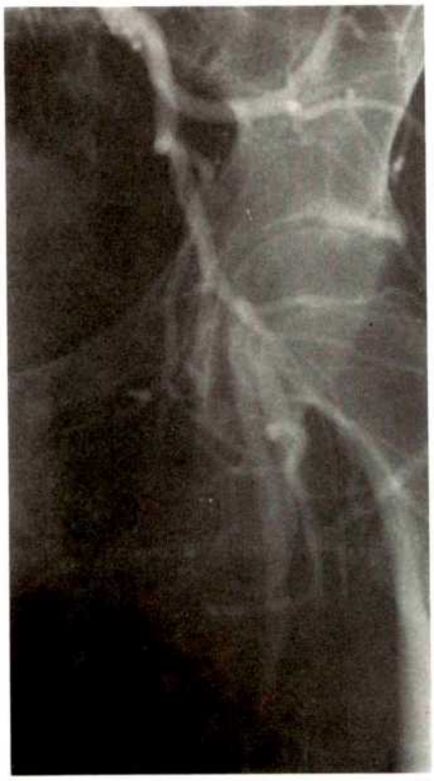

FIG. 1.—*Case* 1. Detail of the preoperative aortogram showing occluded external iliac and proximal common femoral arteries. Note the extensive collaterals from the enlarged internal iliac artery.

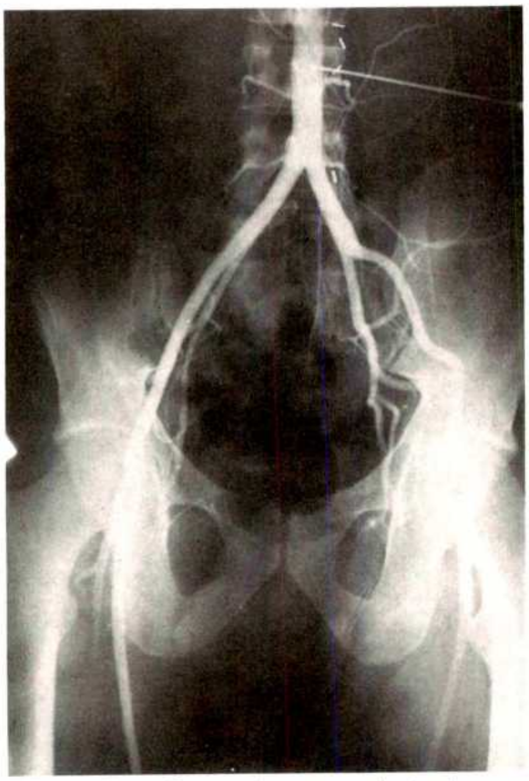

FIG. 2.—*Case* 1. Postoperative aortogram showing the patent iliofemoral vein-graft, the reduced size of the internal iliac arteries, and the difference in the groin collaterals from *Fig.* 1.

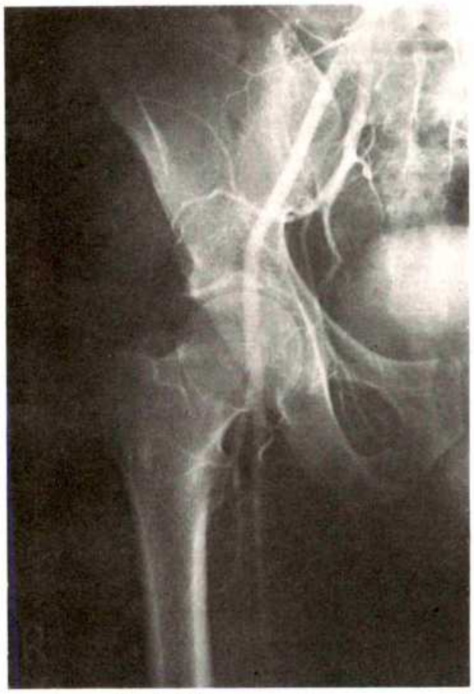

FIG. 3.—*Case* 2. Detail of the postoperative aortogram showing a patent prosthetic iliofemoral graft.

foot. The patient's postoperative course was uneventful. The skin sutures were removed on the eighth postoperative day. An angiogram performed on the thirteenth postoperative day showed a patent functioning by-pass graft (*Fig.* 3). His subsequent progress has been satisfactory and he has returned to sea.

DISCUSSION

Stiles (1965) reviewed the experience of injuries to the iliofemoral arterial segment at St. Mary's Hospital, London. The 4 cases described by this author occurred during the 1950's and were treated by thrombectomy, homograft, Orlon graft, and proximal ligation of a false aneurysm respectively. All had viable limbs on completion of therapy but all were found to have claudication at the 1-year follow-up visit. This author stresses the delay in referral of these cases, together with the need for arteriography following reconstruction to assess the adequacy of repair.

Eastcott (1969), in discussing the aetiology of iliac injuries, mentions the dangers of abdominal retractors and the over-tight application of a tape sling in addition to severe blunt violence to the groin.

The 2 cases described in this paper had severe contusion thrombosis of the iliofemoral artery. Their limbs were viable, although clinically ischaemic, when first seen. On exposure the involved vessels were dark blue in colour, swollen, and non-pulsatile. The lumen was totally occluded. This is the appearance of arterial contusion with intramural haemorrhage and intraluminal thrombosis. These vessels are unsuitable for thrombectomy or any form of direct repair. Use of the by-pass principle is mandatory and the selection of reversed vein or prosthetic tube-graft will depend on the individual surgeon's choice.

Early reconstruction in accordance with these principles resulted in normal limbs in these young men at 1 year following injury.

Acknowledgement.—We are grateful to Mr. K. Kearney, F.R.C.S., who referred *Case* 2.

THE PREVENTION OF POSTOPERATIVE DEEP VENOUS THROMBOSIS WITH DEXTRAN 70

BY A. E. CARTER AND R. EBAN
KING EDWARD MEMORIAL HOSPITAL, LONDON

SUMMARY

One hundred and six patients undergoing major surgery were given dextran 70—500 ml. during operation, 500 ml. on the following day, and then 500 ml. on alternate days until discharge. Of these patients, 1 developed a deep venous thrombosis after the operation (0·94 per cent). One hundred and one patients acted as control subjects and, of these, 10 developed deep venous thrombosis (9·9 per cent). This reduction in incidence of thrombosis is significant at the 2 per cent level, indicating that dextran 70, as macrodex 6 per cent in 5 per cent dextrose, in the régime given is a simple and effective means of reducing deep venous thrombosis after major surgery.

BYGDEMAN (1967) proposed the use of dextran 70 as an agent to prevent unwanted postoperative venous thrombosis. He suggested that 250-500 ml. of a 6 per cent solution daily would be adequate.

In trials to determine a suitable routine method of administration of dextran 70 to prevent postoperative deep venous thrombosis in the lower limb two series of patients were studied. The patients in the first series were given 500 ml. of dextran 70, as macrodex 6 per cent in 5 per cent dextrose, during operation and subsequently on alternate days until discharge. This dosage was not successful in preventing deep venous thrombosis to a significant degree, but was sufficiently encouraging to increase the dosage to 500 ml. of dextran 70 during the operation, 500 ml. on the following day, and thereafter 500 ml. on alternate days until discharge.

The second method reduced the incidence of deep venous thrombosis from 9·9 per cent in 101 control subjects to 0·94 per cent in 106 cases who were given dextran 70, a reduction which is significant at the 2 per cent level ($\chi^2 = 6{\cdot}56$).

MATERIAL AND METHODS

Patient Selection.—Male and female patients over the age of 45 years admitted for non-emergency major surgery were allocated to the same random series as used in a previous report (Carter, Eban, and Perrett, 1971). Similarly, all the patients with known varicose veins, peripheral arterial disease, cardiac or respiratory insufficiency, or a history of previous thrombotic episodes were excluded. No patient who had had major surgery within the previous 6 months was included.

Of 207 patients admitted to the trial, 106 cases (64 males and 42 females) were given dextran 70 as macrodex 6 per cent in 5 per cent dextrose, and 101 cases (65 males and 36 females) formed the controls who were given 4·3 per cent dextrose in 0·18 per cent saline in the same doses as the dextran 70.

Dextran 70 Dosage.—The treated group received 500 ml. of dextran 70 intravenously as a 6 per cent solution, the infusion starting immediately anaesthesia had been induced and lasting 4 hours or, if blood had to be given, being completed before blood was transfused. A further 500 ml. of dextran 70 were given on the day after operation within 24 hours of the intra-operative dose, and thereafter 500 ml. daily until discharge from hospital.

The controls received 500 ml. of 4·3 per cent dextrose in 0·18 per cent saline in identical volumes at the same times.

Diagnosis of Deep Venous Thrombosis.—The method of Flanc, Kakkar, and Clarke (1968) was used. Thyroid uptake of iodine was blocked with 100 mg. of sodium iodide not less than 1 hour before operation (intravenously) or more than 12 hours (orally) before giving 100 μc. of ^{125}I-labelled human fibrinogen (Radiochemical Centre). Both lower limbs were scanned with a Pitman 235 Isotope Localisator immediately before operation, just before the patient left the recovery unit, and thereafter daily until discharge from hospital.

Every case suspected of having a thrombosis had a venogram performed within 24 hours of the suspicion being raised.

Ambulation.—Every patient in this series was ambulant on the day after operation. Those with intravenous infusions or other encumbrances were walked around their bed at least three times daily until they were ambulant without help.

Table I.—DISTRIBUTION OF CASES BY SEX, AGE, AND SITE OF OPERATION

SITE	TREATED GROUP						CONTROL GROUP					
	Age (yr.)						*Age* (yr.)					
	45–50	51–55	56–60	61–65	66–70	71+	45–50	51–55	56–60	61–65	66–70	71+
Males												
Upper abdomen	4	1	4	3	4	3	4	0	10	5 (1)	1	2
Lower abdomen	1	4	6	9	7	10	2 (1)	2	7	7	7 (1)	12 (1)
Other	0	0	0	7	1	0	2	0	0	0	2	2
Total	5	5	10	19	12	13	8 (1)	2	17	12 (1)	10 (1)	16 (1)
Females

Total	5	2	8	10 (1)	4	13	3	4 (1)	4	2	3 (1)	20 (4)

Figures in parentheses indicate the number of cases of thrombosis.

RESULTS

Table I shows the distribution by age, sex, and site of operation of the 106 treated cases and the 101 controls. They are further analysed according to the site of operation to try to illustrate the relative risks between the different sites. It should be noted that in the males there is a preponderance of lower abdominal operations owing to the large number of prostatectomies in the series. There are only a few non-abdominal operations among the females as the cases of breast cancer in this unit are included in another study that precludes the use of ^{125}I.

In the males the incidence of thrombosis in the treated group is 0 in 64 cases and in the control group 4 in 65 cases. The value of P for this difference is 0·062, which is significant at the 10 per cent level but not at the 5 per cent level. In the females the incidence of thrombosis in the treated cases is 1 in 42 cases and in the controls 6 in 36 cases. The value of P is 0·034, which is significant at the 5 per cent level. Pooling both sexes gives an overall rate of thrombosis in the treated cases of 1 in 106 and in the controls of 10 in 101. This difference is significant at the 2 per cent level ($\chi^2 = 6·56$).

It is generally held that there is an increased risk of thrombosis in cases treated for malignant disease. *Table II* shows the distribution of such cases in this series. In males the incidence of thrombosis in the malignant cases was 0 in 11 against 4 in 54 in the non-malignant cases ($P = 0·47$). In females thrombosis occurred in 4 of 11 malignant cases and in 2 of 25 non-malignant cases ($P = 0·057$). There was, therefore, in this series a strong indication that thrombosis is more likely in females with malignant disease but no such indication in males.

No significant differences were found in the incidence of thrombosis attributable to age, type of anaesthetic (e.g., spinal/epidural or general), time spent on the operating table, or the need for blood transfusion or the quantity of blood given. There was no significant difference between the cases operated upon within 36 hours of admission (the majority) and those in hospital for periods of up to 23 days before surgery. None of the patients who were in hospital for any period of time was confined to bed before operation.

Table II.—DISTRIBUTION OF CASES BETWEEN MALIGNANT AND NON-MALIGNANT DISEASE

TYPE OF DISEASE	CONTROL GROUP		TREATED GROUP	
	Male	Female	Male	Female
Malignant	11	11 (4)	20	16 (1)
Non-malignant	54 (4)	25 (2)	44	26

Figures in parentheses indicate the number of cases of thrombosis.

The time of recognition of venous thrombosis was variable. *Table III* shows the distribution of the times of recognition. Previous experience with ^{125}I-fibrinogen localization of thrombosis suggested that the time of its recognition, presumably the time of its onset, could be as late as the tenth day after operation. For this reason dextran 70 was given throughout each treated patient's stay in hospital. *Table III* shows that although the majority of thromboses are recognized within 3 days of operation, 2 became apparent on the sixth day and 1 on the tenth postoperative day.

No case in this series developed thrombosis of the iliofemoral veins on either side.

Table III.—TIME OF ONSET OF THROMBOSIS

GROUP	AGE (yr.)	DAY AFTER OPERATION
Control Females	72	2
	68	3
	71	3
	81	3
	52	6
	85	6
Males	68	3
	45	3
	84	3
	64	10
Treated Female	67	7

DISCUSSION

The dextrans have been known to have an antithrombotic effect since 1959 (Borgström, Gelin, and Zederfeldt, 1959). Of the various dextrans, that with a molecular weight around 70,000 has been the most satisfactory in clinical use, as a 6 per cent solution. At this weight and concentration doses of the order of 250–500 ml. per day have not resulted in any tendency to unwanted bleeding or of overloading the circulation. Dextran is simple to use and, in the régime used in this series, requires no laboratory control.

Lambie, Barber, Dhall, and Matheson (1970) compared dextran 70 with Warfarin as methods of reducing postoperative deep venous thrombosis. In their series dextran was found to be more effective. Similarly Bonnar and Walsh (1972) found that in their series of major lower abdominal operations dextran reduced the incidence of deep venous thrombosis from 10·7 per cent in the control cases to 0·8 per cent in the treated cases.

In this series the reduction in the incidence of thrombosis has been from 9·9 per cent in the controls to 0·94 per cent in the cases which were given dextran 70. Previous (unreported) experience with dextran 70 had suggested that a single dose of 500 ml. during operation followed by 500 ml. on alternate days was not enough to reduce the incidence of thrombosis to a significant degree but was sufficiently encouraging to increase the dose to 500 ml. during operation, 500 ml. on the following day, and thereafter 500 ml. on alternate days until discharge. The result has been an overall significant reduction in thrombosis in treated cases although the males only showed a reduction in thrombosis at the 10 per cent level. The low incidence of thrombosis in the controls renders comparisons difficult, so that as thrombosis is more common in females a significance at the 2 per cent level is gained only by including both sexes in the assessment.

There appears, therefore, to be little doubt that dextran 70, used in the régime reported here, is effective in reducing thrombosis in the type of patient admitted to regional hospitals undertaking a wide variety of major surgical procedures on unselected patients.

Acknowledgements.—We wish to thank Pharmacia (Great Britain) Ltd. for their extensive financial support of this study and, particularly, Dr. Peter Allen of that company for his continuous help and for the statistical assessment; also the King Edward Memorial Hospital's League of Friends who purchased the Pitman 235 Isotope Localisator.

We are grateful to Sister Nancy Medlock and the staff of the intensive care unit and the chief theatre technician who carried out much of the limb scanning and allocated the patients to the random series.

CARCINOID TUMOURS OF THE COLON

By J. E. SCOTT*
PRINCESS MARGARET HOSPITAL, SWINDON

SUMMARY

Four cases of carcinoid tumour of the colon are presented together with a brief review of the literature.

CASE REPORTS

Case 1.—A 70-year-old male presented with a 2-month history of anorexia and melaena. During this period he had lost 11 kg. in weight. He had had a partial gastrectomy for a perforated duodenal ulcer 14 years previously. On examination he was cachectic and clinically anaemic. Abdominal examination revealed a firm, irregular, mobile mass just above the level of the umbilicus. His haemoglobin was 8·3 g. per cent. The patient's condition improved considerably over the next 4 days, during which time he had a 5-unit blood transfusion. However, on the fifth day of his admission he collapsed with a further massive haemorrhage and died rapidly. Post-mortem examination revealed a carcinoid tumour of the splenic flexure measuring 4 cm. in diameter which involved the full thickness of the bowel wall; there were metastases in the para-aortic and coeliac nodes and also in the liver.

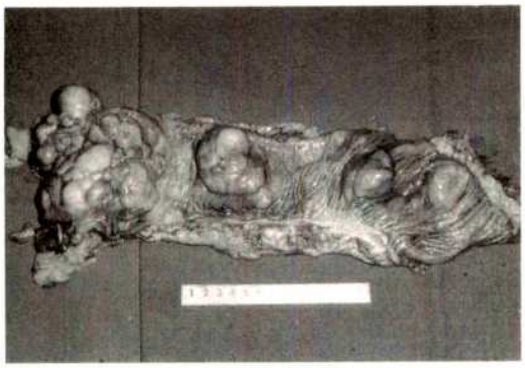

FIG. 1.—*Case* 4. The operative specimen showing one large tumour and several small ones.

Case 2.—A 51-year-old male was admitted with a 10-month history of intermittent colicky lower abdominal pain with no other associated symptoms. His family history revealed that a brother and sister had both died of carcinoma of the large bowel. On examination there was a tender, mobile mass in the right middle quadrant of the abdomen. Laboratory investigations showed an E.S.R. of 50 mm. per hour and a haemoglobin of 11·0 g. per cent. After a preoperative blood transfusion, laparotomy revealed a tumour in the ascending colon 4 cm. distal to the ileocaecal valve. There were no palpable metastases. A routine right hemicolectomy was performed, and histology of the operation specimen showed it to be a carcinoid tumour with no involvement of the local lymph-nodes. A postoperative urinary 5-hydroxy-indole acetic acid measurement was 3·3 mg. per 24 hours (normal < 10 mg. per 24 hours). The patient is well with no sign of recurrence 2 years after operation.

Case 3.—A 68-year-old female was admitted with a 6-week history of bilateral sciatica. During this time she had felt unwell and had lost 7 kg. in weight, although she had no other presenting symptoms. On examination there was a firm mobile abdominal mass just to the right of the umbilicus. Examination of the central nervous system revealed absent ankle reflexes. Laboratory investigations showed a haemoglobin of 12·0 g. per cent and an E.S.R. of 45 mm. per hour; protein concentration of the cerebrospinal fluid at a lumbar puncture was 80 mg. per cent; serial faecal occult-blood measurements were all positive. An electro-encephalogram showed a left midtemporal structural disturbance. Shortly after admission the patient developed papilloedema, became comatosed, and died. Post-mortem examination revealed a carcinoid tumour in the right half of the transverse colon about 2 cm. in diameter, with metastases in the mesenteric and coeliac lymph-nodes, in both adrenal glands, and in the liver. There were also metastases throughout the brain.

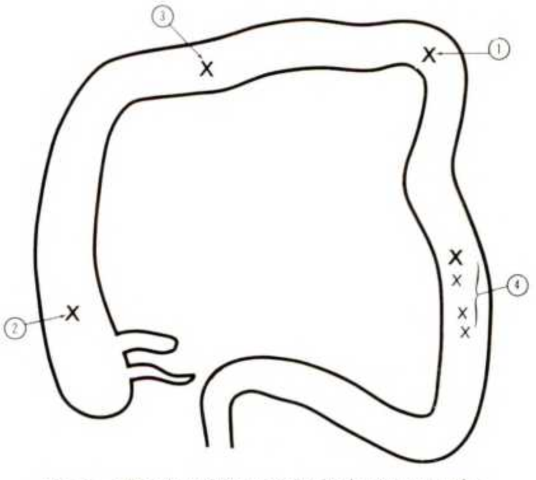

FIG. 2.—The sites of the tumours in the present series.

Case 4.—A 58-year-old female was admitted to a psychiatric hospital for assessment. She had a 20-year history of intermittent anxiety and depression; she had received regular out-patient psychiatric treatment and also three short spells of in-patient care. Repeated clinical examinations and biochemical investigations had revealed no abnormality. However, on this occasion routine examination showed a mobile mass in the left lower quadrant of the abdomen. She gave no history of symptoms referable to the gastro-intestinal tract and her lack of history was corroborated by her daughter with whom she was living. Laboratory investigations showed no abnormality, but a barium-enema examination revealed several filling defects in the descending colon, and at operation a large submucosal tumour was found in the descending colon with several small lesions below it (*Fig.* 1). There were no palpable lymphatic or hepatic metastases. A standard anterior resection was performed and histology showed the lesion to be a carcinoid tumour which had invaded the full thickness of the bowel wall, but with no involvement of the local lymph-nodes. A urinary

5-hydroxy-indole acetic acid measurement postoperatively was 5·2 mg. per 24 hours. The patient is well with no sign of recurrence 1 year after operation.

DISCUSSION

Carcinoid tumours of the colon are extremely rare. Anthony and Drury (1970) collected 100 cases of carcinoid tumour in a 12-year period from 1956 to 1968 from the files of the Central Middlesex Hospital, the Middlesex Hospital, and St. Mark's Hospital, London, and did not find one such tumour in the colon. A review of 356 carcinoid tumours of the gastro-intestinal tract by MacDonald (1956) contained only 6 occurring in the colon, but he does not mention where abouts in the colon they arose.

Crittenden, Byllesby, and Dodds (1970) reported a carcinoid tumour presenting as an annular lesion in the ascending colon. Rosato, Anderson, and Andrus (1970) described 4 cases of carcinoid tumour of the colon, 2 in the ascending colon and 2 in the descending colon. Case (1969) reported a carcinoid tumour in the transverse colon. Of the 4 tumours presented here, 1 was in the ascending colon, 1 in the transverse colon, 1 at the splenic flexure, and 1 in the descending colon (*Fig.* 2). Thus, of the few reported cases, carcinoid tumours do not appear to show a predilection for any particular site within the colon. This is in strict contrast to adenocarcinomas of the colon, 70 per cent of which arise in the sigmoid colon and 15 per cent in the ascending colon.

Multiple primary tumours have occasionally been reported in association with carcinoid tumours of the gastro-intestinal tract; thus out of 72 cases reported by Kuiper, Gracie, and Pollard (1970), there were multiple tumours in 8 patients, although none of these was in the colon. In the present *Case* 4 the distal tumours were probably implantation metastases, although the possibility that they were multiple primaries cannot be eliminated.

In common with other gastro-intestinal carcinoid tumours those of the colon produce no early symptoms. They may present as an asymptomatic mass in the abdomen, as obstruction, as an incidental finding during laparotomy, or at autopsy. Even where there are extensive hepatic metastases the development of the carcinoid syndrome appears to be rare. Thus, in MacDonald's (1956) series, of 149 extra-appendicular carcinoid tumours, widespread hepatic metastases were present in 23 cases, and of these, only 3 patients had symptoms of the carcinoid syndrome. The 2 patients reported here whose tumours were discovered at autopsy and in whom there were extensive hepatic metastases did not have symptoms of the carcinoid syndrome. One striking feature in the symptoms of the 4 patients presented here was the marked weight-loss; 11 kg. in 3 months in *Case* 1, 14 kg. in 6 months in *Case* 2, and 7 kg. in 3 months in *Case* 3. Kuiper and others (1970) also drew attention to this feature, reporting weight-losses of 11, 11·3, and 45 kg. respectively in 3 patients with carcinoid tumours of the colon prior to diagnosis.

Several authors have reported a high incidence of a second neoplasm in association with carcinoid tumours. Thus, Moertel, Sauer, Dockerty, and Baggentoss (1961) reported an incidence of 29 per cent in a series of small-bowel carcinoid tumours, Foreman (1952) found a 47 per cent association, and Warren and Coyle (1951) reported a 33 per cent association of a second neoplasm with carcinoid tumours. In none of the cases reported here was a second lesion found.

As with other tumours of the colon the most important factor in determining the prognosis is whether or not there are hepatic metastases present at the time of exploration. Of 5 carcinoid tumours of the colon reported by Kuiper and others (1970), there were hepatic metastases at the time of operation in 3 patients all of whom died within 3 years, whereas the other 2 patients who did not have hepatic metastases were alive 10 years later.

Acknowledgements—I should like to thank Mr. P. H. Powley for permission to publish these cases and for his advice, and Professor D. G. Grahame Smith for his help in the management of *Case* 4.

A STERILE 'USE-ONCE' CLIP APPLICATOR FOR SKIN CLOSURE

By DAVID ANNIS

LIVERPOOL ROYAL INFIRMARY

SUMMARY

A sterile disposable applicator for skin clips has been used for the closure of skin incisions in 117 consecutive operations. These have included most of the standard incisions in the head, neck, trunk, and limbs. The instrument has proved satisfactory in use, the skin incisions having healed satisfactorily with much time having been saved in their closure.

METAL clips have been used for the closure of skin incisions for more than 60 years. For the majority of surgeons their use has been limited to the closure of a very few incisions, mostly transverse and mainly in situations where the scar will ultimately be exposed. The collar incision for thyroidectomy is, of course, the incision for which many surgeons regularly use skin clips. However, a minority of surgeons have used skin clips for the entire range of surgical incisions.

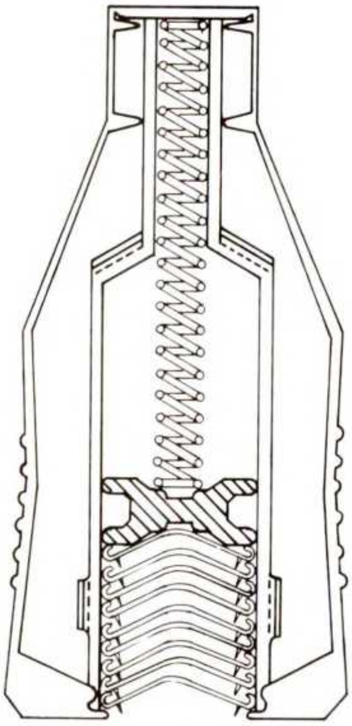

FIG. 1.—The applicator.

Michel and Kifa clips are held in their carriage and applied singly. There are instruments for holding a 'bank' of clips that present the clips in the jaws of the instrument ready for application. These instruments have the advantage of speed and economy of action, but require to be loaded and to be autoclaved before use.

A sterile pre-packed applicator containing 20 × 18-mm. double-toothed stainless-steel clips has been developed.* The applicator and its contents have been designed to be used for the closure of one skin incision, after which the applicator is discarded.

The device is illustrated in *Figs.* 1 and 2. A polycarbonate case containing 20 clips is presented in a double-wrapped sterile packet. A squeezing pressure on the sides of the device approximates the dogs that hold back the bank of clips and closes the presenting clip. Release of pressure frees this clip and allows the next clip to fall into place.

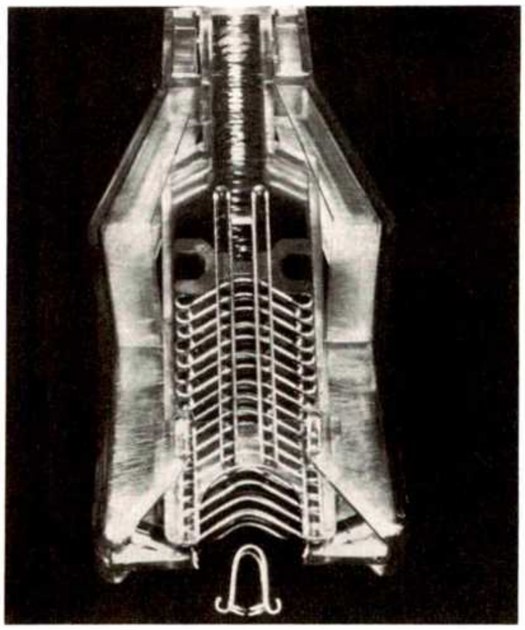

FIG. 2.—The applicator showing the clip after closure.

The technique of application is simple but differs from that usually followed when applying Michel clips. Most, but not all, surgeons apply Michel clips immediately *beyond* the skin-approximating forceps. That is, most right-handed surgeons will move from the left-hand to the right-hand end of the incision, approximating the skin with forceps in the left hand and applying the clip with the right hand.

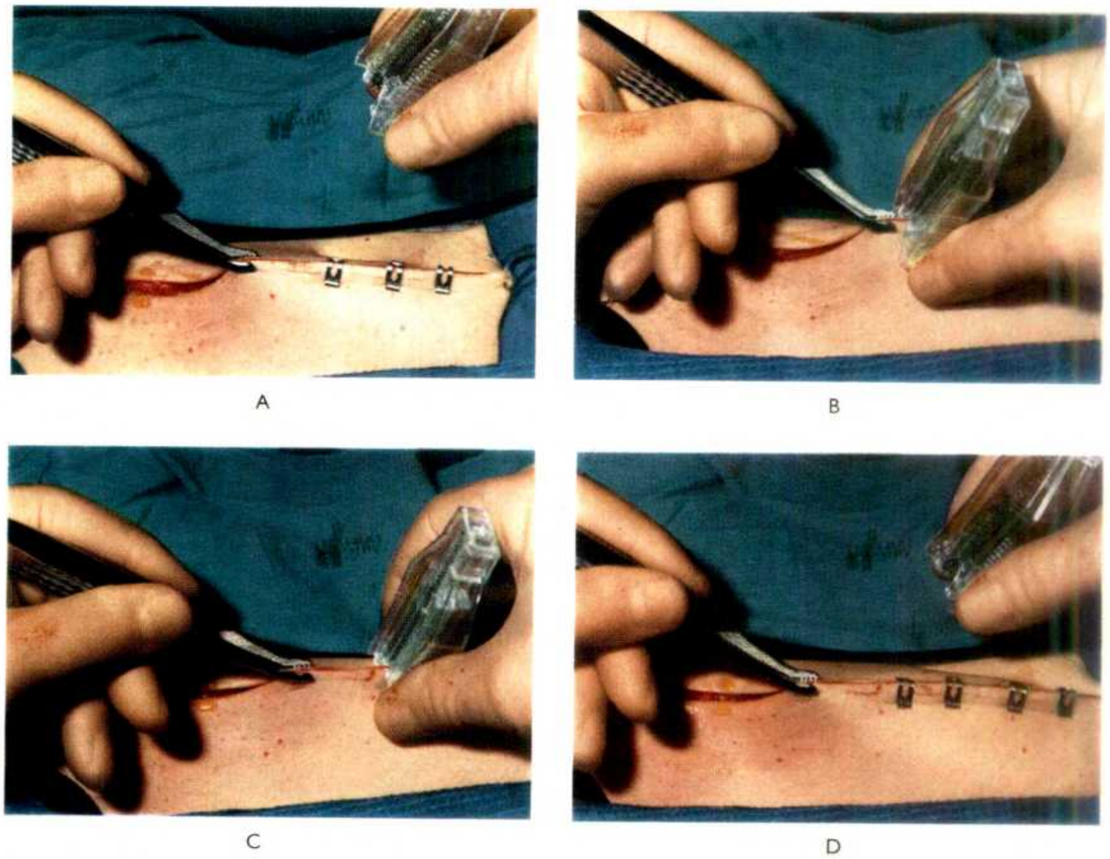
---

* The device has been developed by the Medical Aids Innovation Unit of I.C.I. Ltd., Runcorn, Cheshire.

Using the Avlox '18' device it has been found better for the right-handed surgeon to begin at the right end of the incision, holding the approximating forceps in the left hand and applying the clips with the Avlox '18' device in his right hand *behind* the approximating forceps. This is illustrated in *Fig*. 3.

It is necessary to take hold of both sides of the skin incision simultaneously in the grasp of a sharp-toothed approximating forceps and to bring the skin edges evenly together, raising them to form a low ridge on to which the clip is closed. A Childe's or Ward's forceps has been found ideal for this purpose (*Fig*. 3A). The clip having been closed on the skin (*Fig*. 3B), pressure is maintained on the device so that the clip is not released until the approximating forceps has been moved on and has grasped the skin edges again about half an inch farther along the incision (*Fig*. 3C). Only then is the clip released from the instrument by relaxing the pressure upon it (*Fig*. 3D). The next clip is then applied behind the approximating forceps and usually about half an inch farther along the wound (*Fig*. 3E). This progression in a two-handed manner is continued until the incision is closed. It can be seen that at all times the skin edges are held together either in the grasp of the approximating forceps or in the Avlox '18' device. This allows the skin edges to be brought neatly together.

The instrument has been used for 117 consecutive skin closures and these have included all the standard incisions in the chest, abdomen, neck, and limbs (*Table I*). Not all patients have sufficiently supple skin to allow a ridge to be made and the clips to be satisfactorily placed. In particular, it has been found difficult to apply the clips in areas where the skin is especially thick and the subcutaneous fat is firmly attached to it, such as at the posterior end of an oblique renal incision and at the posterior ends of thoracotomy incisions.



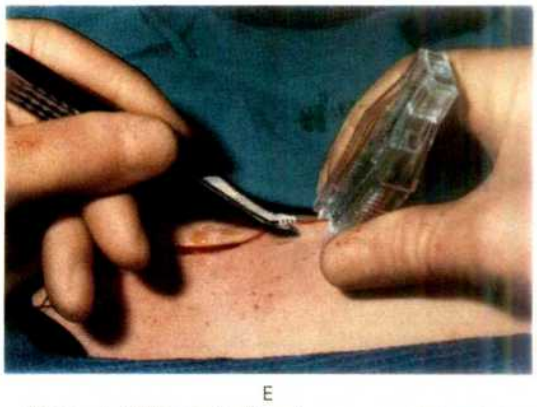


FIG. 3.—A, Taking up the skin edges to receive the fourth clip. B, The fourth clip applied. C, Pressure on the fourth clip is maintained while the approximating forceps is advanced. D, The fourth clip released. E, The fifth clip applied.

Even so, satisfactory skin closure and good skin healing have been achieved in over 95 per cent (113 out of 117 cases) of the incisions closed. It is true that transverse incisions in general are more easily closed with clips than are longitudinal incisions. Nevertheless, the device and the clips that it delivers have been found entirely satisfactory for the closure of all standard longitudinal incisions in the abdomen.

Table I.—SUMMARY OF A SERIES OF CONSECUTIVE OPERATIONS IN WHICH AVLOX '18' CLIPS HAVE BEEN USED

Type of Operation	*No. of Operations*
Head and neck	
Thyroidectomy	7
Parathyroid tumour	3
Branchial cyst	1
Submaxillary gland excision	1
Breast	
Simple excision of cysts, etc.	4
Mastectomy	12
Abdomen	
Cholecystectomy	25
Gastric surgery	13
Cholecystoduodenostomy	1
Pancreaticoduodenectomy	1
Pancreatic insulinoma	1
Resection of colon	8
Colostomy	1
Laparotomy	4
Appendicectomy	1
Adrenalectomy	4
Nephrectomy	3
Oophorectomy	1
Ileal conduit urinary diversion	2
Prostatectomy	3
Hernia	18
Miscellaneous	3
Total	117

Healing has been as good in every way as can be achieved by suturing and there has been a noticeable absence of minor wound infection, probably because the clips do not completely pierce the skin. There is an impression that healing has occurred a little more rapidly than with suturing techniques. The scars are linear and without cross-hatching, the clip marks disappearing entirely within 10 weeks.

The time of removal of the clips has varied and of course depends on the condition of the individual incision, but in the majority of cases it has been found possible to remove alternate clips from thyroidectomy incisions on the second postoperative day and the remaining clips on the third day. In simple abdominal incisions, such as those for hernia repair, the clips have regularly been removed on the fourth postoperative day, and in incisions for major abdominal surgery they have usually been removed on the sixth or seventh day after the operation.

Whilst it is difficult to claim that healing has been more than marginally better with the use of clips, there is no doubt that the application of clips is very much faster than the use of sutures or of individually applied skin clips.

In summary, the application of clips from the device described has proved at least as effective as suturing techniques, and because of the speed with which the clips can be applied has taken much of the tedium out of skin closure. It might be added that the device has been much appreciated by the theatre staff, being presented complete, sterile, and available for immediate use.

THE MANAGEMENT OF VILLOUS TUMOURS OF THE LARGE BOWEL

BY A. G. PARKS AND A. E. STUART
THE LONDON HOSPITAL AND ST. MARK'S HOSPITAL, LONDON

SUMMARY

Thirty patients with villous tumours of the rectum are described. With the criterion that invasion of the muscularis mucosae is necessary to make a diagnosis of malignant change the incidence of malignancy was 17 per cent. The technique of local excision per anum using submucosal infiltration is described, and the management of large mucosal defects and of total papillomatosis of the rectum is discussed. Local infection and incontinence have not been features in this series and every patient has had a sphincter-conserving operation. The recurrence rate was 10 per cent and recurrences can be treated by further local excision.

ALTHOUGH villous tumours of the large bowel can be classified histologically into villous papillomas and papillary adenomas, the term 'villous tumour', first used by Holmes in 1861, is a useful one as the features of both types can be found in the same tumour and their behaviour is similar. The pathological and clinical features of these tumours have been described previously and will not be considered here in detail (Ewing, 1950; Harp, Waugh, and Docherty, 1962; Southwood, 1962; Schapiro, 1965). Eighty-five per cent of villous tumours occur in the rectum and sigmoid colon. They are characteristically sessile and papillary, and occur in an older age-group (average age, 65 years) than large-bowel cancer. The most frequent mode of presentation is with diarrhoea, bleeding, and the passage of mucus (Hanley, Hines, Ray, McPherson, and Hibbert, 1962; Nicoloff, Ellis, and Humphrey, 1968). The quantity of mucus produced may be impossible to control and the patient may present with incontinence. As the mucus has a high potassium content, patients occasionally develop severe electrolyte imbalance (Cooling and Marrack, 1957; Case, 1968; Cook, 1969).

Colonic villous tumours rarely constitute a surgical problem as they nearly always require an abdominal resection, although a very small one can be removed with a colonoscope and occasionally sigmoid pedunculated lesions can be intussuscepted into the rectum and removed locally through the anus, or snared through a sigmoidoscope.

PROBLEMS OF MANAGEMENT OF RECTAL VILLOUS TUMOURS

The majority of rectal villous tumours are sessile and can involve a wide area of the rectal mucosa. There is some controversy about the way that these tumours should be treated. Many methods have been described (*Table I*). There are three principal methods: some form of local treatment (excision or diathermy); abdominal resection (segmental excision or colotomy and local excision); abdominoperineal excision of the rectum and permanent colostomy. It will be seen from *Table II* that some surgeons are conservative and others radical in their management of these tumours. There are two principal reasons advanced for radical treatment: first, the tendency of villous tumours to undergo malignant change, and, secondly, the technical problem of treating the extensive rectal villous tumour.

Table I.—METHODS USED IN THE TREATMENT OF VILLOUS TUMOURS

Excision with biopsy forceps
Diathermy snare
Fulguration
Local excision per anum
Posterior proctotomy and excision (Kraske's approach)
Anal sphincter division and excision (Bevan's procedure)
Colotomy and polypectomy
Segmental colonic excision
Anterior resection and anastomosis
Anterior resection and pull-through procedure
Abdominoperineal excision and colostomy
Radon seeds
External radiotherapy

1. Malignant Potential.—The percentage of villous tumours that have undergone malignant change varies from series to series, largely according to the criteria of malignancy accepted by different pathologists (*Table III*). Focal areas of cellular atypicality are common in these tumours and areas showing hyperchromatism, loss of nuclear polarity, and frequent mitoses may be interpreted as early carcinoma or carcinoma-in-situ. However, if one takes invasion of the muscularis mucosae as the only satisfactory criterion of malignancy (Schapiro, 1965; Ziffren, 1965) invasive carcinoma is found in approximately 1 in 5 cases (*Table IV*). Because malignant change is frequently focal in nature preoperative biopsies may be misleading (Wheat and Ackerman, 1958; Dreese, Gradinger, Hellwig, Welch, and McCusker, 1962). It is only after examination of the whole tumour that the pathologist can be sure that no malignant degeneration has taken place (Birnbaum, 1967), but if the surgeon routinely performs an abdominoperineal excision of the rectum for even extensive lower rectal villous tumours then there is a 60–80 per cent chance that such a radical procedure was unnecessary.

2. Technical Problems.—The second reason sometimes advocated for performing a radical operation is the technical problem encountered in exposing and excising locally a large villous tumour. Pedunculated tumours are easily excised per anum. Small sessile lesions can be excised by raising up an artificial pedicle of the surrounding mucosa by traction on the tumour and then ligating this pseudo-pedicle with a transfixion suture in the same way that pedunculated tumours are removed (Gabriel, 1963; Goligher, 1967). If this technique is attempted with large sessile tumours there is a danger of producing a defect in the rectum owing to the pseudo-pedicle containing the full thickness of the rectal wall. As villous tumours frequently extend microscopically beyond the visible margin of the lesion and only a limited excision can be done in this way, local recurrence is likely. Extensive tumours confined to the

Table IV.—SUMMARY OF DETAILS OF THE PRESENT SERIES

CASE	AGE AND SEX	TUMOUR SIZE (maximum diameter)	TIME AND TYPE OF OPERATION	HISTOLOGY	FOLLOW-UP	COMMENTS
1. C. S.	63 F.	3 cm.	1960. Local excision	Villous papilloma	6 yr.	Small recurrences in 1960 and 1966 (villous papillomas). Died in 1966 from breast cancer
2. C. D.	84 F.	8 cm.	1964. Local excision	Villous papilloma	1 yr.	Died 1965 from 'myocardial degeneration'
3. F. B.	53 M.	8 cm. (height; involving 60 per cent of rectal circumference)	1964. Local excision and imbrication	Villous papilloma	7 yr.	No recurrence
4. J. M.	56 M.	2 cm. (+ polyp 1·5 cm. diameter at 14 cm.)	1964. Local excision (+ snare of polyp)	Papillary adenoma (+ adenomatous polyp)	7 yr.	No recurrence
5. T. M.	78 M.	3 cm.	1965. Local excision	Papillary adenoma	6 yr.	No recurrence
6. F. E.	71 F.	5 cm.	1965. Local excision	Papillary adenoma	6 yr.	Symptom-free (sigmoidoscopy refused)
7. E. K.	57 F.	3 cm. (+ polyp at 14 cm.)	1967. Local excision	Villous papilloma (+ adenomatous polyp)	4 yr.	No recurrence
8. T. H.	31 M.	3 cm.	1967. Local excision	Papillary adenoma	4 yr.	No recurrence
9. A. B.	71 F.	Encircling rectum to 13 cm.	1967. Local excision and pull-through procedure. Mikulicz resection for carcinoma of the transverse colon	Villous and small low-grade A carcinoma. Colonic carcinoma high-grade C1	1 yr.	Died from carcinomatosis
10. F. K.	59 M.	4 cm.	1967. Local excision	Papillary adenoma	5 yr.	No recurrence
11. M. J.	71 F.	Encircling rectum, 7 cm. length (+ polyp transverse colon)	1968. Local excision, pull-through procedure	Villous papilloma (+ adenomatous polyp)	3 yr.	No recurrence
12. J. S.	65 M.	3 cm.	1962. Local excision	Villous papilloma	10 yr.	2 recurrences in 1969, measuring 2 and 4 cm. Larger lesion showed malignant change. Local excision. No recurrence up till 1972
13. H. H.	76 M.	2 cm. (+ 2 small polyps)	1968. Local excision	Villous papilloma + malignant change	1½ yr.	Previous excision of primary hepatoma in 1967. Died in 1970 from unrelated causes
14. J. M.	75 M.	Encircling rectum, 10 cm. length	1969. Local excision and imbrication	Villous papilloma	6 mth.	Recurrence in 1972. Local excision. Histology showed villous papilloma
15. S. G.	63 M.	5 cm.	1969. Local excision and imbrication	Villous papilloma	2 yr.	No recurrence
16. W. P.	57 M.	8 cm.	1969. Local excision	Villous papilloma + malignant change	2 yr.	Proceeded to anterior resection (no residual tumour in specimen). No recurrence
17. N. W.	75 F.	Encircling rectum, 12 cm.	1969. Local excision and imbrication	Villous papilloma	3 yr.	No recurrence
18. K. T.	70 F.	2 tumours both 2 cm.	1969. Local excision	Villous papilloma	2 yr.	No recurrence
19. D. C.	36 F.	3 cm.	1969. Local excision	Sessile adenomatous polyp	2 yr.	No recurrence
20. J. H.	57 M.	5 cm.	1971. Local excision	Villous papilloma	1½ yr.	No recurrence
21. M. S.	63 F.	Encircling 9 cm. length	1971. Local excision and imbrication	Villous papilloma	1 yr.	No recurrence
22. R. C.	60 M.	4 cm.	1971. Local excision	Villous papilloma	1 yr.	No recurrence
23. A. M.	59 F.	5 cm.	1971. Local excision	Papillary adenoma	6 mth.	No recurrence
24. G. T.	82 F.	7 cm.	1971. Local excision	Villous papilloma	6 mth.	No recurrence. Died; road accident
25. L.	80 F.	10 cm.	1971. Local excision	Villous papilloma	1 yr.	No recurrence
26. N. H.	F.	10 cm.	1971. Local excision and imbrication	Villous papilloma	9 mth.	No recurrence
27. M.	64 M.	Almost encircling 9 cm. length	1971. Local excision and pull-through procedure	Villous papilloma	1 yr.	No recurrence
28. J. M.	33 M.	4 tumours, largest 2·5 cm., associated polyposis coli	1971. Local excision, colectomy, caecorectal anastomosis	Papillary adenomata	6 mth.	No recurrence
29. J. M.	73 F.	6 cm.	1971. Local excision	Papillary adenoma + malignant change	15 mth.	Nodule scar 9 mth. later, local excision. Small carcinoma completely removed. Histology showed 'new primary'. No sign of recurrence 4 mth. later
30. H. M.	64 M.	2 polyps 1 cm.	1971. Local excision	Papillary adenomata	1 yr.	Previous pelvic colon carcinoma resected in 1967. 1972, multiple adenomatous polyps of the colon

upper rectum can be managed with an anterior resection. However, many of the extensive lesions also involve the lower rectum.

Several operations have been designed to improve the access to rectal tumours. Lockwood and Taylor (1956) and Wilson and Gordon (1969) recommended the Kraske approach first described in 1885. Through an incision from the fifth sacral vertebra to the anal margin, the coccyx is removed and the levator ani muscles are divided in the midline with conservation of the external anal sphincter. The posterior wall of the rectum is then incised to expose the tumour. The main complication of this approach is the development of a proctocutaneous fistula, occurring in 20 per cent of cases in one series (Wilson and Gordon, 1969).

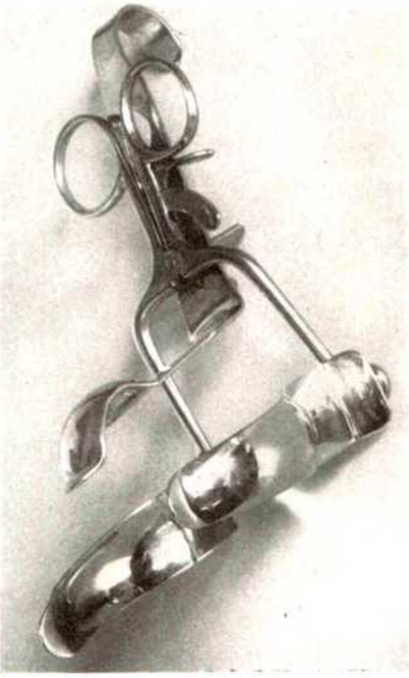

FIG. 1.—Three-bladed self-retaining retractor.

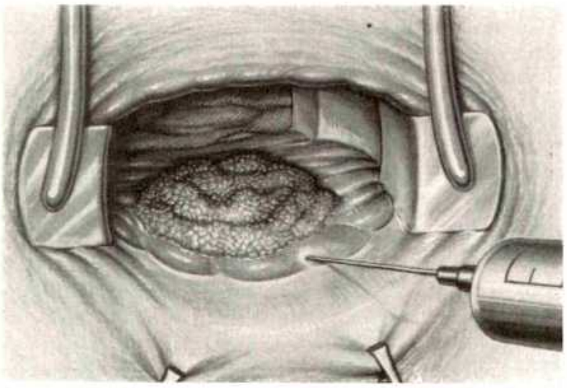

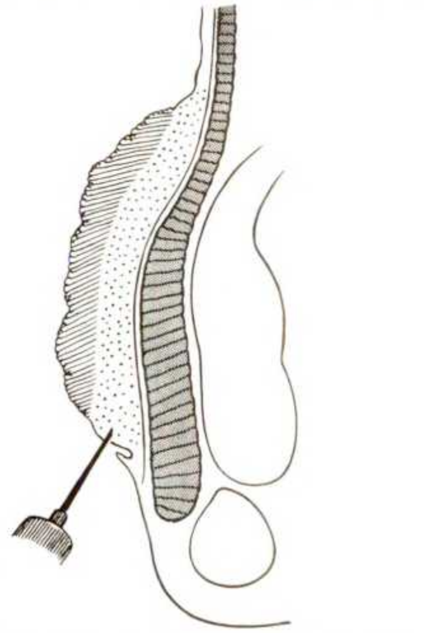

FIG. 2.—Submucosal infiltration with 1 in 300,000 adrenaline in saline. (*Reproduced from Parks, A. G. (1966), in 'Clinical Surgery', Vol. 10 (ed. Rob, C., and Smith, R.), p. 541. London: Butterworths.*)

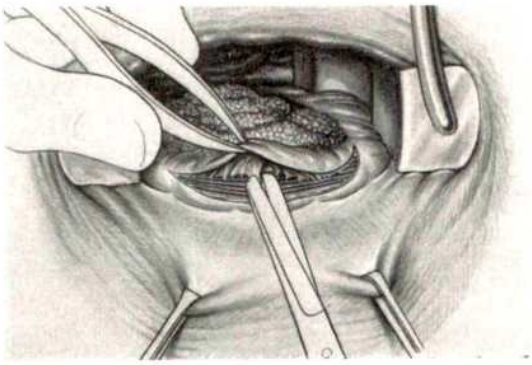
Mason (1970, 1972) has used the Bevan procedure of total sphincter section in the treatment of villous tumours and some carcinomas (Bevan, 1917). The external anal sphincter is completely divided, so laying open the rectum and anal canal. The external anal sphincter is then carefully repaired after excision of the tumour. Mason has had no case of incontinence although over one-third of his cases were complicated by local infection and 1 patient developed a fistula.

PRESENT SERIES

All of the 30 patients in the present series have been treated by per-anal local excision of villous tumours of the rectum. The sex incidence was equal and the average age at operation was 65 years (range, 31–84 years). The average size of the villous tumour was 6 cm. in diameter and 6 cases (20 per cent) were circumferential lesions. Three of these 6 patients had total papillomatosis of the rectum. Three patients had had previous treatment for villous tumours and in 6 cases multiple lesions were present or other polyps were associated with the villous tumour in the rectum. The incidence of malignant change in the series was 17 per cent. A carcinoma elsewhere in the large bowel occurred in 2 cases and has been more frequent in other series (Southwood, 1962; Wilson and Gordon, 1969); hence a barium-enema examination is essential in all cases. An association with malignancy elsewhere in the body has been recorded by other authors (Liechty and Raterman, 1963), and this was found in 2 patients in the present series.

TECHNIQUE OF PER-ANAL EXCISION OF VILLOUS TUMOURS OF THE RECTUM

The technique of local excision (Parks, 1966) depends on two principles. First, that the anal canal is a far more distensible structure than is commonly realized and with a relaxant anaesthetic the anus can be widely opened and exposure maintained with a three-bladed self-retaining anal retractor (*Fig.* 1). The second principle is that the submucosa of the rectum is an easily distensible space. Fluid injected into it spreads rapidly in all directions and distends the space to a thickness of 1–2 cm. This greatly facilitates the dissection of a mucosal lesion from the underlying circular muscle. Submucosal infiltration can also indicate areas of malignant change, as invasion of the submucosa will produce tethering during injection and that area will fail to lift off the muscle. The presence of induration is another guide although previous surgical diathermy and secondary infection can produce both induration and tethering and can make local excision more difficult. It is often helpful to do frozen sections on suspicious areas at operation.



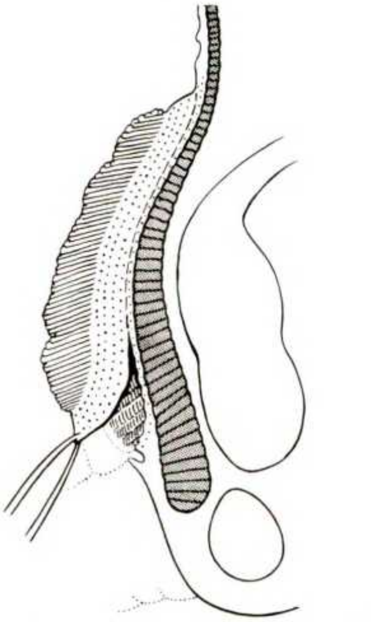


FIG. 3.—Dissection of the tumour off the circular muscle. (*Reproduced from Parks, A. G. (1966), in 'Clinical Surgery', Vol. 10 (ed. Rob, C., and Smith, R.), p. 541. London: Butterworths.*)

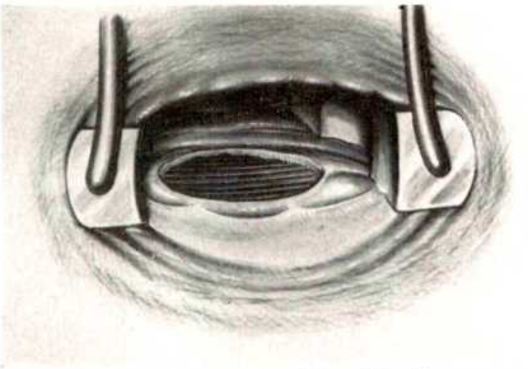

FIG. 4.—Mucosal defect after excision of the villous tumour. (*Reproduced from Parks, A. G. (1966), in 'Clinical Surgery', Vol. 10 (ed. Rob, C., and Smith, R.), p. 541. London: Butterworths.*)

1. Technique for Small Sessile Lesions (2–10 cm., 21 Cases).—After anal dilatation the self-retaining retractor is inserted to expose the tumour, which is carefully palpated for areas of induration. A needle is then inserted into the submucosa of the normal rectal wall adjacent to the tumour and isotonic saline containing adrenaline, 1 part in 300,000, is injected (*Fig.* 2). Sufficient saline is used to lift the whole tumour off the circular muscle of the rectal wall. An incision in the normal mucosa surrounding the tumour is made 1 cm. from the edge of the tumour (*Fig.* 3). The margin is necessary as histology shows that villous tumours can extend beyond the visible margin. Dissection is then carried out with scissors in the submucosal plane close to the circular muscle (*Fig.* 4). After excision all bleeding points are dealt with using diathermy coagulation. Careful haemostasis is necessary in these cases as a large volume of blood can collect in the rectum and lower colon in the postoperative period, without any external evidence of haemorrhage. No suturing of the rectal mucosa is required in most cases as even quite large bare areas of the rectal wall heal with little narrowing of the rectum.

2. Technique for More Extensive Lesions (6 Cases).—In 3 patients in this group the tumour involved the whole circumference of the rectum in a band 9–12 cm. in length (*Fig.* 5). These extensive tumours have to be removed in several pieces but the technique is essentially the same as that for small lesions (*Fig.* 6). When excision of one segment has been completed the retractor is removed and re-inserted to expose a fresh portion of the tumour. The extensive bare area can be reduced by imbricating the rectal wall in a longitudinal plane, approximating the upper mucosal margin to the lower one (*Fig.* 7). This can be done by inserting interrupted 00 chromic catgut sutures through the upper mucosal margin and then inserting the needle several times into the circular muscle before emerging from the lower cut edge of the mucosa. When these interrupted sutures are tied the effect is to concertina the circular muscle, reducing the bare area to a small transverse defect or even closing it altogether (*Fig.* 8).

3. Management of Total Papillomatosis of the Rectum (3 Cases).—Some patients have extensive villous change that can involve the whole of the rectal mucosa. Very frequently an abdominoperineal resection is performed in such cases. However, the whole of the rectal muscosa can be excised in three to four longitudinal strips using a similar technique to that discussed above. Healing would be complicated by a rectal stricture unless the denuded muscle wall can be relined with mucosa. This can be achieved by pulling down a sleeve of sigmoid colon through the denuded rectum and suturing it to the anal canal. Through a left lower paramedian incision the rectum is transected at the level of the mucosal excision. The sigmoid colon is carefully examined for any extension of the villous tumour above the level of excision and the rest of the colon is carefully palpated to exclude further lesions. Any villous change in the sigmoid colon can be treated by partial colectomy. The sigmoid colon is then drawn through the denuded rectum and sutured to the squamous epithelium of the mid-anal canal at the pectinate line (*Fig.* 9). A few sutures are placed between the cut end of the upper rectum and the wall of the colon. A temporary transverse colostomy is then performed which may be closed 3 weeks later.

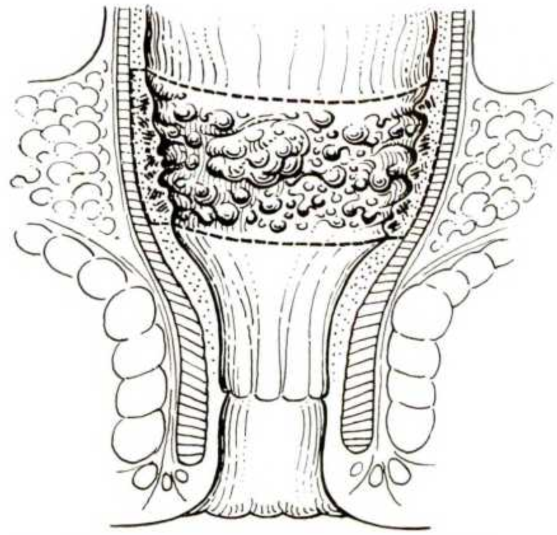

FIG. 5.—Circumferential villous tumour of the rectum.

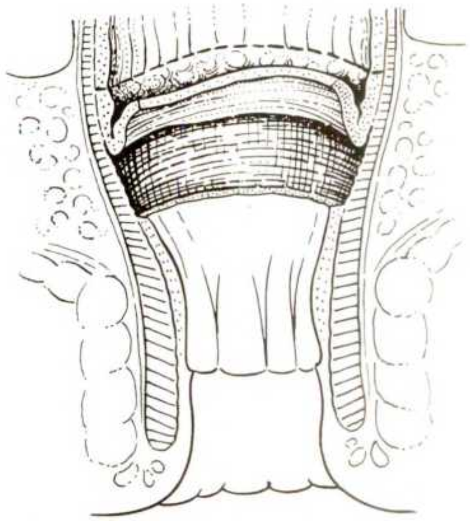

FIG. 6.—Partial excision of a circumferential villous tumour

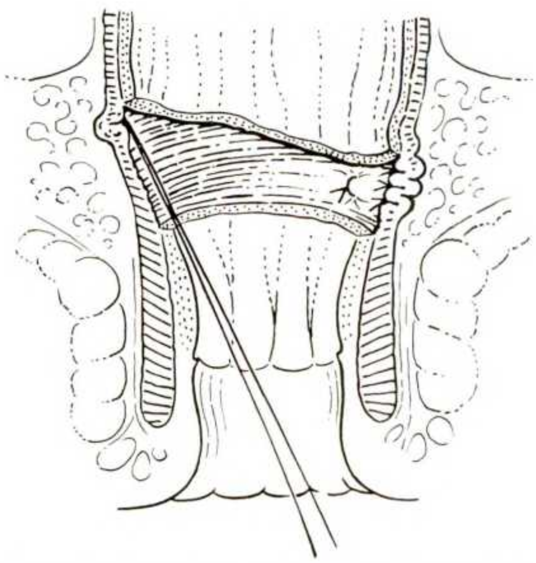

FIG. 7.—Use of interrupted sutures to imbricate circular muscle.

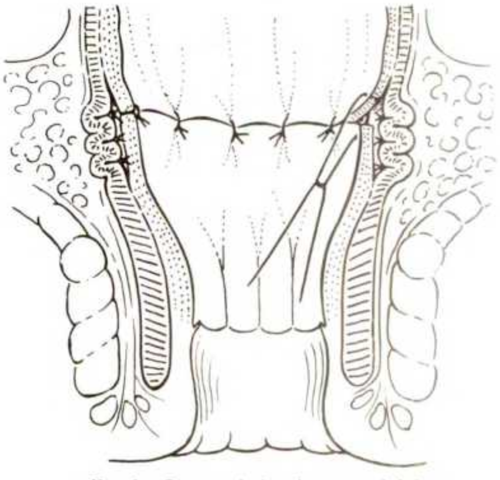

FIG. 8.—Sutures closing the mucosal defect.

The reconstituted rectum now has two muscle coats and an epithelial lining derived from the colon. It is known that rectal sensation depends principally on the tension in the muscle of the rectal wall rather than on nerve-endings in the mucosa (Parks, Porter, and Melzak, 1962), and in the 3 cases in which this more extensive procedure has been performed the functional results have been excellent and the patients are fully continent. This type of procedure is similar to that described by Soave (1964) for the treatment of Hirschsprung's disease.

RESULTS

In this series of 30 cases there has been no operative mortality and no problem with local infection. The average follow-up has been 3 years (range 6 months–10 years). Twenty-one patients had local excision of lesions varying in size from 2 to 10 cm. in diameter. A further 6 patients had imbrication of the circular muscle in addition to local excision for more extensive lesions. Half of these were completely encircling lesions. The remaining 3 patients had marked villous change over most of the rectal mucosa and after a local excision of the rectal mucosa a sigmoid pull-through procedure was performed.

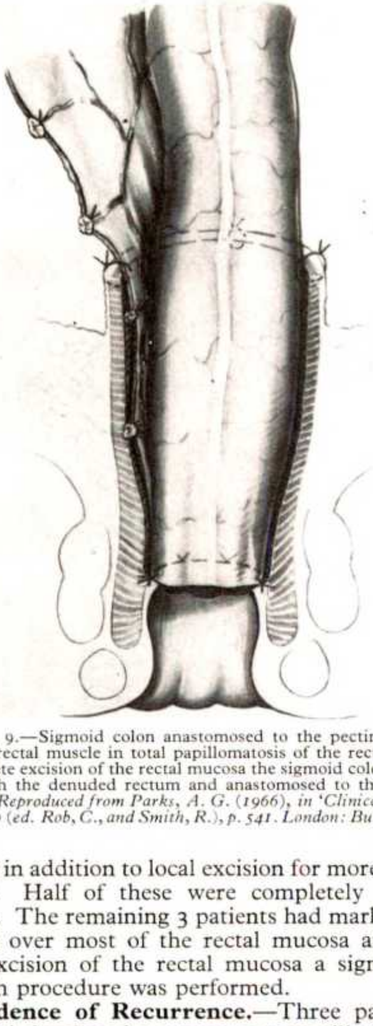

FIG. 9.—Sigmoid colon anastomosed to the pectinate line to reline rectal muscle in total papillomatosis of the rectum. After complete excision of the rectal mucosa the sigmoid colon is pulled through the denuded rectum and anastomosed to the pectinate line. (*Reproduced from Parks, A. G. (1966), in 'Clinical Surgery', Vol. 10 (ed. Rob, C., and Smith, R.), p. 541. London: Butterworths.*)

Incidence of Recurrence.—Three patients (10 per cent) developed recurrent or new villous tumours in the rectum. The recurrences occurred 3, 6, and 7 years after the primary lesions had been excised and were all treated by further local excision. Two of the recurrences were entirely benign. The third recurrence was a 4-cm. tumour with an area of carcinoma invading the submucosa at the apex of the tumour. There has been no further recurrence 3 years later.

Patients with Malignant Change.—The total incidence of malignant change in this series has been 17 per cent (5 cases). It is interesting to note that only 1 of the 6 patients with circumferential lesions in the rectum had malignant change. This patient (*Case* 9) had an extensive circumferential villous tumour of the rectum extending into the sigmoid colon and an associated carcinoma of the transverse colon. The carcinoma was treated with a Mikulicz resection, leaving the two ends of the colon as a transverse colostomy. Three weeks later the whole of the rectal mucosa was excised and a pull-through procedure was performed, anastomosing the sigmoid colon to the dentate line. Examination of the resected sigmoid colon revealed a further carcinoma at the upper end of the extensive villous tumour, and although this proved to be a low-grade A carcinoma the lesion in the transverse colon was a high-grade C1 adenocarcinoma and the patient died a year later with generalized carcinomatosis.

The other 4 cases were found to have early invasive carcinoma on histology after local excision of the villous tumours. One patient had a subsequent anterior resection and no residual tumour was found in the resected specimen. The other 3 patients had no further surgery. One patient died of unrelated causes a year later and another developed a small recurrent carcinoma 9 months later which was again excised locally. Histology suggested that the latter lesion was a new primary tumour and that it had been completely excised. The fourth patient has had no recurrence 3 years later.

DISCUSSION

Although villous tumours are uncommon compared with carcinoma of the rectum they are of surgical importance and interest because of their tendency to undergo malignant change, the severity of the symptoms that they cause, and the large area of the rectal wall that they can involve. A wide difference of opinion has been expressed as to the way that these should be managed (*Tables I, II*). This largely hinges on the pathologist's interpretation of the histological appearance. Although some authors quote a malignancy rate of over 40 per cent (*Table III*), provided that invasion is made the criterion of malignancy, the figure becomes much nearer 20 per cent, even with large tumours. That this criterion is acceptable is supported by the fact that adequate local excision of cases showing carcinoma-in-situ rarely subsequently develop metastatic or recurrent carcinoma (Ziffren, 1965). It is therefore unjustifiable to perform an abdominoperineal excision of the rectum as a routine procedure. The results of this series and others suggest that even if malignant change with early invasion has taken place, radical excision of the rectum may not be necessary as the malignancy is usually confined to the superficial layers and it is rare for there to be metastases to glands or pararectal tissues without an obvious gross carcinoma replacing the villous tumour. In this series of 30 cases, although the incidence of malignant change was 17 per cent, no patient has had a sphincter-destroying operation.

The technique of per-anal local excision using submucosal infiltration has been described and it is emphasized that this technique can be used even with large lesions; indeed, the whole rectal mucosa can be excised in this way. Small bare areas heal without any narrowing of the rectum but larger defects can be reduced in size by the technique of imbrication of the rectal wall. It is of interest that local infection has not been a problem in any of these cases. The Soave

(1964) technique of using a sleeve of sigmoid colon to line the totally denuded rectal wall has been used on three occasions and good faecal control has resulted in each case. Diathermy treatment of villous tumours has a high recurrence rate and makes subsequent local excision very difficult. Diathermy coagulation should be restricted to local recurrences.

MANAGEMENT OF UNCOMPLICATED DIVERTICULAR DISEASE BY COLONIC RESECTION IN PATIENTS AT ST. MARK'S HOSPITAL, 1964–9

By J. C. B. Penfold
ST. MARK'S HOSPITAL, LONDON

Summary

One-hundred and thirty-nine resections were performed for diverticular disease at St. Mark's Hospital, London, during the period from 1964 to 1969. One hundred and three of the resections were done on selected cases before any of the clinically recognized complications of the disease had occurred. In 46 of the resected specimens no evidence of inflammation could be found despite meticulous examination by the pathologist.

The surgical procedures were accompanied by no mortality, moderate morbidity, and a gratifying relief of symptoms, which are contrary to the generally held belief that surgery for diverticular disease is hazardous.

Over the past decade the understanding of the clinicopathological nature of diverticular disease has changed appreciably. The findings of muscular thickening and the frequent absence of inflammation in the resected specimens have been stressed (Morson, 1963; Arfwidsson, 1964; Fleischner, Ming, and Henken, 1964; Goligher, 1967; Reilly, 1967; Tagart, 1969). With this changing understanding of the disease, a change in the management may be expected.

---

* Present address: Department of Surgery, Repatriation General Hospital, Heidelberg, Vic. 3077, Australia.

In the past surgery has been reserved for the management of complications, e.g., abscess, perforation, fistula, and haemorrhage. More recently surgery has been recommended for certain cases of uncomplicated diverticular disease (Todd, 1955; Colcock, 1958; Thompson, 1959; Reilly, 1964; Wilson, 1965, 1970), although clinically it is often difficult to distinguish the complicated from the uncomplicated type (Fleischner and others, 1964; Tagart, 1969; Parks and Connell, 1970). The medical management of symptomatic uncomplicated diverticular disease is unsatisfactory (Goligher, 1967), but the natural history of the disease is one of spontaneous remissions with few recurrences or complications (Bolt and Hughes, 1966; Parks, 1970). However, if complications do occur they are often serious and unheralded.

Thus, the aim of treatment in future may be to undertake elective surgery before serious complications occur provided that it is accomplished by an acceptable morbidity and mortality. It seemed relevant, therefore, to examine the results of surgical management of uncomplicated diverticular disease at St. Mark's Hospital in order to establish the safety and efficiency of surgery in such cases.

METHODS

The case notes of all the patients who underwent colonic resection for diverticular disease during the years 1964–9 were reviewed. The uncomplicated cases were examined specifically for their clinicopathological features and the nature of the resection, and these findings were correlated with the immediate and late results. In this paper 'uncomplicated' cases are defined by exclusion; by the absence of any recognized preoperative complication, namely paracolic abscess, perforation, fistula, or massive haemorrhage.

PATIENTS

There were 139 cases, of which 36 were complicated, leaving 103 uncomplicated cases for study. These were subdivided according to the indication for operation. Fifty-five patients were operated on for severe symptoms (group I), and 48 cases because cancer of the bowel could not be excluded preoperatively (group II). The colonoscope was not used during this period, but now colonoscopy may be expected to eliminate much of the diagnostic uncertainty in the latter type of case (Williams and Muto, 1972). The average age of the patients was 59 years (range, 48–77 years). There were 67 males and 36 females.

RESULTS

Clinicopathological Features.—

Group I.—Severe recurrent pain was the main symptom in all except 1 patient, who complained of severe mucous diarrhoea. Bleeding per rectum did not occur in this group.

The pain was either colicky or constant but varied considerably in character between patients. The constant pain was described as either nagging or burning and was mostly confined to the left side, although more generalized pain was experienced in several patients (sometimes referred to as reflex dyspepsia (Todd, 1970)). The colic was described as episodic by all the patients and usually as cramping. In many cases it was brought on by eating and was eased by defaecation.

Fifty-two of the 55 specimens resected showed marked muscular thickening and diverticula. The clinicopathological correlation of these cases is shown in *Table I*.

Table I.—CLINICOPATHOLOGICAL CORRELATION IN THE 55 PATIENTS IN GROUP I

SYMPTOMS	NO. OF CASES	PATHOLOGY		
		Diverticula	Muscle Thickening	Inflammation
Constant pain	31	31	29	20
Colicky pain	18	18	18	7
Both	5	5	5	3
Excess mucous diarrhoea	1	1	—	—

Table II.—CLINICAL FEATURES IN THE 48 PATIENTS IN GROUP II

Clinical Features	*No. of Cases*
Recurrent pain	11
Rectal bleeding	7
Both	13
Mass and pain	9
Mass and rectal bleeding	2
Mass, rectal bleeding, and pain	5
Mass and diarrhoea	1

Table III.—CLINICOPATHOLOGICAL CORRELATION IN THE 48 PATIENTS IN GROUP II

SYMPTOMS	NO. OF CASES	PATHOLOGY		
		Diverticula	Muscle Thickening	Inflammation
Constant pain	17	17	17	10
Colicky pain	11	11	11	7
Both	10	10	10	5
No pain	10	10	9	5

Group II.—Thirty-eight of the 48 patients in this group also had troublesome symptoms (*Table II*). Rectal bleeding refers to recurrent macroscopic bleeding, excluding the massive type. The masses which occurred did not have the definite clinical features of an abscess although the clinical differentiation between the complicated and the uncomplicated case becomes difficult here. The masses were felt either rectally or abdominally.

All but one of the specimens showed muscular thickening and diverticula. Seventeen specimens contained polyps. Inflammation was absent in 21 cases. All the specimens containing malignant neoplasms have been excluded. The clinicopathological correlation is shown in *Table III*.

Radiology.—In the symptomatic group barium-enema examinations demonstrated severe disease in 13 patients, moderate disease in 7, and a mild condition in 9 cases. In 7 patients there were strictures. The remaining 19 patients had not had a barium-enema examination in the 12 months preceding surgery.

In group II, barium-enema examinations demonstrated polypoid filling defects in 20 patients and short strictures in 15, both features adding to the clinical suspicion of possible cancer. In the remaining 13 cases diverticula alone were demonstrated.

Operative Procedure.—Eighty-eight of the 103 resections were performed in one stage. In all cases the anastomosis was to the upper rectum; however, the upper extent of the resection was variable (*Table IV*).

Table IV.—TYPE OF OPERATION PERFORMED FOR UNCOMPLICATED DIVERTICULAR DISEASE COMPARED WITH PRESENCE OF INFLAMMATION IN THE OPERATIVE SPECIMEN

OPERATION	NO. OF CASES	NO INFLAMMATION IN SPECIMEN	INFLAMMATION IN SPECIMEN
Sigmoid colectomy			
One-stage	63	32	31
Two-stage	7	1	6
Three-stage	2	0	2
Hartmann's operation	3	0	3
Left hemicolectomy			
One-stage	25	12	13
Two-stage	2	1	1
Three-stage	0	0	0
Synchronous combined excision	1	0	1

Table V.—TYPE OF OPERATION PERFORMED FOR UNCOMPLICATED DIVERTICULAR DISEASE COMPARED WITH OPERATIVE MORBIDITY

OPERATION	NO. OF CASES	COMPLICATIONS			
		Nil	Wound Infection	Surgical	Medical
Sigmoid colectomy					
One-stage	63	49	3	7	4
Two-stage	7	5	1	2	0
Three-stage	2	2	0	0	0
Hartmann's operation	3	2	1	0	1
Left hemicolectomy					
One-stage	25	12	4	6	4
Two-stage	2	2	0	0	0
Synchronous combined excision	1	0	0	1	0

Table VI.—OPERATIVE SEPSIS COMPARED WITH SEPTIC COMPLICATIONS AFTER OPERATION FOR UNCOMPLICATED DIVERTICULAR DISEASE

OPERATIVE SPECIMEN	NO. OF CASES	COMPLICATIONS		
		Wound Infection	Residual Abscess	Faecal Fistula
Inflammation present	57	9	6	0
Inflammation absent	46	4	1	1

One-stage resections were mainly performed in cases where sepsis was not apparent. Twenty-two one-stage resections had concomitant caecostomies performed by surgeons who were interested in this procedure. The three Hartmann's operations were followed later by colonic anastomoses. The synchronous combined excision was for what was considered at operation to be a malignancy. No patients underwent sigmoid myotomy.

Morbidity.—The operative morbidity is shown in *Table V.* The surgical complications were residual abscesses (5), acute retention of urine (3), prolonged ileus probably due to residual abscesses (2), wound dehiscence (2), secondary haemorrhage requiring blood transfusion (2), faecal fistula that closed spontaneously (1), and bowel obstruction (1). The medical complications were chest infections (4), deep-vein thrombosis (3), superficial thrombophlebitis (1), and myocardial infarction (1). A few patients had more than one complication.

Thus of the 103 resections, 72 (71 per cent) had no significant complication, 9 (9 per cent) had wound infections, 16 (16 per cent) had surgical complications, and 9 (9 per cent) had medical complications. The morbidity was almost identical in the two groups studied. *Table VI* demonstrates strikingly that operative sepsis still presents a problem despite newer antibiotics and techniques to combat it.

Mortality.—There were no operative deaths in this series.

Follow-up.—A complete follow-up was performed on all the cases who had troublesome symptoms prior to surgery and in whom the resected specimen had shown no evidence of inflammation, excluding those patients living outside the British Isles. The patients either were examined or replied to a postal questionnaire. The duration of the follow-up from the time of surgery varied from 1½ to 7 years.

Table VII.—RESULTS OBTAINED FROM THE FOLLOW-UP OF 41 PATIENTS WHO HAD HAD TROUBLESOME SYMPTOMS PRIOR TO SURGERY AND IN WHOM THE RESECTED SPECIMEN HAD SHOWN NO EVIDENCE OF INFLAMMATION

Result		*No. of Cases*
Asymptomatic		23
Symptomatic		14
L.I.F.* pain	5	
L.I.F. pain and constipation	3	
L.I.F. pain and diarrhoea	3	
Constipation only	1	
Diarrhoea only	2	
Died from unrelated disease		4
		41

* Left iliac fossa.

The results are shown in *Table VII.* Although 23 of the 41 patients were symptom-free, 14 patients had some residual symptoms. Pain, when it occurred, was always less severe than preoperatively and was located in the left iliac fossa. Constipation was defined as including those patients who required persistent medication. The diarrhoea remained unaltered from its preoperative state in 4 patients. In the fifth patient, who had had a left hemicolectomy, it was a new complaint of frequent bowel actions each day.

Thus, all the patients have improved considerably, but one-third still have residual symptoms of pain, constipation, or diarrhoea, Only 1 patient is dissatisfied and she is suffering from endogenous depression as well.

DISCUSSION

Elective surgery for symptomatic uncomplicated diverticular disease has been performed safely on 103 patients at St. Mark's Hospital in the past 5 years. There have been many advocates for elective surgery for severe recurring symptoms from diverticular disease over the past 20 years (Gilchrist and

Economou, 1955; Todd, 1955; Ransom, 1956; Colcock, 1958; Bacon and McGregor, 1961; Reilly, 1964; Goligher, 1967; Wilson, 1965, 1970). Even in 1953 Lloyd-Davies reported that two-thirds of his elective resections for diverticular disease were for recurrent obstructive symptoms. Arfwidsson (1964) recommended surgery for severe symptoms in patients with the pre-diverticular stage of the disease.

However, opposition to elective surgery in uncomplicated diverticular disease has been great because of the generally benign course of the disease (Bartlett and McDermott, 1953; Greene, 1957; Hughes, 1959; Thompson, 1959; Leigh, Judd, and Waugh, 1962; Bolt and Hughes, 1966; Kyle, 1968). Furthermore, it is clinically difficult to assess the severity of the symptoms (Thompson, 1970), and radiology is of little additional help (Fleischner, Ming, and Henken, 1965; Todd, 1970). However, as diverticular disease is increasing in Britain (Painter, 1969) and the patients are frequently active working people, it is becoming more important to provide relief of symptoms with minimal risk. In our opinion, elective surgery provides such treatment. Possibly a high-bulk diet will be an alternate treatment for these patients but its value has not yet been conclusively shown (Parks, 1970).

The lack of good correlation between resected specimens and preoperative symptoms is confirmed here (Hughes, 1969; Tagart, 1969). The large number of uninflamed specimens examined suggests that the preoperative pain is from the irritability of the thickened sigmoid muscle (Todd, 1965).

The predominant use of one-stage procedures is in keeping with recent surgical trends. However, multi-staged procedures were used when the ideal conditions for one-stage resections were not present.

The excellent immediate results contrast with a much higher incidence of morbidity reported from Belfast recently (Parks, 1970); however, the main indication for surgery in the latter series was the development of complications of the disease. Furthermore, our results demonstrate that elective surgery for symptoms only can be performed with a minimum of risks and thus invalidates such arguments against this type of surgery.

O'Bierne referred to the rectosigmoid sphincter in 1889, and more recently renewed interest has been shown in this region by other workers (Baker, 1970). All the resections in the present series included this region, whereas the proximal extent varied considerably. Including the rectosigmoid region in every resection may prevent anastomotic breakdown postoperatively and also recurrent symptoms later.

Our follow-up confirms that a significant number of patients have persistent symptoms after resection (Parks, 1970). However, in all but one case these were much less severe and the patients were pleased with the relief obtained by surgery. Whether a longer follow-up will demonstrate a recurrence of diverticula and severe symptoms is unknown but it is not suggested from this study.

We conclude that patients with severe persistent symptoms from uncomplicated diverticular disease can be safely treated by colonic resection with complete relief of symptoms in two-thirds of the patients and marked alleviation in the rest.

AN EVALUATION OF THE FLUORESCEIN TEST AND PHLEBOGRAPHY IN THE DETECTION OF INCOMPETENT PERFORATING VEINS

By K. G. CALLUM, L. J. GRAY, and M. LEA THOMAS
DEPARTMENTS OF SURGERY AND RADIOLOGY, ST. THOMAS'S HOSPITAL, LONDON

SUMMARY

A study has been made of the accuracy of clinical assessment, the fluorescein test, and phlebography in the localization of incompetent perforating veins using an extensive subfascial exploration as the method of assessing the results. Clinical assessment was found to be 48 per cent accurate, the fluorescein test 39 per cent accurate, and phlebography 69 per cent accurate. Although phlebography is the most useful investigation we do not feel that it can be used to restrict a full surgical exploration of the medial side of the leg. However, it is valuable in drawing attention to the presence of incompetent perforating veins on the lateral aspect of the legs which in this series occurred in 1 of every 2 patients.

THE importance of recognizing and locating incompetent perforating veins in the treatment of patients with varicose veins and venous ulcers is well established (Cockett and Elgan Jones, 1953; Sherman, 1964; Arnoldi, 1967). Their exact localization by clinical examination has proved to be difficult, most series showing an accuracy rate of 50–70 per cent (Townsend, Jones, and Williams, 1967; Beesley and Fegan, 1970; Patil, Williams, and Lloyd Williams, 1970). In view of this, various tests have been devised to localize these veins more accurately. Operative phlebography has been shown to be 92 per cent accurate (Townsend and others, 1967) and preoperative phlebography 81·5 per cent (Lea Thomas, McAllister, Rose, and Tonge, 1972). Thermography has an accuracy rate of between 94 per cent (Patil and others, 1970; Elem, Shorey, and Lloyd Williams, 1971) and 62 per cent (Noble and Gunn, 1972). There have been widely varying claims as to the accuracy of the fluorescein test. Thus, Chilvers and Thomas (1970) found it to be 96 per cent accurate, Elem and others (1971) 16 per cent, and Noble and Gunn (1972) 47 per cent. This paper compares the accuracy in predicting the presence of incompetent perforating veins by clinical assessment, the fluorescein test, and phlebography. The accuracy of the tests was assessed at operation using a long subfascial exploration on the medial side of the leg. This is the most reliable way of locating the maximum number of incompetent perforating veins actually present.

MATERIALS AND METHODS

Patients were selected for this trial when incompetent perforating veins (I.P.V.s) were suspected on clinical examination. The method of clinical examination was a combination of those described by Dodd and Cockett (1956) and Fegan (1967). The technique for the fluorescein test was that described by Chilvers and Thomas (1970). The phlebographic technique has been described in detail elsewhere (Lea Thomas and others, 1972). The operative procedure was to make a long incision on the medial side of the leg, from just above the medial malleolus to approximately the junction of the upper and middle thirds, with an extensive subfascial exploration as described by Dodd and Cockett (1956). In addition, any I.P.V.s indicated by any of our three methods of assessment which could not be reached through this incision were explored through separate 2–5-cm. incisions. This method was used to ligate many of the lateral I.P.V.s. Incompetence of the veins was judged by the Turner Warwick bleed-back test (Warwick, 1931). An I.P.V. was recorded as correctly predicted for any given test if it was located at operation within 2·5 cm. of the predicted site.

Although this was not a blind trial the results of each test and the operative findings were recorded on separate but identical diagram charts without reference to each other as far as possible. To analyse the results the diagrams were superimposed on one another.

RESULTS

The total number of legs operated upon was 45 in 33 patients. Twenty were right legs and 25 left. Twenty-one patients were female and 12 male, with an age range of 22–76 years (average 50·7 years).

There were 106 I.P.V.s found in the 45 legs operated on, an average of 2·4 per leg (1·8 on the medial and 0·5 on the lateral aspect).

The results of each method of detection of I.P.V.s have been expressed in two ways. First, the *detection accuracy* is the total number of correctly predicted I.P.V.s expressed as a percentage of the number of I.P.V.s found at operation. Secondly, the *incorrect prediction rate* is the number of incorrectly predicted I.P.V.s as a percentage of the total number of suspected I.P.V.s for that method of detection. The correctly predicted number of I.P.V.s found by clinical examination, the fluorescein test, and phlebography were 51, 41, and 73 respectively, giving a detection accuracy of 48, 39, and 69 per cent. The number of incorrectly predicted I.P.V.s was 27, 38, and 10 respectively, giving an incorrect prediction rate of 35, 48, and 12 per cent. These results are shown in *Table I*.

Medial and Lateral I.P.V.s.—*Tables II* and *III* show the results for the medial and lateral I.P.V.s. Posterior I.P.V.s have been included in the medial group as these were all ligated through the medial incision. These results suggest that clinical assessment and the fluorescein test are even less accurate on the lateral side of the leg. Phlebography gave consistently better results than either clinical assessment or the fluorescein test. The detection accuracy for phlebography was 68 per cent on the medial side and 74 per cent on the lateral side.

Table I.—OVERALL RESULTS OF METHODS OF DETECTION OF I.P.V.s

TEST	NO. OF PERFORATORS*			DEGREE OF ACCURACY (per cent)	
	Suspected Sites	Correctly Predicted	Incorrectly Predicted	Detection Accuracy	Incorrect Prediction Rate
Clinical	78	51	27	48	35
Fluorescein	79	41	38	39	48
Phlebography	83	73	10	69	12

Total number of I.P.V.s found at operation was 106.

Table II.—RESULTS OF METHODS OF DETECTION OF I.P.V.s ON THE MEDIAL SIDE

TEST	NO OF PERFORATORS			DEGREE OF ACCURACY (per cent)	
	Suspected Sites	Correctly Predicted	Incorrectly Predicted	Detection Accuracy	Incorrect Prediction Rate
Clinical	72	47	25	57	35
Fluorescein	64	34	30	41	47
Phlebography	65	56	9	68	14

Total number of I.P.V.s found at operation was 83.

Table III.—RESULTS OF METHODS OF DETECTION OF I.P.V.s ON THE LATERAL SIDE

TEST	NO. OF PERFORATORS			DEGREE OF ACCURACY (per cent)	
	Suspected Sites	Correctly Predicted	Incorrectly Predicted	Detection Accuracy	Incorrect Prediction Rate
Clinical	6	4	2	17	33
Fluorescein	15	7	8	30	53
Phlebography	18	17	1	74	6

Total number of lateral I.P.V.s found at operation was 23.

Table IV.—EFFECTS OF SKIN HEALTH ON THE DETECTION ACCURACY OF I.P.V.s

TEST	DETECTION ACCURACY (per cent)	
	Healthy Skin	Unhealthy Skin
Clinical	53	61
Fluorescein	40	42
Phlebography	67	68

Effects of Skin Health.—The skin was considered unhealthy if there was induration of the lower half of the leg, combined with pigmentation and/or scarring from previous ulceration. Comparison of the accuracy of each method in patients with healthy or unhealthy skin is shown in *Table IV*. The state of the skin did not appear to affect the accuracy of the tests.

Position of the I.P.V.s.—The distribution of all the I.P.V.s is shown in *Figs.* 1 and 2. On the medial side (*Fig.* 1) the extent of the incision is indicated by the lower two arrows. The level which could be easily inspected subfascially to detect and ligate I.P.V.s above the upper limit of the incision is indicated by the uppermost arrow. Only the two highest I.P.V.s required a separate incision to ligate them.

Wound Healing.—The patients were allowed home as soon as the wounds were soundly healed. The average stay in hospital following operation was 12 days (range, 5–28 days). Only 6 out of the 33 patients were in hospital for longer than 12 days. In 5 of these patients the delay was due to staphylococcal wound infection. The remaining patient's discharge was delayed because of a skin-graft applied at the time of operation. There was only 1 case of superficial necrosis of the skin which did not delay the patient's discharge. No patient had full-thickness skin-loss.

DISCUSSION

In many of the other comparative studies of the accuracy of methods of detecting I.P.V.s only small incisions have been made at the suspected sites (Townsend and others, 1967; Patil and others, 1970; Elem and others, 1971; Noble and Gunn, 1972). We believe that only a long subfascial exploration can provide a really accurate assessment of the presence or absence of I.P.V.s, and all the legs in this series have been explored through such an incision on the medial side.

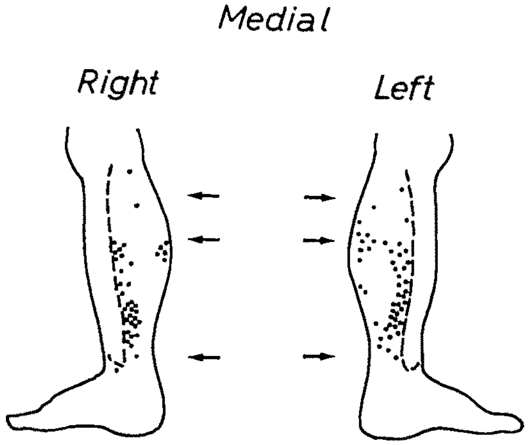

FIG. 1.—Distribution of the I.P.V.s found at operation on the medial side of the leg. The lower two arrows show the extent of the incision, while the upper arrow indicates the level which can be inspected easily.

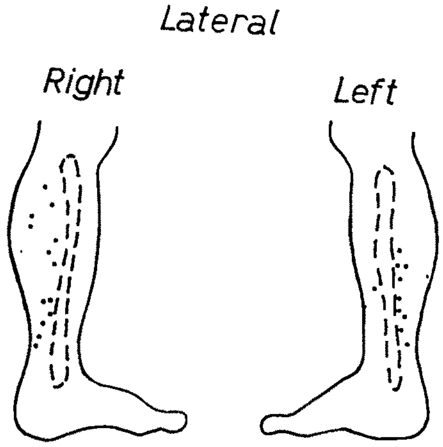

FIG. 2.—Distribution of the I.P.V.s found at operation on the lateral side of the leg.

Clinical assessment of the site of I.P.V.s was accurate in only 48 per cent of cases, a result similar to other reports (Beesley and Fegan, 1970; Noble and Gunn, 1972). However, the decision to explore the perforator region and therefore include a patient in this series was a clinical one and only 1 leg out of the 45 explored was found to have no I.P.V.s at operation. Thus, clinical examination appears to be reliable in indicating the presence of I.P.V.s but is unreliable in showing their exact site.

We had hoped that this series would confirm the good results of the fluorescein test reported by Chilvers and Thomas (1970), as it is simple, safe, and quick to perform. However, our detection accuracy of 39 per cent and the results of Elem and others (1971) and Noble and Gunn (1972) suggest that this method is not sufficiently accurate and that it results in too high an incidence of incorrect predictions (48 per cent). Moreover, it did not show a higher degree of accuracy in legs with healthy skin as was previously suggested.

Phlebography was shown to be the most reliable means of investigation and was particularly useful in demonstrating lateral I.P.V.s. The incidence of incorrect predictions might be expected to be low since in the technique that we use the contrast medium is seen to pass from the deep to the superficial veins on television screening. This contrasts with the fluorescein test which has the inherent inaccuracy of being a blind technique, as the route by which it reaches the skin cannot be directly visualized.

A criticism of phlebography is that the sites of I.P.V.s shown on radiographs are difficult to relate to the patient's leg. In fact, we were able to locate them accurately in 69 per cent of the cases. A further advantage of phlebography over other methods is that it provides additional information about the presence or absence of incompetent valves or obstruction of the deep veins. However, phlebography failed to detect 31 per cent of the I.P.V.s found at operation, so that thorough surgical exploration cannot safely be replaced by multiple small incisions over suspected sites.

Thermography was not used because we did not have access to the necessary equipment. It is not standard equipment in most hospitals and we therefore felt that it was unlikely to become a generally used method.

Using the long medial incision with subfascial exploration (Dodd and Cockett, 1956) we were able to locate and ligate virtually all medial and posterior I.P.V.s (*Fig.* 1). On a number of occasions this incision provided sufficient exposure to ligate lateral I.P.V.s. This operation is often criticized because of the long scar that it leaves and because of the risk of flap necrosis. The latter can be largely avoided by delaying operation until the patient's legs have been properly prepared by a period of using efficient firm supportive bandages and by careful atraumatic technique and suturing the skin without tension. We had no cases of significant flap necrosis and have not found the long scar to be any more unsightly than a number of small scars produced by multiple incisions.

In conclusion we feel that phlebography is the best method of preoperative detection of I.V.P.s but that it is not sufficiently accurate to replace an adequate surgical exploration. It is most useful in assessing people with recurrent varicose veins or venous ulceration, and in cases which are difficult to assess clinically, particularly when it is felt that lateral perforators may be present.

Acknowledgements.—We would like to thank Professor J. B. Kinmonth, Mr. F. B. Cockett, and Professor N. L. Browse for allowing us to study patients who were under their care. We would also like to thank Professor Browse for his valuable advice and criticism.

GASTRIC SECRETORY RESPONSE TO INSULIN INFUSION IN VAGOTOMIZED SUBJECTS*

BY D. C. CARTER, R. R. DOZOIS, AND J. R. KIRKPATRICK

DEPARTMENT OF CLINICAL SURGERY, THE ROYAL INFIRMARY, EDINBURGH

SUMMARY

The results of the insulin-infusion test carried out after vagotomy in 50 patients are presented. In 25 cases a comparison was made between the insulin-infusion test and the conventional Hollander test. A good correlation was observed between the peak acid output induced by insulin infusion and that noted during the Hollander test. It is concluded that with the present criteria for interpretation the insulin-infusion test may be no better than the Hollander technique for defining patients at risk of recurrent dyspepsia. However, the small amounts of insulin used, the gradual lowering of blood-glucose, and the reduced incidence of profound hypoglycaemia which attend the insulin-infusion test suggest that this technique should be adopted for the assessment of vagotomy in preference to the potentially dangerous Hollander test.

THE potentially dangerous Hollander test (Hollander, 1946; Read and Doherty, 1970) has led us to develop an insulin-infusion test aimed at reducing the severity of hypoglycaemic symptoms (Carter, Dozois, and Kirkpatrick, 1972).

The present investigation was designed to study the patterns of the gastric secretory response to an insulin infusion in vagotomized subjects and to compare the acid response to the insulin-infusion test with that produced by the Hollander test. A preliminary report of this work has been presented elsewhere (Dozois, Carter, and Kirkpatrick, 1972).

MATERIAL AND METHODS

The insulin-infusion test was carried out in 50 patients at least 2 months after vagotomy and a drainage procedure. Twenty-five of these 50 patients were also subjected to the Hollander test. The latter test was also conducted at least 2 months after vagotomy and within 2 months of the insulin-infusion test. The subjects ranged in age between 20 and 81 years.

The technique of the insulin-infusion test has previously been reported in detail (Carter and others, 1972). Following a 12-hour overnight fast a nasogastric tube was passed and its ideal gastric position determined by the method of Hassan and Hobsley (1970). Basal gastric secretions were collected for 30 minutes before commencing insulin infusion (0·04 U. per kg. per hr.). Gastric juice was then collected at 15-minute intervals during the 3-hour infusion.

The Hollander test was performed in the usual manner. Following collection of basal secretions a single rapid injection of insulin (0·2 U. per kg.) was given intravenously and gastric juice was collected at 15-minute intervals for 2 hours.

During both tests samples of venous blood were obtained just prior to and every 30 minutes following the start of the infusion (or the injection of insulin). Blood-glucose levels were determined by a glucose-oxidase method using an Autoanalyser.

Each sample of gastric juice was measured in terms of volume (ml.), acid concentration (mEq./l.), and acid output (mEq.). All titrations were made to *p*H 7·0 with 0·1 *N* NaOH solution, using an automatic titrator and a glass electrode (Radiometer, Copenhagen).

DEFINITION OF TERMS

The following parameters of acid secretion were studied:—

1. **Plateau Acid Output (P.$_L$A.O.).**—The sum of the four highest consecutive 15-minute outputs during the infusion, expressed as mEq./hr.

2. **Peak Acid Output (P.A.O.)** (Baron, 1963).—The sum of the two highest consecutive 15-minute outputs during the infusion (or following insulin injection in the Hollander test) multiplied by 2, expressed as mEq./hr.

3. **Mean Plateau Acidity (M.P.$_L$A.).**—The mean concentration of the four highest consecutive

---

* Based on a communication to the Surgical Research Society, July, 1972.

15-minute concentrations during the infusion, expressed in mEq./l.

With regard to blood-glucose the parameters studied were:—

1. Plateau Blood-glucose.—The mean of all blood-glucose readings during the second and third hours of insulin infusion, expressed in mg. per 100 ml.

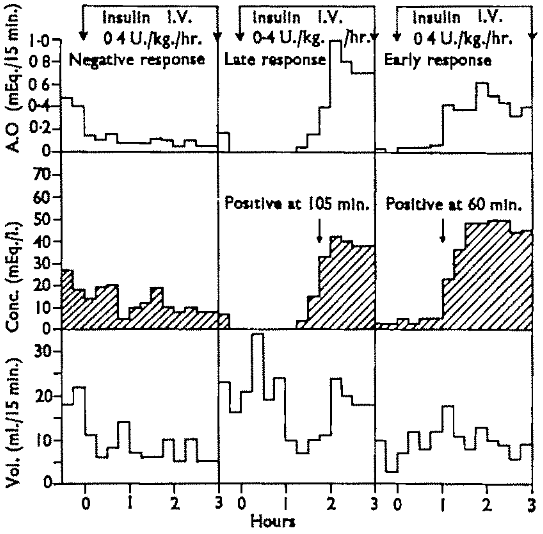

FIG. 1.—Patterns of gastric secretory response to the insulin-infusion test. Positivity of response is based on criterion of mean plateau acidity (*see* text).

2. Lowest Blood-glucose.—The lowest blood-glucose value observed during the insulin infusion (or after insulin injection), expressed in mg. per 100 ml.

Positive Response.—The acid response during the Hollander test was defined as 'positive' when the acid concentration following the injection of insulin was 20 mEq./l. or more in excess of basal values (10 mEq./l. if basal achlorhydria). This positive response was further subdivided into 'early' or 'late' depending on whether it occurred during the first or the second half of the 2-hour test (Burns, Cheng, Cox, Payne, Spencer, and Welbourn, 1969).

With the insulin-infusion test the acid response was considered 'positive' when the mean plateau acidity was at least 20 mEq./l. greater than the mean concentration of basal secretion. This positive response was further subdivided into 'early' or 'late' according to whether it took place during the first or second half of the 3-hour test (*Fig.* 1).

RESULTS

1. Patterns of Gastric Secretory Response to the Insulin-infusion Test.—Twenty-two of the 50 subjects studied had a negative response to the insulin-infusion test, while 15 subjects had an early positive response and 13 subjects a late positive response.

The P.$_{\text{I}}$A.O. of subjects with an early positive response (mean 10·66 mEq. ± S.D. 9·99) and with a late positive response (mean 7·28 mEq. ± S.D. 6·66) did not differ significantly ($P > 0{\cdot}30$, Student's *t*-test for unpaired data), but the mean P.$_{\text{I}}$A.O. of either group differed significantly from that of the negative-response group (mean 0·65 mEq. ± S.D. 0·75, $P < 0{\cdot}001$).

The mean plateau blood-glucose was 26·0 mg. per 100 ml. (± S.D. 11·0) and the mean lowest blood-glucose was 23·3 mg. per 100 ml. (± S.D. 10·6) in the 25 patients also subjected to the Hollander test.

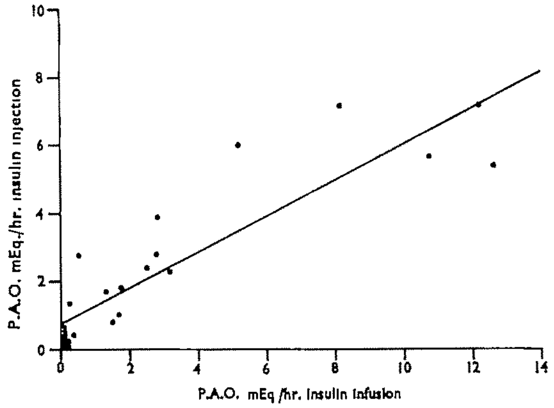

FIG. 2.—Correlation between peak acid output in response to insulin infusion and to the Hollander test in 25 subjects ($r = 0{\cdot}89$; $n = 25$; $P < 0{\cdot}001$; $y = 0{\cdot}53x + 0{\cdot}69$.)

Table I.—PATTERNS OF ACID RESPONSE TO BOTH INSULIN TESTS IN 25 SUBJECTS

INSULIN-INFUSION TEST	HOLLANDER INSULIN TEST		
	Negative	Early Positive	Late Positive
Negative	13	—	3
Early positive	1	2	—
Late positive	—	1	5

	P.A.O		L.B.G	
	I.I.T	H.T.	I.I.T.	H.T.
Mean	2·73	2·14	23·3	11·4
S.D.	3·9	2·4	10·6	5·3
P*	>0·4		<0·001	

I.I.T., Insulin-infusion test. H.T., Hollander test.
* Student's *t*-test.

2. Comparison between the Insulin-infusion Test and the Hollander Test.—In the 25 subjects where both tests were performed the patterns of acid response were almost identical. Of the 16 patients showing a negative response to insulin infusion, 13 showed a negative response to the Hollander test. Eight of the 9 patients with a positive response to insulin infusion also gave a positive response to the Hollander test. These figures are amplified in *Table I.* In 4 of the 5 cases where a discrepancy was observed between the two tests, both tests had been performed within 6 months of vagotomy. The P.A.O. during infusion correlated significantly ($P < 0{\cdot}001$) with the P.A.O. during the Hollander test (*Fig.* 2) and the magnitude of the acid response was similar in the two tests (*Table II*).

The mean lowest blood-glucose for the 25 Hollander tests was 11·42 mg. per 100 ml. (± S.D. 5·3) which was significantly lower ($P < 0{\cdot}001$, Student's *t*-test for paired data) than the lowest blood-glucose obtained with the insulin-infusion test (23·3 mg. per 100 ml. ± S.D. 10·6).

DISCUSSION

The Hollander insulin test is controversial in its interpretation (Stempien, 1962) but remains the only valuable postoperative means of evaluating the completeness of vagotomy. The potential dangers of extreme hypoglycaemia (i.e., < 15 mg. per 100 ml.) with its associated unpleasant symptoms have recently received attention (Read and Doherty, 1970). A survey of 220 Hollander tests performed in our own gastric secretion laboratory has revealed lowest blood-glucose values of 10 mg. per 100 ml. or less in more than half of the tests. With the object of reducing the severity of hypoglycaemia the continuous insulin-infusion test has been developed. In healthy subjects a dose of 0·04 U. per kg. per hr. of insulin was found to produce the highest acid secretion compatible with an acceptably low level of hypoglycaemic symptoms (Carter and others, 1972).

In vagotomized subjects three types of response to insulin infusion have been observed. The negative response was associated with little or no acid response and probably represents complete gastric vagal denervation. The subdivision of the positive response into early and late categories was suggested by the observation that plateau acid secretion occurred in all subjects with intact vagi within 90 minutes of commencing infusion. However, this division seems unlikely to be of prognostic value in that both groups appeared equally capable of secreting significant amounts of acid. This conclusion has already been reached from the results of the Hollander test because both early and late responses are found in subjects with intact vagi (Burns and others, 1969) and recurrent ulcers occur not infrequently in patients showing a late response (Johnston, Thomas, Checketts, and Duthie, 1967).

The magnitude of the acid response to both types of test proved to be almost identical in individual subjects despite the fact that less profound hypoglycaemia followed insulin infusion. The symptom scoring method (Carter and others, 1972) used routinely to assess the side-effects of the insulin-infusion test could not be applied to the Hollander test so that an objective comparison of the two tests is not possible in this context. However, every patient considered the insulin-infusion technique to be less unpleasant and this is in agreement with the findings of Girvan, Baron, Spencer, and Hansky (1973) in their appraisal of the two techniques. With regard to the interpretation of the two tests, complete agreement was noted in 20 of the 25 subjects (*Table I*). Of the 5 subjects showing differences between the tests, the major discrepancy noted was that 3 subjec showed a negative response to the insulin-infusio test, whereas a subsequent Hollander test w interpreted as positive. None of these patients h experienced recurrent dyspepsia to date. Of t other 2 subjects showing differing responses, o differed merely in the timing of the positive respons whereas the remaining patient exhibited an u equivocally early positive response to insulin infusio while the Hollander test carried out 2 mont previously had been negative. Neither of the patients has recurrent dyspepsia. The cause of the discrepancies is, at present, uncertain but in 4 cas the tests were performed within 6 months of surge and in view of the known lack of stability of t gastric response to insulin within this period (Smit Gillespie, Elder, Gillespie, and Kay, 1972) it will b necessary to repeat the tests at a later date. It mu be borne in mind, however, that the Hollande criterion is *arbitrary* and we are currently attemptin to apply alternative criteria based on changes in aci output to relate the interpretation of the insuli infusion test to the subsequent clinical course of t patient. Even if the insulin-infusion test were t remain equal to the Hollander test in the determin tion of inadequate vagotomy, the minimal side-effec and less profound hypoglycaemia which result fro the small doses of insulin infused justify the routin use of the infusion technique in preference to t potentially dangerous conventional procedure.

Acknowledgements.—The authors gratefull acknowledge the support and advice of Profess A. P. M. Forrest, the assistance of Dr. I. W. Perc Robb and the Biochemistry Department, Roy Infirmary, Edinburgh, in the blood-glucose esti mations, and the invaluable help of Staff Nurse Dale in the performance of the insulin tests. Th assistance of Dr. R. J. Prescott in analysis of the dat was gratefully received.

During the performance of this work R. R. was in receipt of the R. S. McLaughlin Foundatio Fellowship.

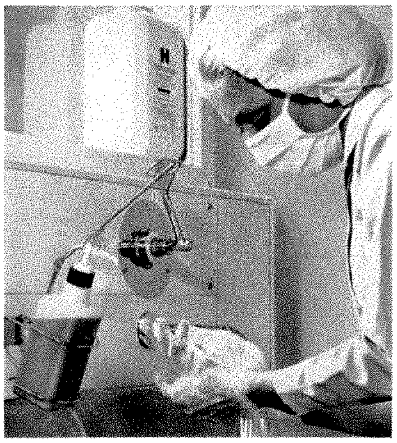
hibiscrub



Antibacterial Activity

From the bacteriological point of view the demand is for a surgical scrub which combines maximum antibacterial activity with pronounced residual effect.

'Hibiscrub' fulfills these requirements. It is not only rapidly effective against both gram positive and gram negative organisms but also exhibits good residual activity – a major advance in the development of surgical scrubs.

Hand Care

The effect of prolonged usage on the hands of surgical staff is a critical factor in the acceptability of any surgical scrub. Sensitivity reactions, excessive detergency etc., can lead to the abandonment of certain scrub regimes.

'Hibiscrub' is positively pleasant to use – nurses using it regularly have reported on the excellent condition of their hands.

A NEW METHOD FOR DETECTING CLOTTING IN SHUNTS USED FOR HAEMODIALYSIS

By J. R. SALAMAN, J. CHU, and D. L. CROSBY

KIDNEY RESEARCH UNIT FOUNDATION INSTITUTE OF RENAL DISEASE AND RENAL DIALYSIS UNIT, CARDIFF ROYAL INFIRMARY

SUMMARY

Thermographic materials were used to monitor the rate of blood-flow through haemodialysis shunts. In an experimental and clinical study it was found that these materials would indicate by a change in colour when blood-flow through a shunt had become diminished or had ceased altogether. As a result clotting episodes were rapidly and easily diagnosed by the patients, and subsequent declotting of the shunts was readily achieved.

THE Silastic arteriovenous shunt has served the needs of chronic haemodialysis for many years. It provides a ready means of access to the patient's circulation whenever dialysis is required but suffers from the disadvantage that it is liable to become thrombosed. For this reason it has been largely replaced by the subcutaneous arteriovenous fistula, which is less liable to develop this complication. Unfortunately it is not possible to establish a fistula in every case and for these patients the shunt is the only alternative. In an attempt to extend the working life of these shunts we have examined possible ways of warning patients when clotting of the shunt is taking place, for early attention to a clotted shunt can usually result in the blood-flow being restored.

A clotted shunt often remains unnoticed by a patient for some hours, although occasionally some pain in the shunted limb may draw his attention to it. Unfortunately this is not a reliable symptom and in most instances clotting is quite painless. Shunt flow rates may be measured with conventional flow meters, but this is not a practical procedure when continuous monitoring is required. The temperature of a well-functioning shunt is very close to that of the blood that is entering it, and since diminished flow or clotting will be accompanied by a fall in shunt temperature we have attempted to use temperature changes as indices of blood-flow. In place of conventional thermometers we have employed thermographic materials to measure shunt temperature since variations in temperature produce an easily recognized change in the colour of the material.

MATERIALS AND METHODS

Samples of thermographic material were obtained from the National Cash Register Corporation. They comprised a layer of micro-encapsulated liquid crystals of a cholesterol derivative applied to a paper or plastic base. Small rectangles of material ('spots') were cut out with scissors and attached to the arterial limb of a shunt with Silastic glue. The material was then protected by covering it with a single layer of cellophane tape (*Fig.* 1). Four types of thermographic material were studied. Each had a defined temperature within which the changes in colour would take place (*Table I*). At the upper end of the range the material would appear blue, and on cooling would then become successively green, red, and black. The materials were first investigated in the laboratory and then the two that had proved most promising were used for a clinical study.

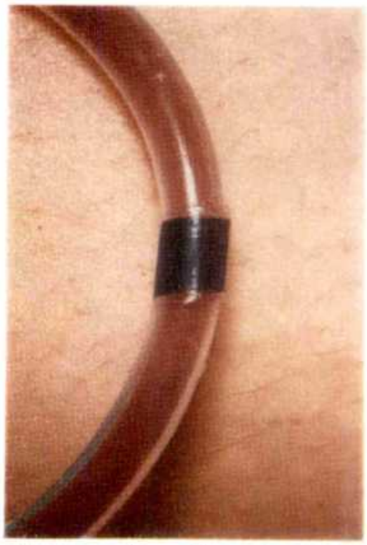

FIG. 1.—A thermographic monitor in place on a haemodialysis shunt. The monitor is registering a blue colour indicating good blood-flow within the shunt.

Table I.—TEMPERATURE RANGE OF THE THERMOGRAPHIC PAPERS USED IN THE PRESENT EXPERIMENTS

Code No.	*Temperature Range* (°C.)
R29	29–33
R33	33–37
R35	35–38
W630	Unspecified

Laboratory Experiment.—Thermographic spots were attached to a segment of shunt tubing which was placed inside a glass condenser. Blood at 37° C. was run through the tubing and the surrounding air temperature was maintained at either 22° C. ('room temperature') or 10° C. ('outside temperature') by pumping water at the correct temperature through the jacket of the condenser. The rate of blood-flow through the shunt was altered by means of a screw-clip on the blood line, and the colour of the thermographic spots was noted at different rates of flow.

Clinical Study.—Twenty-two patients on regular haemodialysis were studied. Thermographic spots of paper R33 were attached to the arterial side of their shunts and the patients were told to observe these spots regularly and to report to the hospital if the colour changed from the normal dark blue to green or black. After 3 months the paper R33 was replaced with paper R35 and the study was continued for a further 3 months.

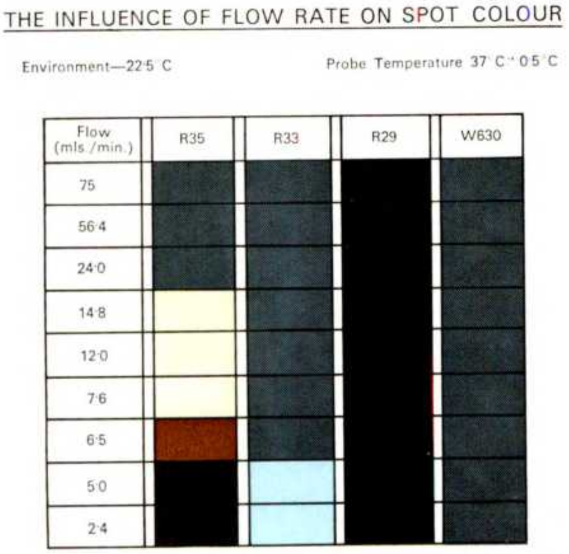

FIG. 2.—The results of *in vitro* experiments in which the colour of four thermographic materials was recorded at different rates of blood-flow. R35 exhibited the greatest change in colour whereas the other materials remained black or blue (reproduced here as a grey).

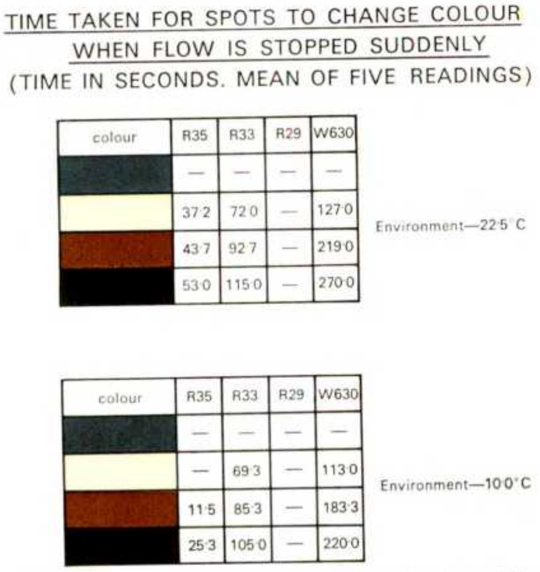

TIME TAKEN FOR SPOTS TO CHANGE COLOUR WHEN FLOW IS STOPPED SUDDENLY (TIME IN SECONDS. MEAN OF FIVE READINGS)

Environment—22·5 C

colour	R35	R33	R29	W630
🟦	—	—	—	—
⬜	37·2	72·0	—	127·0
🟫	43·7	92·7	—	219·0
⬛	53·0	115·0	—	270·0

Environment—10·0 C

colour	R35	R33	R29	W630
🟦	—	—	—	—
⬜	—	69·3	—	113·0
🟫	11·5	85·3	—	183·3
⬛	25·3	105·0	—	220·0

FIG. 4.—The results of an experiment to determine how quickly after arresting the blood-flow four thermographic materials would change colour.

RESULTS

Experimental.—The results obtained from the laboratory experiments are shown in *Figs.* 2, 3, and 4. It will be seen that at an environmental temperature of 22 or 10° C., R35 registered a change in colour when the blood-flow through the shunt was reduced. It was apparent, however, that in a cool environment R35 never attained a blue coloration even when the blood-flow was in excess of 80 ml. per minute (*Fig.* 3). When the flow of blood was arrested suddenly, a change in colour was noted first in R35 and then later in R33 and W630 (*Fig.* 4). R29 behaved erratically and for the most part remained black. It was clear that R35 and R33 were the most sensitive of the four materials tested and these two were selected for the clinical study.

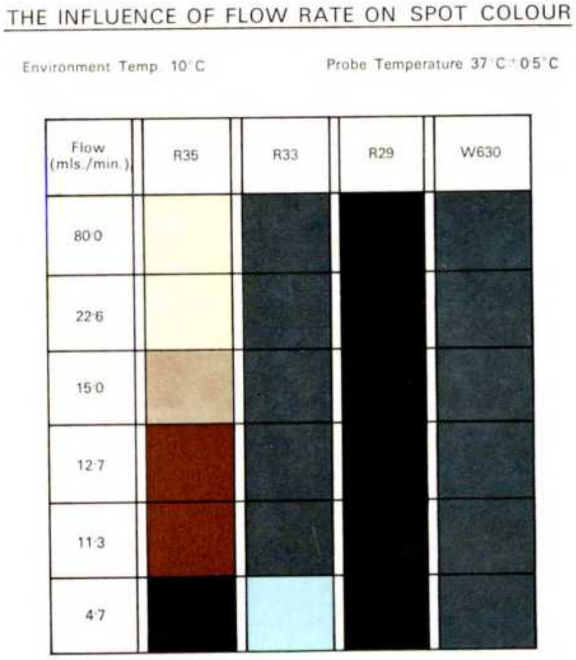

FIG. 3.—The effect of temperature on the performance of four thermographic materials. The experiment was the same as depicted in *Fig.* 2, but the environmental temperature was lowered to 10 C.

Table II.—CLINICAL EXPERIENCE WITH THERMOGRAPHIC MONITORS OF SHUNT FLOW RATES

	TEST MATERIAL	
	R33	R35
No. of shunts studied	20	22
No. of shunts which clotted	10	9
No. of clotting episodes	20	16
No. of clotting episodes detected by the material	20	16
No. of clotting episodes treated successfully	18	14

Clinical.—During the clinical study 19 patients had a total of 36 clotting episodes (*Table II*). In each instance clotting was accompanied by the appropriate change in colour of the shunt spot, and to most of the patients this was the first indication that clotting had occurred. Materials R33 and R35 seemed to be equally effective in registering this event, and in most cases subsequent declotting of the shunt was accomplished without difficulty. When functioning shunts were examined in a cool environment it was frequently noted that the spots of R35 had become green. This was to be expected (*see above*) and the patients were advised to re-examine their shunts in warmer surroundings. Two patients (one with R35 and the other with R33) noted a change in the spot colour before clotting had occurred. These changes were indicative of a poor blood-flow, and by the time the patients had arrived in hospital, clotting had taken place. As a result of this timely action, declotting of these shunts was easily achieved.

DISCUSSION AND CONCLUSION

The thermographic spot provides the dialysis patient with a useful guide as to the rate of blood-flow within his shunt. Not only does it inform him when clotting has occurred, but it can also indicate when flow rates have fallen to levels at which clotting has become imminent. By taking appropriate action at this early stage it should prove possible to extend considerably the working life of many haemodialysis shunts.

THE USE OF GASTROGRAFIN IN THE RELIEF OF RESIDUAL AND LATE BOWEL OBSTRUCTION IN CYSTIC FIBROSIS

By J. F. McPARTLIN, J. A. S. DICKSON,* and V. A. J. SWAIN
THE QUEEN ELIZABETH HOSPITAL FOR CHILDREN, LONDON

SUMMARY

The incidence, pathology, and standard surgical management of meconium ileus are described. In uncomplicated cases an 80 per cent survival rate can be expected. The indications for instillation of Gastrografin into the bowel as an alternative to operation, either as an enema or through an ileostomy, are discussed. Three instances of its successful use to relieve late obstruction are reported. The probable method of action of Gastrografin is suggested, and the precautions to be observed in its use are listed. By avoiding the pulmonary and surgical problems associated with laparotomy the use of Gastrografin should decrease morbidity and mortality.

MECONIUM obstruction in the ileum occurs in between 10 and 15 per cent of children with fibrocystic disease (Di Sant'Agnese, 1956; Santulli, 1969; McPartlin, Dickson, and Swain, 1972). The excessively tenacious meconium produced as a result of the defective pancreatic and intestinal secretions accumulates in and obstructs the mid-ileum, which is dilated and hypertrophied; the distal ileum is firmly contracted on small plugs of grey mucus; the colon is empty. The dilatation of loops of proximal bowel is the cause of complications, ranging from simple volvulus to atresia, gangrene, and peritonitis, in up to 50 per cent of cases.

Table I.—RESULTS OF SURGICAL TREATMENT FOR MECONIUM ILEUS REPORTED IN THE LITERATURE

Present series (1962–70)	Queen Elizabeth Hospital, London	24	17	30	2	15	63

Until recently the only hope of relief in established obstruction was operation combined with intensive care to prevent associated respiratory problems. In most published series not more than 50 per cent of children survived the initial surgical treatment and only 30 per cent at best survived for 1 year (*Table I*). Recent results have been more encouraging, with a long-term survival of 62·5 per cent (80 per cent in uncomplicated cases) (McPartlin and others, 1972). Unpublished information from other centres suggests that this figure may be more representative of contemporary experience. These relatively good results are probably due to improvements in surgical technique and the recognition of the importance of intensive medical care. The most important improvement in surgical management appears to have been the adoption of the Bishop-Koop resection with Roux-en-Y anastomosis (Bishop and Koop, 1957; *Fig.* 1). In this technique the dilated obstructed ileum is resected and the end of the proximal segment is anastomosed to the side of the distal segment, the open end of which is brought to the surface of the abdomen as an ileostomy. Clearing the bowel can be helped by washing out the meconium and mucus plugs with the detergent Tween 80, 1 per cent in tyrode solution. The stoma acts as a safety valve through which the proximal bowel may decompress itself while the inspissated meconium and mucus plugs are digested and the unexpanded distal bowel assumes its normal size and function. By reducing the copious loss of fluid and electrolytes and the digestion of the abdominal wall seen in other forms of ileostomy this technique reduces morbidity and mortality.

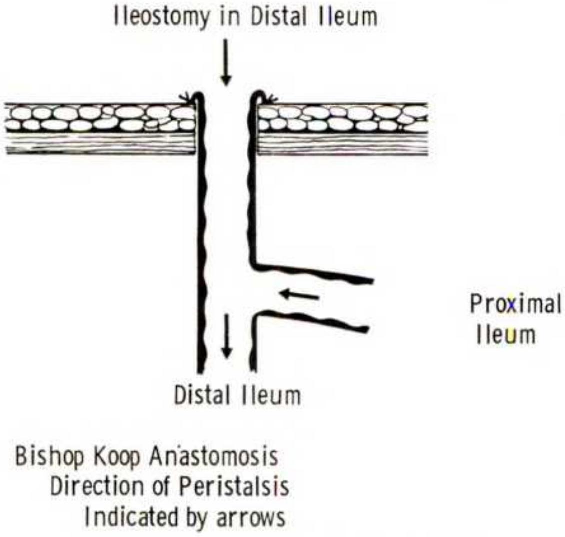

FIG. 1.—Diagram of Bishop-Koop anastomosis.

Noblett (1969), while investigating a patient with uncomplicated meconium ileus, observed relief of the obstruction from a diagnostic Gastrografin (Schering) enema. In this child and 3 subsequent children with meconium ileus the obstruction was relieved and operation avoided by the use of Gastrografin enemas. Similar results have been reported from other centres (Wagget, Bishop, and Koop, 1970; Lillie and Chrispin, 1972) and suggest that the use of Gastrografin or a similar substance (Frech, McAlister, Ternberg, and Strominger, 1970) should have a place in the primary management of meconium ileus.

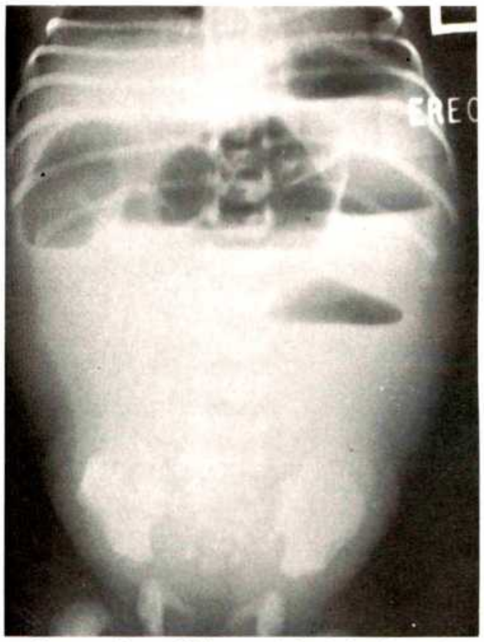

FIG. 2.—*Case* 1. Plain erect abdominal radiograph.

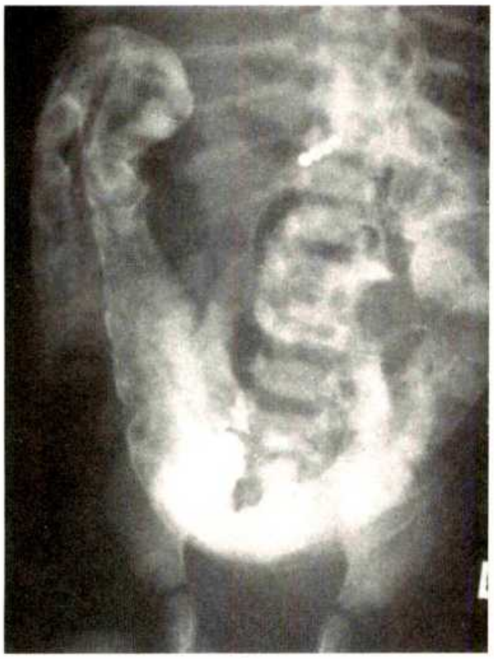

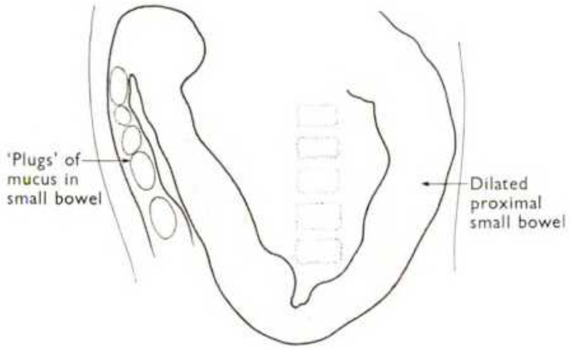

FIG. 3.—*Case* 1. A, Supine radiograph after instillation of Gastrografin. B, Explanatory diagram.

In a number of cases successful relief of meconium ileus is followed later by a recurrent intestinal obstruction due to inspissated faeces (Nixon, 1955; Cordonnier and Izant, 1963). The management of this is often difficult and the use of Gastrografin appears to offer a simple alternative to operation.

CASE REPORTS

Case 1.—A full-term male infant of birth weight 3·15 kg. developed abdominal distension and bilious vomiting shortly after birth. A radiograph (*Fig.* 2) showed a high intestinal obstruction. Laparotomy on the day of birth revealed an ileal obstruction due to an adhesion band with an underlying atresia with incipient gangrene at this level, and a meconium obstruction distally. The atretic and distended loop of bowel was excised and a Bishop-Koop anastomosis was performed. Although a little fluid was passed from the ileostomy there was no action per rectum. By the fourth postoperative day the abdomen was distended and he began to vomit again. A radiograph showed a high small-bowel obstruction.

On the fifth day 5 ml. of Gastrografin were instilled into the ileostomy. On the radiographs this outlined a distal blockage with meconium plugs (*Fig.* 3). A few hours later the patient began to pass meconium per rectum for the first time. He has had no further obstructive episodes and remains well.

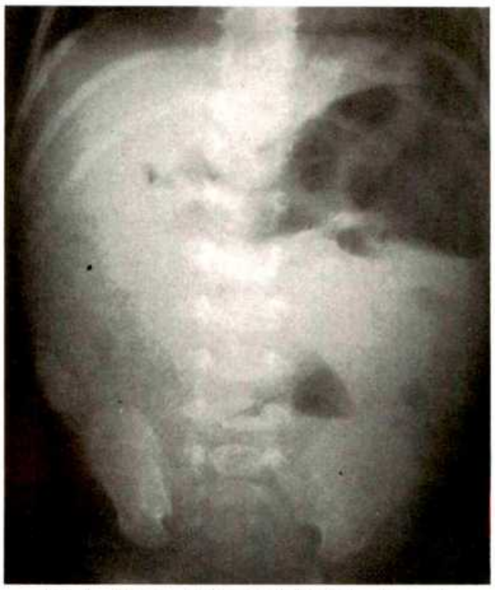

FIG. 4.—*Case* 2. Plain erect abdominal radiograph.

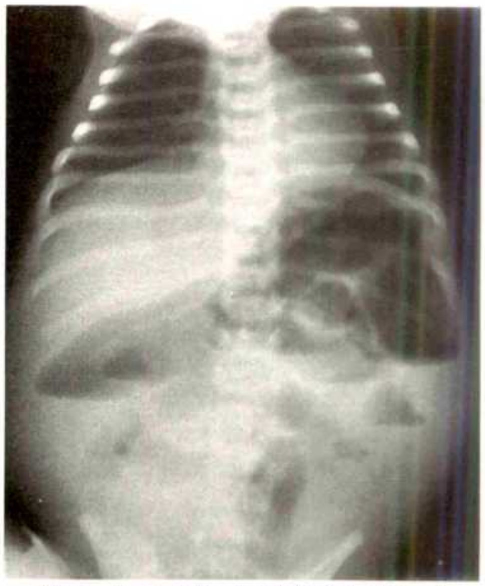

FIG. 5.—*Case* 3. Plain erect abdominal radiograph.

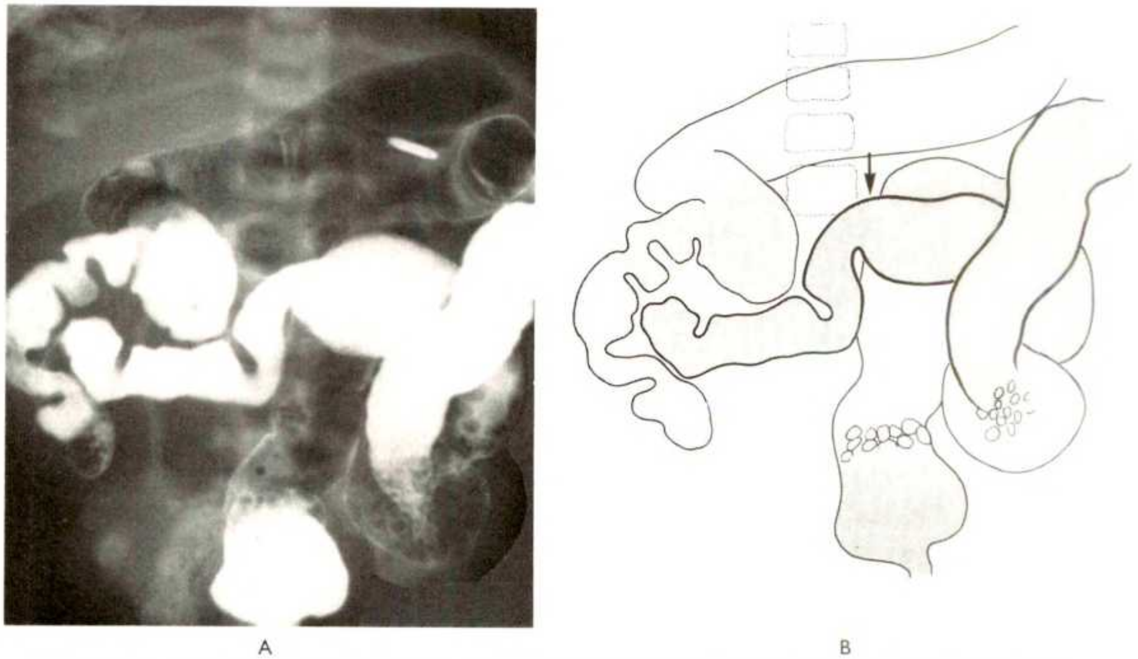

FIG. 6.—*Case* 3. A, Gastrografin-enema film. Arrow indicates site of change in diameter of the bowel. B, Explanatory diagram.

Case 2.—A male of birth weight 2·32 kg. was admitted at the age of 48 hours with abdominal distension and bilious vomiting. A laparotomy performed the same day revealed a meconium obstruction. Thirteen cm. of dilated ileum were excised, meconium plugs were milked out of the bowel, and a Bishop-Koop anastomosis was made. His postoperative course was complicated by several episodes of severe pulmonary infection. The ileostomy worked satisfactorily for a few days, after which he started to pass faeces per rectum. When aged 3 months, in spite of being maintained on the normal medical régime with oral pancreatic enzymes, he began to vomit, his abdomen became distended, and a radiograph showed small-bowel distension with fluid levels. Instillation of Gastrografin into the ileostomy was followed by the passage of a large quantity of faeces, and his abdomen became less distended. Intermittent vomiting continued, and at the age of 4 months a pyloric tumour became palpable. Following a Ramstedt's operation the vomiting ceased. Six weeks later he had a further episode of vomiting and abdominal distension. A radiograph (*Fig.* 4) showed small-bowel distension with faeces in the ascending colon. Gastrografin was injected into the ileostomy. A further radiograph showed the Gastrografin flooding back into normal bowel on the left and some passing on to the right. A few hours later he passed large quantities of faeces. His abdominal distension subsided rapidly and he has had no further obstructive trouble.

Case 3.—A female of birth weight 3·8 kg. was operated on at another hospital in the second day of life for meconium ileus. No resection was performed. She was not given any pancreatic supplements postoperatively.

She was fairly well until a month later when she developed further abdominal distension with vomiting and constipation. A radiograph (*Fig.* 5) showed a small-bowel obstruction and faeces in the descending colon. A Gastrografin enema with radiographic screening control (*Fig.* 6) showed filling of the colon with reflux into the terminal ileum extending back into the distended bowel. A few hours later she began to pass faeces and decompressed herself. She has had no further trouble.

DISCUSSION

The efficacy of Gastrografin in the relief of uncomplicated meconium ileus and faecal obstructions appears to be due to its physical properties. Gastrografin is an aqueous solution containing 10 per cent sodium diatrizoate and 66 per cent meglumine diatrizoate with 1·0 per cent Tween 80, as a wetting agent, and flavouring. This radio-opaque solution is hypertonic and hygroscopic. The presence of the detergent Tween 80 enables the fluid to pass easily around and into masses of inspissated meconium or faeces. The hypertonicity draws fluid into the bowel lumen with softening of the faeces and produces an osmotic diarrhoea aided by the peristalsis induced by the irritant nature of the solution.

The process should be followed with close radiographic supervision, preferably screening, so that leakage into the peritoneal cavity from a perforation or errors in the clinical diagnosis can be immediately recognized. Escape of the contrast medium has been reported in primary meconium obstruction even with very low-pressure injection (Wagget and others, 1970), presumably through a pre-existing perforation. If this is seen early operation is essential.

The successful use of Gastrografin to relieve the obstruction in the event of failure of primary surgery (*Case* 1) and late faecal plugging (*Cases* 2 and 3) suggests that the method has a place in the postoperative as well as in the primary management of meconium ileus.

The following safety precautions are recommended:

1. The procedure must be treated with the gravity of an operation and should be carried out under the supervision of the surgeon in charge, with the child prepared for immediate transfer to the operating theatre.
2. The instillation should be under radiographic control.
3. In view of the loss of fluid into the bowel during the examination, the state of the child's hydration must be watched, and it may be wise to have an intravenous infusion running.

PEROPERATIVE CHOLANGIOGRAPHY

By MYAT THU YA, D. ROBINSON, and A. A. GUNN
BANGOUR GENERAL HOSPITAL, WEST LOTHIAN

SUMMARY

Operative cholangiography was performed in 30 patients by a technique using a modified Foley catheter introduced into the common bile-duct after exploration. The visualization was satisfactory with flow into the duodenum, and additional stones, strictures, and congenital abnormalities were detected. This procedure is likely to reduce the incidence of residual stones following choledochotomy.

OPERATIVE cholangiography is an accepted technique for the detection of any abnormality in the biliary tree and has been shown to reduce the need for choledochotomy—a procedure associated with an increased morbidity and mortality. However, there remains the problem of establishing the normality of the duct system after the removal of any stones. T-tube cholangiography has been used for this purpose and although good pictures can be obtained of the proximal ducts the distal common bile-duct is often poorly shown and the dye frequently fails to pass into the duodenum (Griffin and Wild, 1967; Lawson and Gunn, 1970). Serial films and cine-radiology can improve the results but the former is time-consuming and the latter not always available. Furthermore, the presence of the T-tube distorts the duct and can permit the introduction of air-bubbles.

It has been suggested (Lawson and Gunn, 1970) that satisfactory visualization of the ducts can be obtained by the use of a Foley catheter passed into the common duct after the exploration. This paper reports the results achieved by this method.

MATERIAL

Two hundred and fifty-five patients were admitted for surgical treatment of benign biliary-tract disease in the 3-year period between 1969 and 1972 and operative cholangiography was a routine procedure. Choledochotomy was indicated in 57 patients on the basis of the clinical features modified by the operative cholangiography (*Table I*).

Table I.—RESULTS OF EXPLORATION OF THE COMMON BILE-DUCT IN 57 PATIENTS UNDERGOING CHOLEDOCHOTOMY

Findings	*No. of Cases*
Stones	40
Stones and stricture	8
Stricture	5
Acute pancreatitis	2
No abnormality	2

Stones were found in 40 patients, stones and strictures in 8, and stricture alone in 5 patients. Two patients had acute pancreatitis associated with cholelithiasis and the common bile-duct was drained to relieve pressure in the pancreaticobiliary system. Two patients had the duct explored and no abnormality was found.

Thirty patients had Foley cholangiography by the method described here; of the remaining 27 patients, 21 were treated before the method was standard practice, and 2 had choledochoduodenostomy and 3 had sphincterotomy as additional procedures and Foley cholangiograms were not attempted. In 1 patient the procedure was omitted.

METHODS

A 10 FG female Foley catheter was modified by cutting off the end distal to the balloon (*Fig.* 1), and was then tested for any damage to the balloon. The proximal end was shortened to take a 10-ml. syringe.

After exploration of the duct the catheter was introduced into the common bile-duct just distal to the choledochotomy and the balloon was inflated. Water was injected down the catheter to test that satisfactory occlusion of the common duct had been obtained. All foreign bodies such as swabs and packs were removed, and films were taken during the injection of 25 per cent Hypaque. One film was usually sufficient.

The balloon was deflated, the catheter was moved into the common hepatic duct, and the procedure was repeated. In the absence of a choledochoduodenostomy the choledochotomy was closed around a T-tube and thereby postoperative cholangiography was possible at 10 days.

RESULTS

All the patients had films that showed satisfactory filling of both the hepatic ducts and the common bile-duct (*Table II*); in 28 patients the films revealed good flow into the duodenum and in 2 patients there was a stricture that was causing obstruction.

Table II.—RESULTS OF FOLEY CHOLANGIOGRAPHY IN 30 PATIENTS

Findings	*No. of Cases*
Visualization of hepatic ducts	30
Visualization of common bile-duct	30
Flow into duodenum	28
Additional stone	3
Stricture	5
Tumour of common bile-duct	1

Additional stones were discovered in 3 patients (*Fig.* 2), and after removal of these stones further films using the same technique showed that the duct had been cleared. Ten-day postoperative films through the T-tube revealed no other stones and no patient has developed further symptoms in the short follow-up period (3–33 months).

DISCUSSION

Modification of the Catheter.—The standard Foley catheter has an end that projects more than 1 cm. beyond the balloon with a subterminal opening, and if not removed this can simulate a stone. This modification can damage the balloon which must be tested before introduction. The proximal end of the catheter requires trimming of the connexion so that an accurate fit is obtained with the syringe and air-bubbles are avoided.

Position of the Balloon.—The balloon should be inflated as close to the opening in the common duct as possible so that maximal filling of the lower part of the duct with flow into the duodenum can be obtained. Inflation of the balloon must occlude the duct to prevent extravasation by back-flow through the opening in the duct. The balloon gives a round filling defect which can be recognized and is usually seen as a convex indentation into the column of radio-opaque medium.

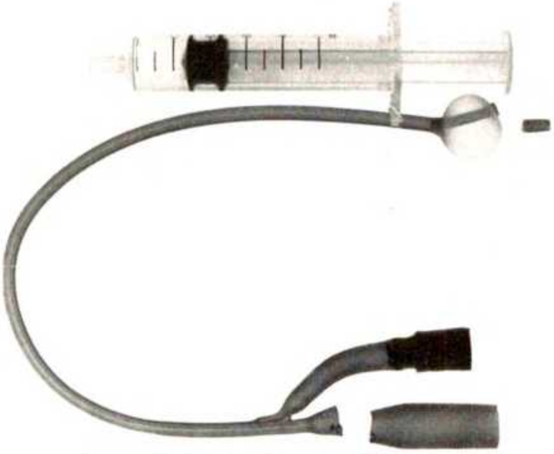

FIG. 1.—Modification of a 10 FG Foley catheter.

Table III.—COMPARISON OF THE MEAN OF THE DIAMETER OF THE COMMON BILE-DUCT BY DIFFERENT TECHNIQUES

TECHNIQUE	DIAMETER (cm.)		
	Maximum	Minimum	Lower End
Operative cholangiogram	1·41	0·56	0·68
Foley cholangiogram	1·27	0·49	0·59
T-tube cholangiogram	1·27	0·41	0·48

Volume of Hypaque.—The volume of Hypaque injected distally varied from 5 to 10 ml. and is not critical in that any excess passes into the duodenum while the film is taken. In the presence of obstruction resistance is felt and further injection results in backflow around the balloon of the Foley catheter.

The volume injected into the hepatic ducts depends on the size of the duct and is continued until resistance is felt. Excessive amount results in over-opacification and stones may be hidden.

Pancreatic Duct Filling.—Eleven patients showed filling of the pancreatic duct on the Foley cholangiogram compared with 3 patients showing filling on the initial operative films and 2 on the 10-day T-tube cholangiogram. The reflux of medium into the pancreatic duct under pressure could be potentially dangerous with damage to the pancreas but this has not been detected.

Interpretation of the Films.—It is appreciated that these films were taken under pressure and that this might lead to distortion of the duct system with the risk of misinterpretation of the findings. Comparison of the appearance of the duct in the initial, Foley, and T-tube films shows little difference and this was confirmed by the mean of the diameter of the duct at different points (*Table III*).

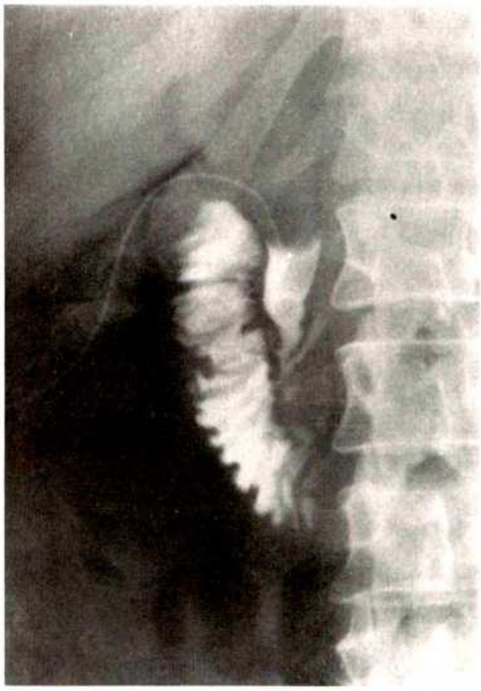

FIG. 2.—Foley cholangiogram showing residual stones and reflux into the pancreatic duct.

Indications.—In this series this technique was only used when choledochotomy was not followed by choledochoduodenostomy or sphincterotomy. However, this restriction was probably unwise in that more detail could be obtained of the abnormality and of the appearance of the sphincterotomy.

CONCLUSION

The Foley cholangiogram has been shown to be an easy and useful technique after operations on the common bile-duct and should limit the number of residual stones after choledochotomy for choledocholithiasis.

This procedure will also reveal stricture deformity at the lower end of the common bile-duct.

VAGOTOMY AND PYLOROPLASTY IN THE ELECTIVE TREATMENT OF GASTRIC ULCER

By W. R. LAWSON and J. S. F. HUTCHISON
DIVISION OF SURGERY, ROYAL INFIRMARY, GLASGOW

SUMMARY

Vagotomy and pyloroplasty have been used in the elective treatment of gastric ulcer in 72 patients. In 33 patients there was associated duodenal ulcer (G.D.U.). In the other 39 patients (G.U.) there was no evidence of duodenal ulcer. Patients with pre-pyloric gastric ulcer were excluded. The operative mortality was nil.

At an average follow-up of 3½ years the functional results in the G.U. group were good for 89 per cent of the cases, satisfactory for 5·5 per cent, and poor for 5·5 per cent compared with 73, 10, and 17 per cent respectively in the G.D.U. group. Two patients in each group showed recurrent ulcer, an incidence of 5·4 per cent in the G.U. group and 6·7 per cent in the G.D.U. group. There is no statistically significant difference in these results.

Vagotomy and pyloroplasty appear to comprise a satisfactory treatment for gastric ulcer whether or not the ulcer is associated with duodenal ulcer. The present findings do not support the view that the good results previously reported were due to the inclusion of patients with pre-pyloric gastric ulcer or with associated duodenal ulcer.

Three patients showed malignancy in the ulcer and a further case has been recorded in the total of 102 patients undergoing surgery during the period of the review (an incidence of 4 per cent), underlining the need for biopsy of the ulcer in all cases.

IN the treatment of benign gastric ulcer good results following vagotomy and pyloroplasty have been reported by Hendry and Bahrani (1965), Farris and Smith (1966), McNeill, McAdam, and Hutchison (1969), Burge, Gill, Maclean, and Stedeford (1970), de Miguel (1970), and Kraft, Myers, Overton, and Fry (1971).

Only Duthie and his co-workers have presented a statistical evaluation of the results of vagotomy and pyloroplasty for gastric ulcer. Duthie, Moore, Bardsley, and Clark (1970) suggested that previously reported good results might be due to the inclusion of patients who would be expected to do very well following such a procedure, namely, those with associated duodenal ulceration and those with pre-pyloric gastric ulcers.

Douglas and Duthie (1971) examined their results with reference to the site of the gastric ulcer and the coexistence of a duodenal ulcer and found that the functional results were better when the gastric ulcer was associated with a duodenal ulcer. Kennedy, Kelly, and George (1972) reported similar findings, although others (Clarke, Lewis, and Williams, 1972) considered that vagotomy and pyloroplasty were not a satisfactory treatment for gastric ulcer associated with duodenal ulcer.

The present paper reviews the results of vagotomy and pyloroplasty in the elective treatment of gastric ulcer. The patients have been assessed in two groups: those with chronic gastric ulcer alone (G.U.) and those with chronic gastric ulcer associated with duodenal ulcer (G.D.U.). The two groups are compared on the basis of (1) operative morbidity, (2) functional after-effects of surgery, and (3) recurrent ulceration. The incidence of malignancy has been assessed. The results have been submitted to statistical analysis.

MATERIALS AND METHODS

During the 5-year period from January, 1966, to December, 1970, the total number of patients undergoing surgery for chronic gastric ulcer was 102. Thirty patients have been excluded from this review for the following reasons: 6 patients had pre-pyloric gastric ulcer, 8 patients had vagotomy and pyloroplasty as an emergency procedure for bleeding, 3 patients had only vagotomy or pyloroplasty alone, 4 patients had vagotomy and gastro-enterostomy, 6 patients had gastrectomy, and only 3 patients have been lost to follow-up. The remaining 72 patients who were treated electively by vagotomy and pyloroplasty were studied.

At operation the ulcer edge was biopsied in four quadrants or the ulcer was excised completely and the material was submitted for immediate histological examination by a frozen-section technique. The drainage procedure was a Heineke-Mikulicz pyloroplasty with a one-layer closure. The type of vagotomy varied, being truncal in 16 cases (9 G.U., 7 G.D.U.), bilateral selective in 26 cases (11 G.U., 15 G.D.U.), and anterior selective in 30 cases (19 G.U., 11 G.D.U.).

Five of the 72 patients have died since the time of surgery and the remaining 67 patients have been traced and interviewed. Each patient was allocated to one of four grades using a modification of the classification of gastric symptoms introduced by Visick (1948). Patients in grade I are those with no gastric symptoms; those in grade II have minor gastric symptoms readily controlled by slight modification of diet or habit; those in grade III have moderate symptoms which are not simply controlled by minor adjustments but which do not interfere with work or social life; grade IV includes patients with symptoms which interfere with work or social life, and which are as bad or worse than before surgery, those with recurrent ulcer, and those who have required a second operation for suspected recurrence.

Barium-meal examination was carried out in 61 patients during review in 1971–2, but 6 patients who were totally symptom free refused barium-meal examination. Patients with symptoms or radiological signs suggestive of recurrent ulceration were investigated further by gastroscopy, insulin test, and repeat barium meal.

RESULTS

Data from all 72 patients have been used in calculating the average age, length of history, length of follow-up, and operative morbidity. Figures relating to postoperative assessment are based on the results in the 67 surviving patients.

Of the 72 patients, 33 had a gastric ulcer associated with active or healed duodenal ulceration. In the other 39 patients there was no evidence of duodenal ulceration either on barium-meal examination or at the time of operation. The average age at operation and duration of follow-up were similar in both groups, but symptoms had been present for a longer period in the G.D.U. group (*Table I*). The minimum period of follow-up was 1 year and 48 patients were followed up for more than 3 years.

Table I.—DETAILS OF THE GROUPS STUDIED IN THE PRESENT SERIES

	G.U. GROUP			G.D.U. GROUP		
	Male	Female	Both	Male	Female	Both
Age at operation (yr.)	52·1	46·6	48·3	56·0	50·7	53·4
Duration of symptoms (yr.)	3·8	7·4	5·8	12·6	9·3	11·0
Duration of follow-up (yr.)	3·4	3·8	3·7	3·1	3·5	3·3
No. of patients	12	27	39	17	16	33

Table II.—INCIDENCE OF POSTOPERATIVE COMPLICATIONS

COMPLICATIONS	G.U. GROUP	G.D.U. GROUP
Wound	5	6
Chest	6	4
Renal	2	—
Deep-vein thrombosis	1	—
Splenectomy	—	1
Patients with complications*	12	11
Total No. of patients	39	33

* Two patients in the G.U. group each suffered two complications.

Operative Morbidity.—All 72 patients survived operation. One patient in the G.D.U. group required splenectomy at the time of operation because the splenic capsule was inadvertently stripped but her convalescence was uneventful. None of the patients developed breakdown of the pyloroplasty suture line or any other intra-abdominal complication. *Table II* shows the complications which arose. In the G.U. group 12 patients showed complications and in the G.D.U. group 11 patients were affected. The commonest complications were wound haematomas or infections and chest infections.

Late Deaths.—Five patients out of the 72 died between operation and the most recent follow-up. *Table III* shows the details in these cases. One patient died of gastric carcinoma more than 5 years after the initial surgery. The biopsy at the initial operation was reported as simple and the tumour did not present until 3 years later. Another patient died 4 months after operation from pulmonary tuberculosis. She had suffered from this condition for many years and the disease was known to be active at the time of her operation. The other deaths were due to myocardial infarction (2) and congestive cardiac failure associated with bronchitis (1).

Functional Results of Surgery.—Of the 67 surviving patients, 37 were in the G.U. group and 30 were in the G.D.U. group. The symptomatic grading at follow-up is shown in *Table IV*. Patients in both grades I and II (no gastric symptoms or mild symptoms readily controlled) can be considered as having good results. In the G.U. group 33 out of 37 patients (89 per cent) are in those grades and in the G.D.U. group 22 out of 30 patients (73 per cent) are in grades I and II. Those in grade III can still be regarded as satisfactory results. Patients who have had recurrent ulcer or a second operation for suspected recurrence have been graded IV although following further surgery only 1 patient now falls into grade IV with symptoms worse than before the initial surgery. The reasons for the poor functional results are shown in *Table V*.

Table III.—DETAILS OF THE LATE DEATHS

PATIENT	AGE AT OPERATION (yr.)	SURVIVAL (yr.)	CAUSE OF DEATH	GASTRIC GRADE	ULCER TYPE
C. McF.	67	2·6	Congestive cardiac failure. Bronchitis*	I	G.D.U.
J. C.	65	0·6	Coronary	I	G.D.U.
J. McC.	47	4·3	Coronary	I	G.D.U.
J. N.	55	0·3	Pulmonary tubercle	I	G.U.
E. M.	46	5·3	Gastric carcinoma	IV	G.U.

* Ulcer healed at post-mortem examination.

Table IV.—COMPARISON OF THE RESULTS ACCORDING TO VISICK GRADING

VISICK GRADE	G.U. GROUP		G.D.U. GROUP	
	No.	Per cent	No.	Per cent
I	21	56·6	15	50·0
II	12	32·4	7	23·4
III	2	5·5	3	9·9
IV	2	5·5	5	16·7
Total No. of patients	37		30	

Table V.—ANALYSIS OF THE POOR RESULTS

	G.U. GROUP	G.D.U. GROUP
Recurrent ulcer	2	2
Reoperation for suspected recurrence	—	2
Reoperation for carcinoma	—	1

There is no significant difference in the functional results between the G.U. group and the G.D.U. group either when the four grades are examined separately ($\chi^2 = 3·024$, d.f. 3, $P < 0·5 > 0·1$) or when grades I and II are combined ($\chi^2 = 2·902$, d.f. 2, $P < 0·5 > 0·1$).

Recurrent Gastric Ulcer.—Four patients have shown a definite recurrent gastric ulcer. There have been 2 recurrences in each group, producing recurrence rates of 5·4 per cent in the G.U. group and 6·7 per cent in the G.D.U. group. There is no significant difference in the recurrence rate between the two groups ($\chi^2=0{\cdot}0469$, d.f. 1, $P<0{\cdot}9>0{\cdot}5$). Two patients with recurrent ulcer had positive insulin tests, and in the other 2 patients details of the insulin response before the second operation are missing from the case records.

No other patients in this series have shown recurrence of either the gastric ulcer or a duodenal ulcer. Two patients have, however, had further surgery on account of recurrent symptoms. In both cases there was no sign of ulcer recurrence either at gastroscopy or laparotomy, and insulin tests were negative.

Malignancy.—In this series of 72 patients 3 cases of gastric carcinoma associated with chronic gastric ulcer have been noted (4·2 per cent). Two of these cases were diagnosed histologically at operation, but the third had a negative initial biopsy and presented 3 years later. Sixty-six of the patients had frozen-section examination of the biopsy or excised ulcer so that the likelihood of the ulcer being shown to be malignant at the time of surgery is 3 per cent (2 out of 66 cases).

A fourth case of malignancy was noted in the other 30 patients not included in this review, giving an overall incidence of malignancy of 3·9 per cent (4 out of 102 cases).

DISCUSSION

The incidence of combined duodenal and gastric ulceration in the present series is 46 per cent. If all the cases of benign gastric ulcer submitted to surgery during the 5 years of the review are considered then the incidence of combined ulcer is 40 per cent. This is somewhat higher than that noted by Douglas and Duthie (1971) but is similar to that found by Rumball (1971).

There was no mortality in the group of 72 patients undergoing vagotomy and pyloroplasty electively for benign gastric ulcer. Postoperative morbidity was noted in about one-third of the patients in each group. It is noteworthy that there were no postoperative bowel complications. This is in contrast to the incidence of gastric fistula (6 per cent) and paralytic ileus (6 per cent) reported following Billroth-I gastrectomy by Duthie and others (1970). The complications occurring in the present review were mainly chest and wound infections.

The functional results of surgery were essentially the same in both groups of patients. In the G.U. group there were 89 per cent good results (grades I and II), 5·5 per cent satisfactory results (grade III), and 5·5 per cent poor results (grade IV). In the G.D.U. group there were 73·4 per cent good, 9·9 per cent satisfactory, and 16·7 per cent poor results. There is no statistically significant difference in these results ($\chi^2=2{\cdot}902$, d.f. 2, $P<0{\cdot}5>0{\cdot}1$). Other workers have recorded good functional results similar to the present ones following vagotomy and pyloroplasty in patients with gastric ulcer not associated with duodenal disease. De Miguel (1970), reporting on 38 patients, found 84 per cent to be in grades I and II with a follow-up of up to 4½ years, and Sawyers, Scott, and Graham (1971) found 77 per cent of 22 patients to be in these grades with a follow-up of up to 6 years. This is in contrast to the findings of Douglas and Duthie (1971), who found similar good results with the G.D.U. group but their G.U. group had significantly poorer results ($\chi^2=8{\cdot}1989$, d.f. 2, $P<0{\cdot}02$).

The reason for the difference in functional results between the present series and that of Douglas and Duthie (1971) is not immediately clear. The number of patients in the two series is similar. However, the proportion of male and female patients in the two series differs. In the groups of Douglas and Duthie there was a preponderance of male patients, the male : female ratios being 1·7 : 1 in the G.U. group and 4·3 : 1 in the G.D.U. group. In the present series, while the numbers of males and females were about equal in the G.D.U. group, the G.U. group contained more than twice as many females as males. This does not appear to be the explanation of the different functional results obtained here as there is no significant difference on χ^2 testing when the present groups are broken down on the basis of sex (males, $P<0{\cdot}5>0{\cdot}1$; females, $P<0{\cdot}975>0{\cdot}9$).

In the present series about one-third of the patients had the ulcer completely excised in a wedge of stomach, but there is no significant difference in the functional results between the G.U. and G.D.U. groups when examined by χ^2 testing on the basis of excision or no excision ($P<0{\cdot}5>0{\cdot}1$).

Another difference between the two series is in the proportion of patients undergoing truncal or selective vagotomy. In the series of Douglas and Duthie (1971) most patients had truncal vagotomy but 7 patients in each group had selective vagotomy. In the present series χ^2 testing showed no difference in the functional results between the G.U. and G.D.U. groups on the basis of the type of vagotomy employed (truncal, $P<0{\cdot}99$; anterior selective, $P<0{\cdot}9>0{\cdot}5$; bilateral selective, $P<0{\cdot}5>0{\cdot}1$).

The difference between the functional results in the present report and those noted by Douglas and Duthie (1971) is probably more apparent than real. While recurrence in the present series occurred in equal numbers in both the G.U. and G.D.U. patients, Douglas and Duthie had 5 recurrent ulcers in the G.U. group and none in the G.D.U. group. Commenting on this difference in recurrence they point out, 'although not by itself significant ($P<0{\cdot}1>0{\cdot}05$) it accounts to a large extent for the differences [in functional results] between the two groups'. The other 3 patients in the G.U. group of Douglas and Duthie included in the poor functional results could equally well occur by chance in either group (1 patient had postoperative haemorrhage requiring gastrectomy and the other 2 had diarrhoea), and taken on their own they do not represent statistically significant occurrences.

It would appear then that there might be no real difference in the poor results between the G.U. and G.D.U. groups reported by Douglas and Duthie, as significance has only been produced by the accumulation of several chance occurrences each of which by itself is not statistically significant. Our present finding that there is no statistically significant difference in functional results between patients with G.U. and those with G.D.U. undergoing vagotomy and pyloroplasty has been made in a group of patients separated on the basis of associated duodenal ulceration and where patients with pre-pyloric ulceration have been excluded from the G.U. group. The functional results grading was similar to that used by Duthie and his co-workers.

This present finding does not support the suggestion of Duthie and others (1970) that earlier favourable reports on the results of vagotomy and pyloroplasty for gastric ulcer have been simply due to the inclusion of patients with associated duodenal ulceration or pre-pyloric gastric ulceration. It would appear, therefore, that the procedure of vagotomy and pyloroplasty is equally effective, as far as functional results are concerned, whether used for isolated gastric ulcer or that associated with duodenal ulceration.

In the present series recurrent ulceration was noted in 2 patients with G.U. and in 2 patients with G.D.U., the incidence in each group being 5·4 and 6·7 per cent respectively. Reports on the incidence of recurrent gastric ulcer following vagotomy and pyloroplasty appear at a casual glance to show higher recurrent ulcer rates when the operation is used in the case of isolated gastric ulcer (Lewis and Qvist, 1971; Sawyers and others, 1971) and lower recurrence rates when used in the treatment of combined gastric and duodenal ulceration (Burge and others, 1970; Wasunna, Kennedy, Gillespie, and Kay, 1971). However, Douglas and Duthie (1971) have shown that there was no statistically significant difference in the ulcer recurrence rate between G.U. and G.D.U. groups and the present findings support this view. It is also interesting to note that contrary to popular belief there was no statistically significant difference in recurrent ulcer rates when the results of vagotomy and pyloroplasty were compared with those of Billroth-I gastrectomy in a controlled trial (Duthie and others, 1970).

Four patients out of the grand total of 102 were found to have malignant ulcers. This incidence (4 per cent) is similar to that reported by others (Duthie and others, 1970; de Miguel, 1970). Three of the tumours noted in the present series appeared to be undoubtedly localized areas of change within the peptic ulcer. In the fourth patient the initial biopsy was negative and the tumour did not present until 3 years later.

Duthie and Smith (1968) have advocated biopsy of all the edges of the ulcers and our experience supports this view. In one of the present cases limited biopsy was reported as benign on frozen-section examination but when the locally excised ulcer was submitted for routine histology a localized area of malignant change was found. In another case localized biopsy was reported on frozen section as showing an aplastic carcinoma and led to the patient having total gastrectomy. However, none of the other blocks taken from the whole specimen in that case showed malignant change. Biopsy of the ulcer should be carried out even when the ulcer appears at operation to be healing. Biopsy should also be done routinely in the patients with associated duodenal ulceration as the coexistence of the two ulcers does not exclude malignancy in the gastric one. Indeed, one of our cases of gastric carcinoma had a duodenal ulcer and at operation the gastric ulcer appeared to be healing. With adequate routine biopsy malignancy should not be missed when the ulcer is left behind.

CONCLUSION

Vagotomy and pyloroplasty appear to comprise a satisfactory treatment for gastric ulcer whether or not the ulcer is associated with duodenal ulcer, giving good functional results in more than 80 per cent of patients. The present findings do not support the suggestion of Duthie and others (1970) that the good results previously reported have been due to the inclusion of patients with pre-pyloric gastric ulcer or with associated duodenal ulcer.

The risk of missing malignancy is not a problem, provided that adequate biopsy or local excision of the ulcer is undertaken at the same time.

Open weave gauze support backing.
Cotton/acrylic pad. Three times more absorbent than cotton wool.
Non-adherent film to protect wound. Perforated to allow exudate through.

Melolin. One dressing idea that really comes off.

Most dressings stick. And a pretty painful business it can be. But with Melolin the wound is protected by a non-adherent perforated film.

Exudate is taken through the perforations into an extra absorbent pad.

When you change the dressing it peels off. If you prefer, you can peel away the pad, leaving the film only on the wound.

Melolin comes individually wrapped (sterile) or in bulk.

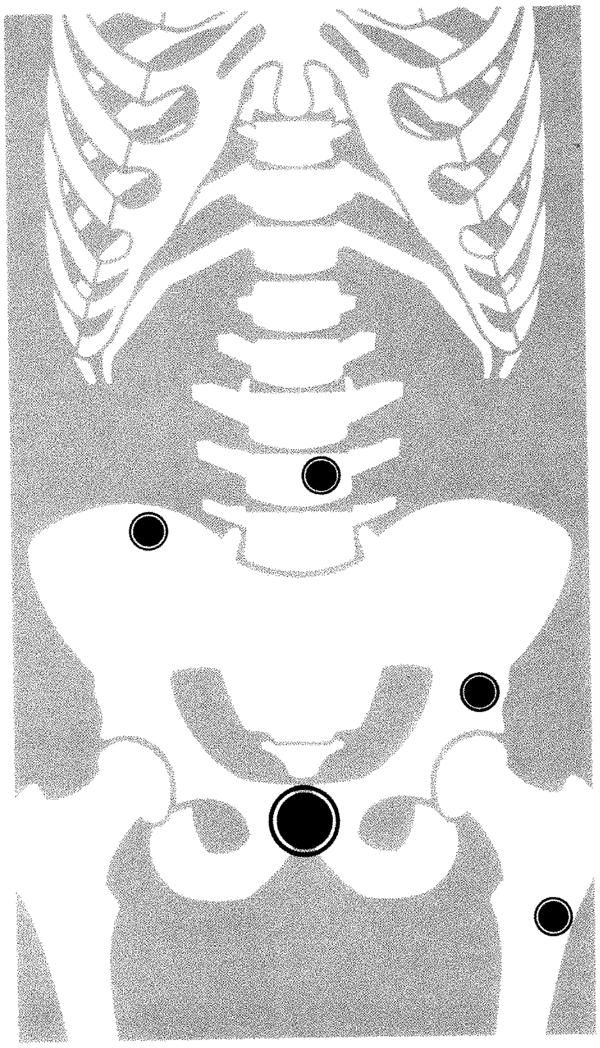
Hospital medicine at its best.

Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.

a selective cytotoxic action - in prostatic carcinoma

THE GASTRO-OESOPHAGEAL JUNCTION BEFORE AND AFTER OPERATIONS FOR DUODENAL ULCER

By P. A. THOMAS and R. J. EARLAM
THE LONDON HOSPITAL

SUMMARY

Thirty-seven patients with duodenal ulceration were studied with oesophageal manometry pre-operatively and then again 6–12 months after operation. In 28 patients who had been treated by truncal vagotomy and either a pyloroplasty or a gastro-enterostomy the length of the zone of elevated pressure at the gastro-oesophageal junction was reduced, although the maximum pressure was unchanged. In 9 patients who had had a Polya partial gastrectomy the zone was also shortened, but there was a significant fall in the maximum pressure as well. It is suggested that this reduction of the resting pressure in the sphincter may account for the gastro-oesophageal reflux which is frequently seen after a Polya partial gastrectomy, and may be caused by low circulating gastrin levels since the antrum has been removed.

GASTRO-OESOPHAGEAL reflux is known to occur after a partial gastrectomy and there have been several reports of oesophagitis and oesophageal stricture after such operations (Bingham, 1958; McKeown, 1958; Benedict, 1960; Cox, 1961). It has been suggested that reflux occurs because the gastro-oesophageal angle is altered by these procedures. There is said to be more reflux after a Billroth-I operation than after a Polya partial gastrectomy (Windsor, 1964), and this is cited as evidence for the loss of this angle since the alleged longitudinal tension after a Billroth-I operation could be expected to eliminate the angle of His. There is, however, no real proof that the gastro-oesophageal angle is different after these two types of partial gastrectomy. Reflux is also present after vagotomy and drainage for a duodenal ulcer (Clarke, Penry, and Ward, 1965) and the loss of the gastro-oesophageal angle cannot be invoked as the cause, so factors other than the loss of a mechanical flap valve may be responsible for reflux. Recent work on the hormonal influences on the sphincter has demonstrated that gastrin increases resting pressures (Giles, Mason, Humphries, and Clark, 1969; Cohen and Lipshutz, 1971; Rosenberg and Harris, 1971), and these hormonal levels are reduced when the antrum is removed (Trudeau and McGuigan, 1971). The present study was undertaken to investigate the gastro-oesophageal sphincter using manometry before and after operations for duodenal ulceration in order to find out whether reflux occurred because the resting pressures were reduced.

PATIENTS AND METHODS

Thirty-seven patients who required surgical treatment for a duodenal ulcer were divided into two groups depending on the type of operation that they underwent. Twenty-eight patients were treated by a truncal vagotomy and either pyloroplasty or gastro-enterostomy. Nine patients were treated by a Polya partial gastrectomy with or without a vagotomy. The choice of operation was usually determined by the maximal acid output as determined by the standard pentagastrin test. If more than 40 mEq. H^+ were secreted in an hour after pentagastrin a partial gastrectomy was performed, but this was often done with levels lower than this.

Pressure measurements at the gastro-oesophageal junction were made with techniques which have previously been described (Earlam, 1970). The recording units were passed through the mouth into the patient's stomach. Pressure measurements were made with three water-filled polythene tubes (external diameter 1·65 mm., internal diameter 1·12 mm.). The distal tube was covered with a 0·5-cm.-diameter balloon and the remaining two tubes had lateral openings 3 and 6 cm. from the balloon. SE 4–8 MK 2 transducers converted pressures to electrical activity which was recorded by an SE 2005 6-channel ultra-violet recorder on 15-cm. paper. The units were drawn slowly through the gastro-oesophageal junction at 0·5-cm. intervals to obtain values for the sphincteric pressure in the resting state. Two resting pressure profiles were obtained in each test.

End-expiratory and end-inspiratory pressures were measured throughout the zone of elevated pressure at the gastro-oesophageal junction. From these, mean pressures were calculated for each patient from open-tip and two balloon recordings. The three parameters used were the length of the zone of elevated pressure, the intragastric pressure, and the difference between the mean maximal sphincteric pressure and the mean intragastric pressure which for the purposes of this study has been called the 'barrier pressure'.

Tests were performed in the week prior to surgery and then between 6 months and 1 year after operation. At the time of the postoperative test all the patients were interviewed and assessed clinically with regard to symptoms of gastro-oesophageal reflux. It was not thought justifiable to perform an oesophagoscopy, a Hollander insulin test, or a further pentagastrin test on any of the postoperative patients in the absence of severe symptoms.

RESULTS

The zone of elevated pressure at the gastro-oesophageal junction (*Table I*) measured 4·4 ± 1·1 cm. (mean ± S.D.) in length in the 37 patients taken as a whole group. Following a vagotomy and drainage operation the length measured by open tip was reduced to 3·5 ± 1·0 cm. and after a Polya gastrectomy to 2·9 ± 0·8 cm. A reduction in length was also demonstrated by balloon measurement. The levels of significance according to Student's *t*-test are shown in *Table I*.

The barrier was not significantly reduced after a vagotomy and drainage operation (*Table I*). Patients who had had a pyloroplasty did not differ from those who had had a gastro-enterostomy. After a Polya partial gastrectomy the barrier pressure was reduced to 3·2 ± 2·5 cm. H_2O by open-tip measurement and to 16·3 ± 8·0 cm. H_2O by balloon recording.

The intragastric pressure was increased after both types of operation (*Table II*).

Of the 37 patients, only 3 had postoperative heartburn, and all of these had had a vagotomy and pyloroplasty. There was neither a hiatus hernia nor a low pressure demonstrated by manometry at the gastro-oesophageal junction in these 3 patients.

Table I.—PRESSURES MEASURED AT THE OESOPHAGEAL JUNCTION BEFORE AND AFTER OPERATION FOR DUODENAL ULCER

TYPE OF OPERATION AND PRESSURE MEASURED	OPEN-TIP RECORDING		BALLOON RECORDING

	$P < 0\cdot01$	

DISCUSSION

The most significant finding in this study is that the zone of elevated pressure at the gastro-oesophageal junction is shortened and reduced in height after a Polya gastrectomy. This finding is compatible with the clinical impression that reflux does occur after such an operation, although in this small series there were no such symptoms. It is suggested that the fall in sphincteric pressure is due to the decrease in circulating gastrin which occurs when the antrum is removed (Trudeau and McGuigan, 1971). Gastrin has been shown to increase the sphincteric tone (Giles and others, 1969; Cohen and Lipshutz, 1971; Rosenberg and Harris, 1971). In patients with the Zollinger-Ellison syndrome, where there is a high circulating gastrin level, sphincter pressures are higher than normal (Isenberg, Csendes, and Walsh, 1971). The reduction in the length of the zone of elevated pressure demonstrates that the sphincter remains at the hiatus and has not been displaced. There is no way of demonstrating by manometry whether a gastro-oesophageal angle exists or not, so that the results of this study cannot settle this particular point.

The pressure characteristics of the gastro-oesophageal junction in duodenal ulceration have already been described in a larger series of patients (Earlam, 1972). The height of the barrier pressure is within normal limits but the length is increased. It was suggested in that study that this increased length in the whole group was due to an increased number of cases with proximally displaced sphincters which allowed reflux. Since none of these patients had a radiologically demonstrable hiatus hernia the displaced sphincter should be considered as a small hiatus hernia which can only be demonstrated by manometry.

Both before and after a vagotomy and drainage operation the resting pressure at the gastro-oesophageal junction is normal. This pressure is produced by a combination of gastro-oesophageal sphincteric squeeze and the superimposed effect of the crura, and it is known that displacement of the sphincter alone may reduce the pressure by eliminating the diaphragmatic component. In the present study the effect of reducing a hiatus hernia would be expected to increase the pressure, just by combining the effect of the sphincter and the diaphragm, but there are obviously other factors which are involved which would counterbalance this effect. Gastrin is well known to have an effect on the gastro-oesophageal sphincter and the resting level of gastrin may be different after a vagotomy (Korman, Hansky, and Scott, 1972), but other gastro-intestinal hormones, such as secretin, cholecystokinin, and pancreozymin (Thomas and Earlam, 1973), also have an effect on the sphincter and the level of these hormones may be altered. There are also other factors, such as acid in the fundus which increases sphincteric pressure (Giles, Humphries, Mason, and Clark, 1969) whereas acid in the antrum reduces the pressure, presumably by the gastrin mechanism. In the presence of so many factors which could be altered by a vagotomy and drainage procedure no conclusion can be drawn from this study as to which reflexes or what hormonal levels have been altered by the operation. More dynamic tests of sphincteric function are obviously needed to test the altered reflexes. This study demonstrates only that the resting sphincteric pressure is unaltered by a truncal vagotomy.

This study has demonstrated that the zone of elevated pressure at the gastro-oesophageal junction is reduced in length after a truncal vagotomy and drainage operation. Any decrease in length can either be an artefact due to the overall reduction in pressure or be caused by the superimposition of sphincteric and diaphragmatic pressures by reduction of a hiatus hernia. Since the barrier pressure was not significantly reduced after a truncal vagotomy the reduction in the length of the zone of elevated pressure is most likely due to the correction of a hiatus hernia. In a truncal vagotomy the oesophagus is usually reduced well below the hiatus so that the main trunks of the vagus can be divided as they lie near the oesophagus and the oesophageal wall cleared of small fibres. The resulting fibrosis probably prevents the gastro-oesophageal junction from slipping back too far into the chest and it remains reduced. In none of the present series was any stitches inserted into the crura to tighten the hiatus.

These results differ from two previous studies comparing the gastro-oesophageal pressure profiles before and after truncal vagotomy and a drainage operation, which both found that there was a significant fall in pressure (Williams and Woodward, 1967; Mann and Hardcastle, 1968), but these studies were done within a few weeks of the operation. The results of the present study are not incompatible with these earlier findings since the pressures have been measured 6–12 months after truncal vagotomy, when full recovery of the sphincter would be expected.

There is considerable controversy over the technicalities of oesophageal manometry as to whether perfused or non-perfused open-tip tubes should be used. The method used in this study was to fill the small polythene tubes with water without continuous perfusion. Since perfusion always increases the pressures recorded and accentuates differences, the addition of perfusion would have not altered the results. Perfusion techniques differ according to the size and length of the tubing used as well as the rates of perfusion, and therefore have the additional difficulty of standardization. The advantage of the present system is that the technique is exactly the same as that used by many other workers so the results can be compared.

The effect of gastro-oesophageal reflux depends on the nature of the substance being refluxed as well as on the ability of the sphincter to prevent reflux. If the acid and pepsin levels in the stomach have been satisfactorily reduced by removing the antrum and part of the body of the stomach, gastro-oesophageal reflux of the gastrin contents is unlikely to cause symptoms arising from the lower oesophagus, even though some reflux may occur through a weak sphincter. After a vagotomy and drainage operation the level of acid produced by the stomach is not reduced to such a low level and the acidity may be still high owing to an incomplete vagotomy so that there remains enough noxious material capable of being refluxed. Since after such an operation there is no evidence that the sphincter is weakened, the resistance to reflux is usually capable of preventing symptoms even though the gastric contents are more acid than after a partial gastrectomy.

The clinical implications of this study are related to surgical techniques. Since there is evidence that the sphincter is reduced into the abdomen after a truncal vagotomy and drainage operation, there appears to be no rationale for inserting stitches into the crura or maintaining the position of the cardia as a routine, unless the hiatus is known to be wide and flaccid. This study provides no information as to the position of the gastro-oesophageal sphincter after a selective or highly selective vagotomy, in which procedures the lower oesophagus is not so thoroughly mobilized.

Acknowledgements—We would like to thank the physicians and surgeons in charge of the patients at the London Hospital and the patients themselves for allowing these studies to be performed.

Part of this work was carried out while one of the authors (P. A. T.) held a Wellcome Surgical Research Fellowship.

MUCOUS EXTRAVASATION THEORY AS A CAUSE OF PLUNGING RANULAS

By W. E. W. ROEDIGER,* P. LLOYD, AND H. H. LAWSON

DEPARTMENTS OF SURGERY AND MAXILLO-FACIAL SURGERY, BARAGWANATH HOSPITAL, AND THE UNIVERSITY OF THE WITWATERSRAND, JOHANNESBURG

SUMMARY

The theory that plunging ranulas arise as a result of mucous extravasation from the sublingual salivary gland is investigated.

Biochemical, histochemical, and histological results support the view that plunging ranulas are salivary gland extravasations, which most probably arise from the sublingual gland.

Two cases of plunging ranula were treated by primary excision of the sublingual gland through the mouth.

The successful results support the view that the extravasating source is the sublingual gland.

THE pathogenesis and treatment of plunging (cervical, burrowing) ranula, in contradistinction to those of non-plunging (oral) ranula, have been the subject of conflicting opinion.

The experimental study of Bhaskar, Bolden, and Weinmann (1956b) in animals has shown that ranulas may be due to mucous extravasation from the salivary glands. Killey, Seward, and Kay (1971) suggested that plunging ranulas appear as a result of mucous extravasation from the posterior portion of the sublingual gland but they do not give proof of this theory.

Usually a plunging ranula is approached through a suitably placed cervical incision and the cyst is excised (Gardham and Suggit, 1969). This approach is technically difficult because the extensions of the ranula are too wide for complete and effectual excision. The recurrence rate is high. An alternate method, that of removing the sublingual gland, was undertaken by Crile (1957) for recurrent plunging ranulas, and thereafter employed for oral ranulas with considerable success by Catone, Merrill, and Henney (1969).

Two patients with plunging ranula were studied in order to examine the validity of the mucous extravasation theory and to establish the source of the secretions. Both patients were treated by primary excision of the sublingual gland through the mouth without any cervical approach.

PATIENTS AND METHODS

The patients were 2 African females aged 14 and 29 years respectively (*Cases* 1 and 2). Both had a typical plunging ranula, which in *Case* 1 had marked retropharyngeal extensions (*Fig.* 1). The following procedures were undertaken:—

1. Aspiration and biochemical analyses of the ranula contents for amylase and protein were done and these were compared with the serum amylase and protein levels.

2. Histological amylase estimation of the sublingual gland was undertaken. One anterior and one posterior portion of the second gland (*Case* 2) were quenched in liquid nitrogen and suitable cryostat sections were analysed both quantitatively and qualitatively for amylase activity according to the method of Shear (1972).

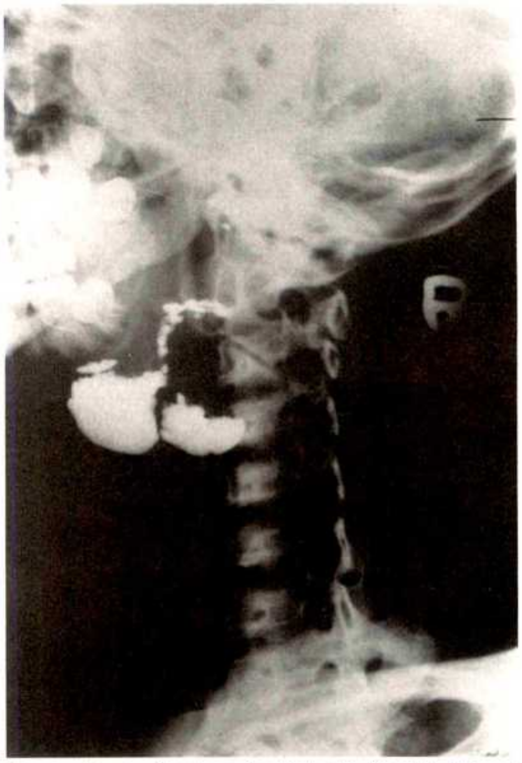

FIG. 1.—*Case* 1. Ranula partly filled with Lipiodol. There is marked retropharyngeal and cervical extension of the cyst.

3. The histological nature of the cyst wall was carefully studied.

4. A dissection of three cadaver sublingual glands was undertaken in order to assess the anatomy of this gland.

RESULTS

The aspirates from both ranulas were mucoid and although one was blood-stained no inflammatory cells were detected. The total protein and amylase levels are shown in *Table I*. The amylase levels of the aspirate were, respectively, four and six times higher than the prevailing serum level and almost twice as high as the normal upper limit of the serum amylase.

Table I.—AMYLASE AND PROTEIN LEVELS OF THE RANULA CONTENTS COMPARED WITH THOSE OF THE SERUM

	CASE 1		CASE 2	
	Serum	Cyst Fluid	Serum	Cyst Fluid
Volume	—	5. ml, blood-stained, no inflammatory cells	—	4 ml., clear, mucoid, amorphous
Amylase (Street-Close units)*	17	60	10	60
Total protein (g. per cent)	8·4	4·5	10·1	2·8

* Normal serum amylase is 9–35 Street-Close units.

Histochemically, amylase activity was detected only in the posterior portion of the sublingual gland and was localized to the serous acini which were associated with numerous mucous acini (*Fig.* 2). Amylase activity was found in the cyst and in between the lobules of the gland. The quantitative amylase activity of cryostat sections of the sublingual gland was 0·00028 mg. maltose production per μg. of protein.

In both cases portions of the ranula wall contained no epithelial lining in any of the sections studied. The lining consisted of two layers; an inner layer of chronic fibrous tissue rich in macrophages and an outer loose vascular fibrous tissue layer (*Fig.* 3). Foci of sialo-adenitis were seen but no gland atrophy was observed.

In none of the dissections of the three cadaver sublingual glands was a distinct superficial and deep lobe of the sublingual noted as is sometimes described. Drainage of the gland was usually by small ductules to the plica sublingualis, but in 1 case a large aberrant ductule, draining into the submandibular duct, was found (*Fig.* 4).

Postoperative follow-up of both patients revealed no recurrence after 8 months.

DISCUSSION

In the pathogenesis of oral ranulas an extravasation or retention of salivary gland secretions is implied. The gland of origin is variably given as minor salivary glands, the sublingual gland, or the submandibular gland (Thoma, 1970; Lucas, 1972).

Extravasation of Secretions.—The diffuse ramification of the ranula shown in *Case* 1 strongly suggests diffusion of an extravasating fluid, and the fibrous lining, with no surface epithelial cells, probably reflects a tissue response to the extravasated fluid. Experimentally it is possible to produce similar fibrous-lined cysts by dividing salivary gland ducts, thereby letting the secretions escape into the tissue spaces (Bhaskar and others, 1956b). Standish and Shafer (1959) showed that 93 out of 97 oral ranulas had a fibrous lining not unlike those observed in the present 2 cases. These points support the view that extravasation causes plunging ranulas.

Retention and Duct Obstruction.—Clinically, total duct obstruction of the salivary glands leads to the depression of secretions. Experimentally, Bhaskar and others (1956a) demonstrated that mouse submandibular duct ligation led to gland atrophy. On the other hand, it has been shown clinically that partial duct obstruction does not lead to gland atrophy (Patey, 1971). No gland atrophy was noted in either of our cases.

An anatomical abnormality of the draining ducts, as is shown in one of the dissections, may, following obstruction, predispose to extravasation of salivary secretions.

Source of Extravasation.—The sublingual gland, owing to its numerous mucous acini, produces secretions which have a higher protein content than those of the submandibular gland which has seromucous acini. Jenkins (1966) states that whereas the protein level of normal submandibular secretion is 0·10 g. per cent and of normal parotid secretion 0·21 g. per cent the protein level of the sublingual gland secretions is considerably higher. The high protein content of the ranula fluid suggests a sublingual gland origin (*Table I*).

The amylase concentration gradient between the cyst fluid and the serum implies that there is an active secreting source though the gland of origin is not thereby established. The human submandibular gland produces a considerable amount of amylase (Shear, 1972). Amylase measurements from cryostat sections of human submandibular gland show 0·048 mg. maltose production per μg. of protein (unpublished data), which is an amylase activity 170 times higher than that found in the sublingual gland above. The quantitative differences of submandibular and sublingual tissue amylase may be significant. The extravasated fluid in the 2 cases presented here showed only moderately raised levels which may be more in keeping with a sublingual gland origin. Further quantitative correlation between normal and pathological tissue amylase in sublingual and submandibular glands needs to be undertaken.

Sublingual Gland Removal.—Removal of the sublingual gland is based on the inference that plunging ranulas are extravasation phenomena from this gland. Excision of the salivary gland removes the secreting source, thereby preventing recurrences, and also avoids the problem of a difficult neck dissection.

As far as the authors were able to ascertain, excision of the sublingual gland has been undertaken for recurrent plunging ranulas (Crile, 1957; Whitlock and Summersgill, 1962) but has not been employed as the initial form of treatment. In the 3 recurrent ranulas of Crile and Whitlock and Summersgill several attempts were made at removal through an external cervical incision. Recurrence of the ranulas occurred in their cases after the submandibular but not the sublingual gland had been removed, presumably because the sublingual gland was still present.

Catone and others (1969) described 9 cases of non-plunging ranula which were treated successfully by sublingual gland excision.

By excising the sublingual gland a technical marsupialization is achieved. In addition, gland removal safeguards against possible recurrence by effectively removing the secreting source.

Acknowledgements.—The cases are reported with the kind permission of the Superintendent, Baragwanath Hospital, Johannesburg. The authors are indebted to Professor M. Shear, Department of Oral Pathology, for undertaking the qualitative and quantitative histochemical amylase estimation, to Mr. G. Decker for allowing us to study *Case* 2, and to Professor P. V. Tobias for permission to dissect cadaver specimens of sublingual glands.

This work was supported by a grant from the South African Medical Research Council (No. M14/73/S1).

AN INVESTIGATION INTO THE SPREAD OF BACTERIAL INFECTION IN LOWER-LIMB AMPUTATIONS

BY P. C. WEAVER,
SENIOR SURGICAL REGISTRAR, WESTMINSTER HOSPITAL TEACHING GROUP, LONDON

AND J. ANGEL
SENIOR REGISTRAR IN ORTHOPAEDICS, THE LONDON HOSPITAL

SUMMARY

An investigation into the spread of bacterial infection in lower-limb amputations carried out for ischaemia and terminal gangrene of the limb is reported. Under the conditions described in the study the spread of infection through the deep tissues of the leg does not appear to be as important as external infection which occurs following contamination in the operating theatre or in the ward when the wound remains unhealed. In many cases where bacterial contamination or infection of the amputation site occurred the organisms responsible had also been isolated from the gangrenous lesions in the limb. Thus documentation of the bacterial flora at the gangrenous site should not be ignored.

DEGENERATIVE vascular disease is today the commonest cause of amputation of the lower limb (Vitali, Harris, and Redhead, 1967). In the ischaemic limb where reconstructive vascular surgery is not possible gangrene or severe rest pain makes amputation necessary. There are many factors concerned in the successful healing of an amputation stump. Breakdown of the wound may occur because of ischaemia, haematoma, infection, and other general conditions, such as malnutrition and uraemia. It was decided to carry out a bacteriological investigation on amputees to try to assess the part played by infection. The stimulus for this survey resulted from an amputation survey with immediate postoperative fitting of a prosthesis carried out at five London teaching hospitals, the initial results of which were reported by Vitali and Redhead in 1967. Although Vitali and Redhead did not record any delay in wound healing, they and the surgeons concerned were unhappy with the way that some subsequent patients developed infection under their plaster dressing which resulted in wound breakdown with delayed healing or amputation to a higher level. This raised the question of how the infection had occurred. The possibilities were: lymphatic or vascular spread from the already infected gangrenous area of the foot, cross-infection of the wound during the operation, either autogenous or from some other operating-theatre source, or, finally, by secondary infection after amputation. Vitali and Redhead (1967) stated that in women the plaster socket easily becomes contaminated with urine and this may have an adverse effect on healing of the stump and may increase the risk of infection.

This bacteriological survey was carried out on patients who had severe ischaemia of a lower limb with established gangrene of the toes or foot who were unsuitable for direct arterial surgery and on whom it had been agreed that amputation was necessary. Blocks of tissue were excised at predetermined levels from the neurovascular bundles of the amputated limbs, under sterile conditions, to ascertain whether or not existing infection in a gangrenous lesion could be tracked up the limb to the site of amputation. Theatre swabs were also cultured and plates of culture medium were left exposed to the operating-theatre atmosphere. We have attempted to correlate these results with the subsequent progress of the wound.

MATERIAL

Twenty-eight patients (21 males and 7 females) requiring lower-limb amputation were investigated in 1970 and 1971. They were selected for this survey where there was distal gangrene of the toes or foot but no extensive gangrene of the limb or generalized cellulitis. Twenty-four of the patients had had arteriography to exclude the possibility of direct arterial surgery, 4 of the patients had had a recent sympathectomy, but none had had recent surgery on the affected limb. Of the 28 cases, 14 had right below-knee amputation (12 men and 2 women), 7 had left below-knee amputation (4 men and 3 women), and 7 had right above-knee amputation (5 men and 2 women). Of this last group, 2 cases were reamputations because the below-knee stump had developed gangrene. The remaining 5 cases were primary planned above-knee amputations. The youngest patient in the series was 45 years old and the eldest 86 years old. The mean age was 71·8 years. Three of the patients were diabetic.

METHODS

On the day prior to amputation swabs were taken from the nose, perineum, and gangrenous lesion. The leg was shaved, where necessary, and prepared with povidone-iodine (Lowbury, Lilly, and Bull, 1964; Ayliffe and Lowbury, 1969). It was again treated with povidone-iodine and covered with gauze before the patient was taken to the operating theatre. A sterile polythene bag was tied over the foot so as to exclude the gangrenous area. As premedication each patient was given 1 MU. of benzylpenicillin intramuscularly and the penicillin was continued in this dosage 6-hourly for 3 days. This was the surgical unit's routine prophylaxis against gas gangrene (Taylor, 1960; Johnstone, 1963; Johnstone and Cockcroft, 1968).

---

* Present address: Senior Registrar in Bacteriology, St. Bartholomew's Hospital, London.

Two blood-agar plates were exposed to the atmosphere of the operating theatre during the period of the operation to measure the degree of possible contamination (Williams, Blowers, Garrod, and Shooter, 1966). At intervals of 15, 35, and 45 minutes after the commencement of the operation, blood-stained theatre swabs were taken for culture. The amputated limb was laid on a separate sterile trolley with its own set of sterile instruments. One of us then rescrubbed wearing a gown, gloves, and mask to take specimens of tissue from the amputated leg at predetermined sites and levels in order to trace the possible spread of infection along the deep lymphatics and vascular channels.

Tissue was removed from the neurovascular bundle immediately adjacent to the gangrenous area of the foot. Next a block of tissue was removed to include the posterior tibial vessels behind the medial malleolus at the ankle. In below-knee amputations a further block of tissue was taken to include the major vessels in the mid-calf region, while in above-knee amputations a block of tissue was taken from the vessels in the popliteal fossa. In all the amputations a final block of vascular tissue was taken from the main neurovascular bundle at the site of amputation. In order to exclude external contamination the skin surface was seared before it was incised by a sterile knife prior to removing the block of tissue for culture. The specimens of tissues from different sites were inoculated on two blood-agar plates, one MacConkey's medium, and one Robertson's cooked-meat medium, and incubated at 37° C. overnight. Of the two blood-agar plates, one was incubated anaerobically. When there was no growth after primary culture, subcultures were made from the cooked-meat medium. The amount of bacterial growth was classified, depending on the number of colonies, as follows: >300 colonies; $+++$; >200 <300 colonies, $++$; >50 <200 colonies, $+$. When the number of colonies was less than 50 or when the growth was obtained only after subculture it was classed as scanty growth ($\pm$). The scale was also used to assess the heaviness of growth of different types of bacteria that were present at any one site. The final identification of organisms was carried out according to the method described by Cowan and Steel (1965).

In order to determine whether different types of organisms isolated from various sites were the same or similar, a range of tests was employed. For *Staphylococcus aureus* phage typing was carried out. For *Pseudomonas aeruginosa* pyocine typing was performed. With *Proteus* species the antibiotic-sensitivity pattern was studied and Diene's method was applied to differentiate between any two strains. Lastly, for *Escherichia coli* and *Streptococcus faecalis* the sensitivity pattern was taken into account to classify them (serological typing of *E. coli* was not available.)

At the termination of the operation, but before skin closure, the wound was dusted with bacitracin and polymyxin powder and a Redivac suction drain was placed in the wound in order to drain any possible haematoma in the amputation stump. The wound was dressed with sterile gauze, wool, and crêpe bandage. The drain was removed after 48 hours. At this time culture swabs were taken from the wound and from any fluid in the drain. The stump was rebandaged with sterile dressings and crêpe bandage. The sutures were removed 21 days after operation. All the skin sutures were nylon.

RESULTS

Twelve of the amputations healed without trouble. In 8 cases some breakdown of the skin suture line occurred after removal of sutures which was attributed to subjecting the stumps to rather more stress than they were capable of taking during the fitting and use of artificial limbs. In these cases only skin breakdown occurred and eventual healing took place without surgical intervention. In 2 cases it was necessary to trim the wound but the amputation healed at the same level. In 5 cases it was necessary to reamputate at a higher level. The remaining patient died before healing was complete but his amputation wound remained sterile. Five of the group died before rehabilitation could be completed.

Of the main groups of pathogenic bacteria isolated, there were five phage types of *Staph. aureus* (types 29/52/52A/80/81, 80/81, 47/53/75/77, 75/77, and 52A/79), three species of *Proteus* (*mirabilis*, *vulgaris*, and *morganii*), and two strains of *Ps. aeruginosa* (types 10 and 30).

In the nasal and perineal swabs pathogens occurred in 5 cases. *Staph. aureus* was found in the nasal swab of 3 patients, *Str. pyogenes* in the nasal swab of 1 patient, and *Clostridium welchii* was grown from the perineal swab of 1 patient (*Tables I*, *II*, and *III*). In *Case* 6 *Staph. aureus* which was cultured from the postoperative nasal swab subsequently infected a wound which initially healed satisfactorily and later broke down because of trauma. No other pathogens obtained from these cultures gave rise to subsequent infection. In most cases the gangrenous lesion of the toes or foot was infected as was the adjacent tissue of the foot. The incidence of organisms isolated from the gangrenous areas is as follows: *Staph. aureus*, 12; *Proteus* spp., 6; *Str. faecalis*, 5; *E. coli*, 4; *Str. pyogenes*, 2; *Ps. aeruginosa*, 2. In 2 cases the culture proved sterile. In 9 cases either the same organism (e.g., *Staph. aureus*) or a similar species of organism (e.g., *E. coli*, *Proteus*) was isolated from the culture of the vascular tissue at the ankle to that obtained from the culture of tissue adjacent to the gangrenous area of the foot. It was rare to find organisms in the tissue cultures from higher levels and in only 3 cases were similar organisms found at the amputation site. In 15 cases one or more of the cultured gauze operation swabs was found to be contaminated. There was contamination of the wound in 8 cases and in 7 of these the same organism was found in the gangrenous area. There were only 3 cases of primary wound infection resulting in breakdown of the wound and this occurred in *Cases* 4, 13, and 27.

In the plates exposed to the atmosphere of the operating theatre 21 were contaminated; 9 with micrococci, 5 with *Staph. albus*, and 4 with *Staph. aureus*. In *Case* 4 a penicillin- and tetracyline-resistent *Staph. aureus* was cultured from the exposed theatre plate (an organism not previously cultured from this

patient). An organism of the same phage type was again cultured from the wound and drain, and it subsequently produced a wound infection necessitating a higher amputation which also failed as a result of infection. The patient died from a cerebrovascular accident and bronchopneumonia following the second amputation.

From the results in *Tables I*, *II*, and *III* it can be seen that where wound breakdown occurred, apart from the 3 cases of primary infection already mentioned, the wounds remained sterile for several days according to routine culture. These wounds later became infected with organisms found either on the patient or within the general ward in which recovery was taking place. An analysis of the primary and secondary stump infection is shown in *Table IV*.

Table IV.—ANALYSIS OF THE PRIMARY AND SECONDARY INFECTION IN 13 CASES

PATHOGENS	NO. OF CASES	OTHER SITES WHERE PATHOGENS FOUND
Staph. aureus only	7	Foot 3, nowhere else 2, theatre plates 2, nose 1
Proteus only	3	Foot 2, nowhere else 1
Str. faecalis only	1	Foot
Proteus + *E. coli*	1	Both organisms found in foot
Staph. aureus + *Proteus*	1	Nowhere else

Of the 13 amputation stumps that suffered from primary or secondary infection, 10 healed satisfactorily initially but broke down after removal of the sutures. The reason for this was excessive use and perhaps trauma in teaching the patients to use an artificial limb. In the remaining 3 cases the presence of wound infection was a major contributing factor to the failure of wound healing and breakdown of the stump. It must also be noted that in these 3 cases there was considered to be some degree of residual haematoma following inadequate wound drainage (*Case* 4, 13, and 27).

DISCUSSION

A trial of immediate postoperative fitting of prostheses to lower-limb amputees was carried out at six London teaching hospitals by Vitali and Redhead in 1966 and 1967 in order to achieve early rehabilitation. A few distressing cases of stump infection and breakdown raised the questions of the source and spread of such infections, and the present work has been carried out to try to ascertain whether or not infection present in a gangrenous segment of the distal limb could be traced through the deep lymphatic and vascular channels to the site of amputation. A great many factors play their part in wound healing; possible wound infection is clearly an important one, particularly when faced with ischaemic tissue in elderly patients who are frequently further debilitated because of pain and other metabolic disorders such as diabetes and uraemia. Operative factors that are difficult to standardize are the careful and gentle handling of tissues and possible residual haematoma formation. Infection of the amputation wound is possible through intrinsic spread from an already established infected lesion on the ischaemic limb or by autogenous spread from the patient's skin, nose, perineum (Parker, 1969), or gangrenous foot. Cross-infection is also possible from other patients or from medical and nursing staff who may be pathogen carriers. Cross-infection may take place in the operating theatre or during subsequent wound dressing.

A search was made for the patient's own pathogens by culturing swabs taken from the ischaemic lesion of the foot, from the perineum, and from the nasal space. Possible sources of extrinsic contamination were assessed by repeated culture of operation swabs, and the operating-theatre atmosphere was checked with culture plates exposed to the atmosphere during the amputations. At the time of the removal of the first dressing the end of the drain and any fluid within it were cultured together with culture of the swab taken from the wound surface. Where primary wound healing did not occur or where there was subsequent wound breakdown repeated swabs were taken from the wound site.

Tissue cultures were taken from the amputated limb in order to try to assess the possible spread of pathogens from the gangrenous area along the deep vessels and deep lymphatics of the limb. It is appreciated that much lymph drainage is superficial, but cultures of tissues along the course of the long saphenous vein were not taken because of possible direct skin contamination of very superficial structures.

The gangrenous lesions on the feet harboured pathogens on culture in all but 2 cases. In 9 cases organisms similar to those cultured from the gangrenous area were also cultured from the posterior tibial tissue block. In only 3 cases could organisms be traced to lymphovascular tissue blocks taken from the leg and amputation site. In 2 cases (*Cases* 9 and 27) there were wound infection and wound breakdown but with eventual satisfactory healing. Out of the 13 primary or secondary stump infections, in only 2 cases could spread of the organisms be traced to the tissues of the limb. Extrinsic infections in the operating theatre or in the postoperative course form the majority of pathogenic infections occurring in this series. It must again be stressed at this point that these patients were given adequate preoperative intramuscular penicillin cover and that topical antibiotics were used in the wound before suture. This practice might easily have had a bearing upon the results obtained. It is thus more accurate to state that under the conditions in which the amputations in the present series were carried out spread of the infection through the tissues did not appear to be important, but that it is important to take greater steps to protect the amputations from contamination in the operating theatre and in the postoperative period. The results do underline the fact that apparently healed amputation stumps may require only slight trauma to produce wound breakdown, making subsequent infection of the broken-down wound likely when it is nursed in the open ward. Greater care must be taken for a longer period of time with ischaemic amputation stumps. Where wound breakdown does occur, the wound must be protected from infection and preferably isolated, either by isolating the patient or better still by isolating the stump in a controlled environmental chamber of its own, such as the one now under development and trial in the Biomechanical Research and Development

Unit, Department of Health and Social Security, Roehampton.

CONCLUSIONS

Twenty-eight patients undergoing lower-limb amputation were the subjects of a bacteriological study to investigate the possible spread of bacteria present in the gangrenous areas of the feet or toes. Patients were nursed in an open general surgical ward and operation was carried out in a general surgical operating theatre under antibiotic cover. In 16 cases some degree of bacterial contamination was observed. In only 2 cases could bacteria be traced through the tissues of the limb to the amputation site. Other infections suggested extraneous contamination either at the time of the operation or following later traumatic breakdown of a supposedly healed wound. Under the conditions of surgery described external bacterial contamination appears to be more important than the spread of bacteria through the deep lymphatics or deep vessels of the limb.

The study does underline how easily a freshly healed stump may be injured, resulting in wound dehiscence and secondary bacterial infection before healing of the ischaemic tissue occurs by secondary intention.

Acknowledgements.—We would like to express our gratitude to Dr. J. Kohn, Consultant Bacteriologist, and Mr. K. P. Robinson, Consultant Surgeon, for their encouragement, help, and criticism of this study; to the nursing staff of the surgical wards and operating theatres of Queen Mary's Hospital, Roehampton, for their understanding co-operation; and to Miss R. Kitson for the preparation of the manuscript.

A METHOD OF SUPPORTIVE BANDAGING FOR AMPUTATION STUMPS

BY P. C. PUDDIFOOT,
MEDICAL OFFICER, DEPARTMENT OF HEALTH AND SOCIAL SECURITY, LIMB FITTING CENTRE, ROEHAMPTON, LONDON

P. C. WEAVER,
SENIOR SURGICAL REGISTRAR, WESTMINSTER HOSPITAL TEACHING GROUP, LONDON

AND SHEILA A. MARSHALL
SENIOR REMEDIAL GYMNAST, SURGICAL UNIT, QUEEN MARY'S HOSPITAL, ROEHAMPTON, LONDON

SUMMARY

A supportive dressing for amputation stumps as an alternative to conventional bandaging is described. This dressing is effective in controlling oedema and satisfactory healing occurs. It is easily applied by both staff and the patient, and is comfortable to wear.

ONE of the first essentials following amputation is to produce a well-healed non-oedematous stump in order that prosthetic rehabilitation may begin in the shortest possible time. Adequate supportive bandaging is an important contributory factor in achieving this during the postoperative period. The unsatisfactory stumps resulting from poor application of present methods of bandaging have given rise to a stimulus to look for an improved technique. As a result a foam bandage dressing has been developed at the Limb Fitting Centre, Roehampton, and used on lower-limb amputees in the Surgical Unit of Queen Mary's Hospital, London.

MATERIALS

The materials required are: (1) a cotton stump sock* (*Fig.* 1A); (2) two strips of 1·3-cm.-thick polyurethane foam† (*Fig.* 1B and C); (3) a length of Tubigrip sewn up at one end‡ (*Fig.* 1D); (4) a suspender belt for through-knee and above-knee stumps (*Fig.* 1E). The first three items can be sterilized in an autoclave.

METHODS

Below-knee Amputation Stumps.—After positioning any necessary dressing (we are currently using Furacin gauze and dry gauze postoperatively), the cotton sock is pulled on to the stump (*Fig.* 2). We have used a sock 40 cm. in length for all amputations at this level. Two strips of foam 60 cm. long are cut to a suitable width according to the diameter of the stump. One is placed over the stump in an anteroposterior direction, covering the knee-joint; the second is cut to fill the gaps between the sides of the first strip without overlapping, and is shaped in its centre portion where it covers the tapering end of the stump as shown in *Fig.* 1C. It is then placed in position on the stump (*Fig.* 3). A sleeve of Tubigrip, approximately 45 cm. long, of a size which will apply medium tension to the stump is selected. We have used either G5 or G4X Tubigrip. To facilitate application the sleeve is rolled down with the seam on the outside (*Fig.* 4). It can then be stretched over the stump and pulled on firmly to hold the foam in contact with the distal end of the stump. The Tubigrip is unrolled to cover the foam strips and its upper end is trimmed to ensure that it does not extend beyond the edges of the foam and cause constriction around the thigh (*Fig.* 5).

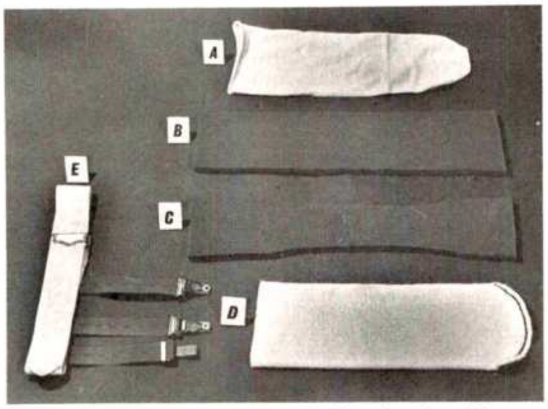

FIG. 1.—A, Cotton stump sock. B, Straight strip of foam. C, Shaped strip of foam. D, Tubigrip sleeve. E, Waist belt.

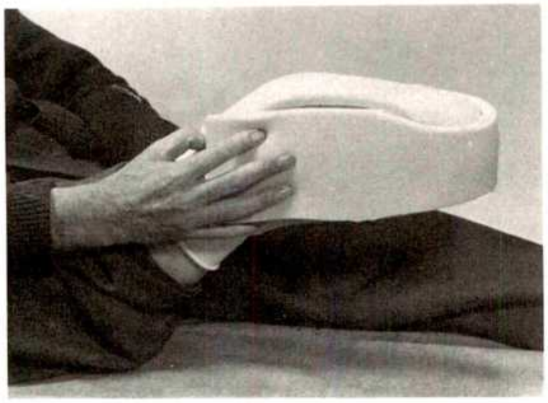

FIG. 3.—The two strips of foam in position.

Through-knee and Above-knee Amputation Stumps.—The method of application is similar to that described for below-knee amputation stumps. To maintain the dressing a waist belt with two or three suspenders is used to which the cotton and Tubigrip socks are attached. To obtain a comfortable fit in the groin the socks may be cut down on the medial side. It may be necessary to use different sizes of all the materials to fit the stump. We have used G5, G6, and G7 Tubigrip on stumps at these levels. The completed dressing is shown in position on an above-knee stump in *Fig.* 6.

RESULTS

The foam bandage dressing has been used on 23 amputation stumps in 19 patients, all of whom had had lower-limb amputations as a result of peripheral vascular disease. The ages of the patients ranged from 62 to 85 years.

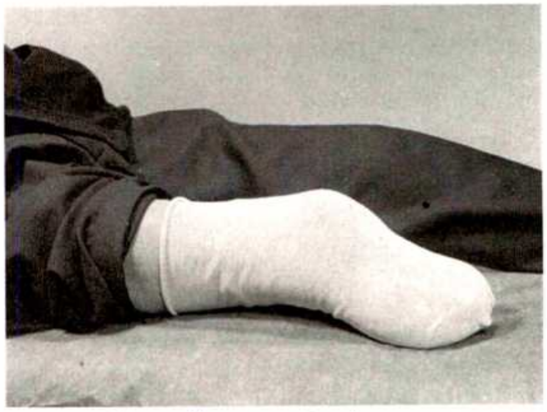

FIG. 2.—The cotton sock on the stump.

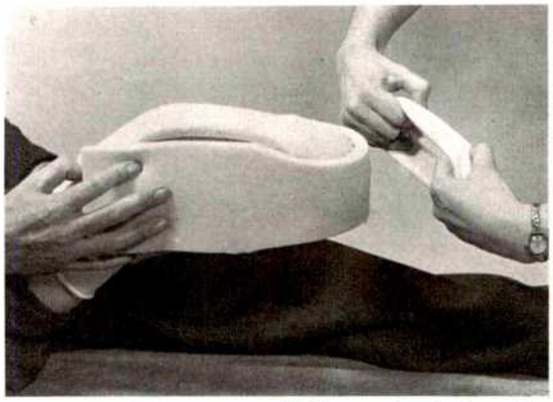

FIG. 4.—The Tubigrip sleeve rolled down and ready for application.

In 4 cases the dressing was applied immediately following amputation, in 7 cases 48 hours after amputation, and in 12 cases after initial wound healing.

In 11 cases where the dressing was applied immediately or soon after amputation satisfactory healing occurred although in 2 cases healing was delayed by superficial wound infection. In the other 12 cases the dressing was used where late ulceration developed or oedema had persisted in the stump. In all cases satisfactory healing took place, oedema was controlled, and the stumps were well shaped.

DISCUSSION

For many years elasticated bandages have been used on amputation stumps (Humm, 1969). In order to be effective these bandages must be expertly applied and constant practice is necessary to acquire the expertise. A bandage incorrectly applied can cause considerable damage to the stump. If circular turns are used instead of figure-of-eight turns the bandage will cause constriction in the middle of the stump. Venous and lymph return is thus restricted and terminal oedema soon develops. Dehiscence of the suture line may then occur, leaving the stump prone to infection. Skin necrosis may occur under a tight fold of bandage ('bandage burn'). Today the majority of lower-limb amputations are carried out on the elderly patient who is suffering from vascular insufficiency (Annual Report of the Chief Medical Officer of the Department of Health and Social Security, 1970) and in whom the healing process is slow. Any breakdown of the stump will therefore delay prosthetic rehabilitation and the patient must remain in hospital for a considerably longer period of time.

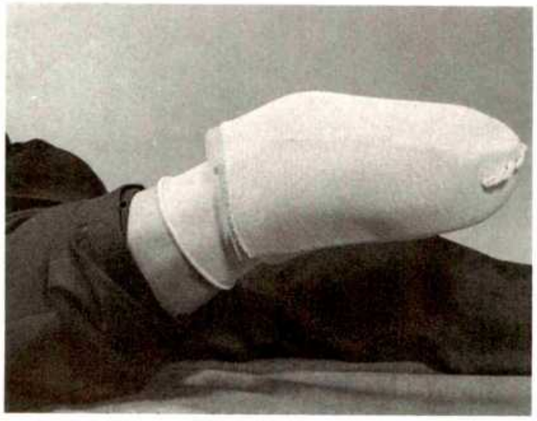

FIG. 5.—The completed dressing on a below-knee stump.

Tubular elastic bandages have often been used on stumps but have not proved satisfactory owing to their tendency to roll down, causing constriction and losing their terminal pressure. The placing of a layer of foam over the area to be covered by the Tubigrip has eliminated this problem. Foam applied directly to the skin causes discomfort, and the cotton sock prevents this. This sock also supports dressings and absorbs perspiration. It should be replaced if it becomes wet or soiled. It is recommended that the Tubigrip be reapplied every 24 hours initially, and then as the patient becomes more active and the stump less painful at least twice a day. It is unnecessary to remove the foam and the cotton sock in the postoperative period. In many patients this dressing will remain in position for at least 3 days. Evidence of the maintenance of terminal pressure can be seen by the impression of the cotton sock on the skin. In only one below-knee amputee did the dressing repeatedly come off during the night, and this patient was disorientated and extremely restless.

The foam dressing is quicker and simpler to apply than a bandage, thus reducing the amount of time required to do dressings in the ward. It can be done by an inexperienced person without the attendant hazards of a badly applied bandage. No serious harm has so far come to any stump when this simple technique has been followed.

Every patient has found this dressing very comfortable to wear, and some have reported an easing of existing stump pain as compared with the conventional stump bandaging.

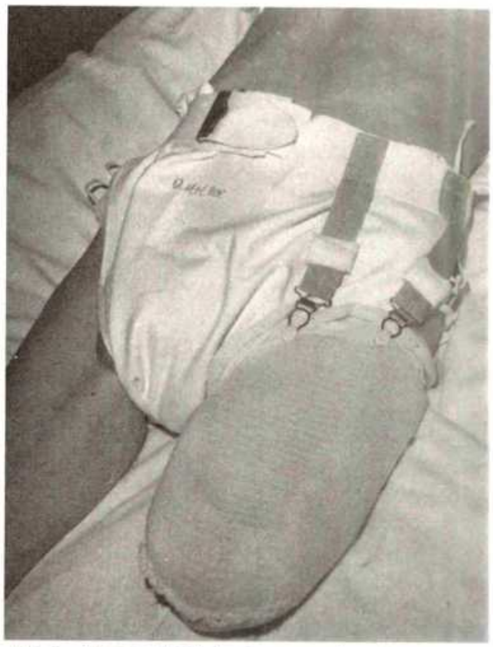

FIG. 6.—The completed dressing on an above-knee stump.

The foam strips can be sealed along their edges with adhesive plaster to form a cap. The patient is then able to apply the dressing himself. Very few elderly amputees are able to bandage their own stumps adequately, but our patients quickly learnt to manage this procedure.

Acknowledgements.—We should like to express our gratitude to Mr. K. P. Robinson and Dr. M. Vitali for their encouragement and permission to use their cases; to the nursing staff of the Surgical Unit of Queen Mary's Hospital for their co-operation and criticism in the trial of this new dressing; to the staff of the Biomechanical Research and Development Unit, Roehampton, for their assistance, and to the Department of Health and Social Security for permission to publish this article.

A FUNCTIONAL AND SOCIAL REVIEW OF LOWER-LIMB AMPUTEES

By P. C. WEAVER and S. A. MARSHALL

WESTMINSTER HOSPITAL TEACHING GROUP, LONDON

SUMMARY

The results of 119 lower-limb amputations for ischaemic disease in 105 patients over a 6-year period are reviewed to assess their progress and rehabilitation. The patients had an average age of 69·84 years at the time of the first amputation. The hospital mortality was 18·1 per cent. Life expectancy after amputation was seldom more than 3 years. A long period of hospitalization was accepted in order to achieve a high proportion of rehabilitated patients. Of those discharged, only 6 who came from their own homes had to be sent to an institution.

A study was made of the 52 surviving amputees. Forty-six patients were visited in their homes. The remaining 6 patients were traced and followed up by letter. A high standard of rehabilitation was maintained once amputees had been satisfactorily settled into the community, even though 11 out of 44 ambulant patients discontinued walking in favour of a wheelchair life.

MANY studies have been carried out on the merits of different levels of lower-limb amputation and various methods of rehabilitation and returning the patient to an environment. The amputee requires considerable in-patient and out-patient hospital care and frequently makes heavy demands upon the social services and welfare workers of the hospital and the community. Every attempt is made to return the patient to his original environment or to an improved environment where previous living conditions were poor. Where patients are unable to achieve sufficient independence to live alone and where there are no relatives to help, other permanent-care homes have to be found.

Little has been written about the continuing welfare of the patient once the hospital treatment has been completed. The Tunbridge Report (Rehabilitation, 1972) emphasizes the need for more research and knowledge about the rehabilitation of the disabled, particularly in the geriatric age range. The major group of amputees is comprised of elderly atherosclerotics.

The Department of Health statistics for 1970 show that of 4559 new patients who attended limb-fitting centres in England, 3176 were suffering from vascular disease (including diabetes). Of this latter group, 84 per cent were over 60 years of age; 87·4 per cent were single-leg amputees and 12·6 per cent were double-leg amputees. There were 2190 males (69 per cent) and 986 females (31 per cent).

In the following study patients who had had lower-limb amputations for peripheral vascular disease in the Westminster Hospital Teaching Group under the care of two consultant surgeons over a 6-year period were reviewed. The review was instigated to determine the needs of the elderly amputee and to assess the degree of rehabilitation maintained by the patients who were still living. This assessment was carried out by visiting the amputees in their home environment and determining their functional ability.

Details are given of all our amputations for vascular disease over the 6-year period. It will be seen that there is a bias towards the below-knee as opposed to higher levels of amputation. No attempt at a trial, controlled or otherwise, has been carried out, and although the surgical staff concerned believe that the below-knee amputee fares better than the above- or through-knee amputee, it is not intended to try to use the results of this work to make a plea for one amputation site over another. It is intended to show how this group of patients fare following amputation surgery and to look at ways of improving the service.

PATIENTS AND METHODS

During the period from December, 1965, to December, 1971, 105 patients with peripheral vascular disease required major amputation of one or both lower limbs. One hundred and nineteen amputations were carried out in the Westminster Hospital Group under the care of two consultant surgeons; 15 of the bilateral amputees had one leg amputated at another hospital.

When the survey was started in 1971, 51 patients (48·6 per cent) were already deceased and 2 patients (1·9 per cent) could not be traced. The remaining 52 patients (49·5 per cent) were made the subject of a separate study which involved visiting the patients at home.

The following aspects were considered. What was the state of rehabilitation? Was the patient wearing his prostheses (if supplied), and how did he function on them? How did wheelchair patients function? Was the patient independent? Were living conditions suitable?

We visited 46 patients in their own environment. We did not give them any warning of our intention to call on them. Six patients were not visited; 5 who lived more than a hundred miles away and 1 who had been admitted to hospital with advanced Parkinson's disease. In these cases information was obtained by postal communication from the patients and their relatives, or by personal interview with the patient at the Limb Fitting Centre or hospital. By the time that the data had been assembled 3 of the patients who had been visited had died.

RESULTS AND DISCUSSION

The Patients.—A series of elderly atherosclerotic amputees is presented (*Table I*). They were treated mainly at Queen Mary's Hospital, Roehampton, though a few were initially treated at the Westminster Hospital and later transferred to Queen Mary's Hospital. Some of the patients had had amputations carried out at other hospitals and were admitted under surgeons in the Westminster Group for amputation surgery to the other leg. The surgeons responsible held views expressed by Romano and Burgess (1971) and Robinson (1972), and adhered to a policy of treating lower-limb ischaemia which was not amenable to arterial surgery by below-knee amputation whenever possible. Amputation at a higher level was performed only when it was thought that a below-knee amputation would fail, or when it had already failed.

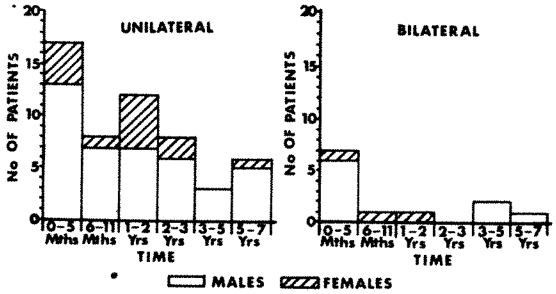

FIG. 1.—Survival times of deceased patients (54) after unilateral or bilateral amputation.

Table I.—REVIEW OF THE ORIGINAL 105 AMPUTEES WHO HAD 134 LOWER-LIMB AMPUTATIONS CARRIED OUT BETWEEN DECEMBER, 1965, AND DECEMBER, 1971

	No. of Cases
Single amputees	76
Double amputees	28
Triple amputees	1
Males	78 (98 amputations)
Females	27 (36 amputations)
Amputations carried out in the Westminster Hospital Group	119
Amputations carried out in other hospitals	15
Patients living in London	56
Patients living elsewhere	49

	Males	*Females*	*Total*
Patients still alive	35	14	49
Patients untraced	2	0	2
Patients dead	41	13	54
Patients who died in hospital	14	5	19
Patients who died after discharge	24	8	32
Patients who died after visit	3	0	3

Additional existing disabilities	*Males*	*Females*	*Total*
Diabetes mellitus	18	15	33
Ischaemic heart disease	20	5	25
Cerebrovascular accident + hemiplegia	7	3	10

Average ages (yr.)	
At first amputation	69·84
At second amputation	71·00
Diabetics (at first amputation)	69·85
Non-diabetics (at first amputation)	69·83

A review of the 105 patients shows an 18·1 per cent hospital mortality. This takes into account mortality during the convalescent and rehabilitation period in addition to the operative mortality occurring within the first 28 days (the operative mortality was 10·5 per cent). Of the patients who were discharged from hospital, only 52 were alive at the commencement of this study. Of those who had died, few had survived for more than 3 years (*Fig.* 1). Only 2 of the survivors had lived for more than 5 years (*Fig.* 2).

Additional existing disabilities in the patients treated are shown in *Table I*; 31·4 per cent of the patients were diabetic. This compares with approximately 25 per cent of all amputees being diagnosed as diabetic in the Annual Report of the Chief Medical Officer of the Department of Health and Social Security for 1970. There was a 23·8 per cent incidence of symptomatic ischaemic heart disease, and 9·5 per cent of the patients had had a cerebrovascular accident resulting in disability which interfered with rehabilitation.

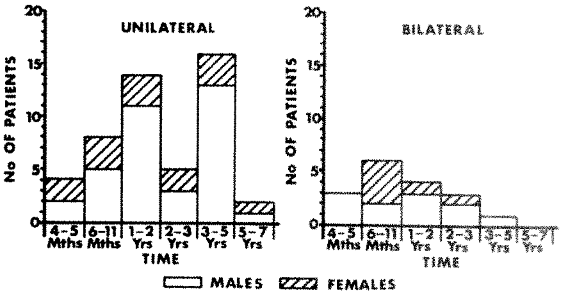

FIG. 2.—Survival times of living patients (49) from unilateral or bilateral amputation to date of visit.

Table II.—AGES OF THE 105 PATIENTS AT THE TIME OF THEIR FIRST AMPUTATION

SEX	AGE (yr.)			
	Under 40	40–59	60–79	Over 80
Males	2	6	61	9
Females	0	2	19	6
Total	2	8	80	15

The average age of the patients in this series at the time of the first amputation was almost 70 years, which is 7 years older than the patients presented by Burgess, Romano, Zettl, and Schrock (1971). The average age of patients requiring amputation of the second leg was 71 years. There was an average time interval of 14 months between amputation of the first and second legs. There was no significant difference in the average age of diabetic patients requiring amputation as compared with non-diabetics. Department of Health statistics for 1970 showed that 84 per cent of primary amputees suffering from vascular disease were over 60 years of age. In this series 91·5 per cent of the patients were over the age of 60 (*Table II*).

Period of Hospitalization.—In a group of patients with a short life expectancy it is important to take into account the length of time spent in hospital following amputation (*Table III*). The single primary below-knee amputee spent an average of 83 days in hospital and only 3 of the 40 successes in this group failed to walk. In the single primary above-knee amputation group the average time spent in hospital was 56 days, but 8 of the 16 successes did not walk. There were only 5 single primary through-knee amputees who all walked and they spent a comparable time in hospital to the above-knee patients.

There were 9 patients admitted with an existing single below-knee amputation who required below-knee

Table III.—MAIN GROUPS OF AMPUTATIONS RELATING MORTALITY, PATIENTS DISCHARGED WALKING, AND TIME SPENT IN HOSPITAL FOLLOWING AMPUTATION

† This patient was blind and deaf and although she could walk accommodation proved difficult to find.
‡ Discharged on crutches.

amputation of the other leg, and 1 patient had bilateral below-knee amputations on the same day. The average time spent in hospital was 110 days and all 10 patients were discharged walking. There were 4 single above-knee amputees who were admitted for above-knee amputation of the other leg; 2 died and the other 2 were discharged in wheelchairs. There were 11 single amputees who had amputation of the second leg at a different level from their original amputation, and 1 patient had bilateral amputations during a single admission. Only 5 of these 12 patients became ambulant. The number of days spent in hospital by the patients whose stumps healed satisfactorily (average 86 days) is influenced by 2 patients who were able to return to geriatric accommodation shortly after surgery.

In commenting on these figures it must be remembered that almost half our patients came from outside the London area, and many of the patients who lived within the London area had unsuitable homes or could not return to their previous accommodation. To obtain a high proportion of rehabilitated patients the necessity of retaining them in hospital until they were capable of an independent existence was accepted (Robinson, 1971). The reduced average time spent in hospital by the single above-knee as compared with the single below-knee amputee was in part due to a difference in wound healing. Of the 40 below-knee amputees whose stumps healed, there was delayed healing in 13 cases (32·5 per cent). Of the 16 above-knee amputees whose stumps healed, there was delayed healing in 3 (18·7 per cent). Another factor was the reduced period of hospitalization of the non-ambulant above-knee amputees.

Rehabilitation.—There are two main aspects to be considered in the postoperative rehabilitation of the amputee.

First, there is physical rehabilitation, which includes training the patient to walk on an artificial limb, and teaching him to use a wheelchair and other ancillary aids. Implicit in this training is the necessity to regain independence. Patients must accept the loss of their limb and the necessity to replace it with an artificial one. In the elderly it is difficult to overcome reduced learning capacity and poor memory. Deafness and impaired vision may be significant handicaps, and corrective measures, where possible, are very important. Other disabilities resulting from cardiovascular disease frequently impose extra problems in locomotion and mental function.

Secondly, there is social rehabilitation, which incorporates the return of the patient to suitable accommodation. Even when the patient returned to his original accommodation it had to be modified with handrails, bath and toilet aids, and to take a wheelchair. Where modifications had to be carried out by local councils long delays were sometimes experienced. Where the patient could not return to his own home or to the home of relatives there were occasionally long delays in obtaining accommodation. The longest delay in our experience was for a female patient who had to stay in hospital for 492 days before accommodation could be found.

A further aspect for the younger amputee is resettlement, to which early consideration must be given.

The patients who lived long distances from the Limb Fitting Centre were deliberately kept in hospital for rehabilitation as treatment on an out-patient basis would have required unacceptably long travelling times each day. From an economic standpoint alone it would have been more expensive than keeping the patient in hospital. There is no easy answer to this problem. If there were decentralization of the limb-fitting services it would be possible for more patients to attend daily for walking training and rehabilitation. One solution to the problem, which would meet our own needs more adequately, would be the construction of a specialized disabled living unit similar to the Mary Marlborough Lodge at the Nuffield

Orthopaedic Centre in Oxford, described by Hamilton and Nichols (1972). It would then be possible to make sure that patients were rehabilitated to the maximum extent before returning to the outside world. It is our experience that when patients curtail their rehabilitation, full use is not made of artificial limbs and other aids and these people tend to revert to a wheelchair life or become bedridden.

Unsuitable	8	42·1	
Old people's homes and	8	15·4	
Old people's flatlets	1	1·9	
Unsuitable	0	0·0	
Hospital	1	1·9	

Chilvers and Browse (1971) stressed the difficulty of returning patients to their own homes and 7 out of 20 of their cases were discharged to institutions. While they were waiting for suitable accommodation these patients occupied acute surgical beds for many weeks. Of our 105 patients, 18 were discharged to institutions. Twelve of these patients were admitted from institutions; 6 came from their own home and were discharged into institutional care.

Follow-up of Surviving Amputees.—The 52 surviving amputees had 69 lower-limb amputations carried out between June, 1966, and December, 1971. The details of this group (*Table IV*) show no striking difference from the original 105 amputees. As can be seen in *Table V*, there is a preponderance of single and bilateral below-knee amputees. *Table VI* shows that 92 per cent of the group are over the age of 60.

Twelve patients (23 per cent) had some discomfort in the form of stump or phantom pain. In 5 of these patients this discomfort was severe enough to be contributory to either cessation of walking or limiting the use of the prosthesis.

State of Rehabilitation.—*Table VII* documents the supply and use of prostheses and wheelchairs; it also indicates the state of rehabilitation of the patients and whether this had changed from that listed on discharge from hospital. Thirty-three patients (63·5 per cent) continued to walk, 11 patients (21 per cent) had discontinued walking, and 8 patients (15 per cent) did not walk. This latter group is divided into two sections. The patients listed under 'did not walk' originally tried to use a prosthesis in hospital but failed to attain any degree of competence and were then rehabilitated in a wheelchair. Under the heading 'prostheses not supplied' are listed patients where no attempt at walking was made. Most of the sub-group figures are too small for serious comment, but we should like to draw attention to the fact that 5 out of 8 bilateral below-knee amputees continued to walk, whereas all the bilateral above-knee amputees found a wheelchair existence more satisfactory.

Table VI.—AGES OF THE 52 LIVING AMPUTEES AT THE TIME OF THEIR FIRST AMPUTATION

SEX	AGE (yr.)		
	40–59	60–79	Over 80
Males	4	31	3
Females	0	10	4
Total	4	41	7

Of the 33 patients who continued to use their prostheses, 5 were not wearing their limbs when visited (1 bilateral, 1 above-knee, and 3 below-knee amputees). The bilateral amputee had not completed his walking training, and his prostheses had been kept at the hospital. The above-knee amputee said she found it difficult to put on her pylon. Of the 3 below-knee amputees, 1 had congestive cardiac failure, 1 was recovering from hemiplegia, and 1 had severe stump pain.

The patient's continued use of his prosthesis was apparently determined to some extent by his social situation, irrespective of amputation level. Of 28 patients who lived at home with relatives, 25 (89·3 per cent) continued to walk. Of 9 patients who lived alone, 5 (55·6 per cent) continued to walk (1 had not completed his walking training and therefore could not be assessed). In these patients difficulty in putting on the prosthesis and fear of falling are deterrents to limb-wearing. Patients who lived in geriatric accommodation were generally not encouraged to use their prostheses, and only 2 out of 7 (28·6 per cent) continued to do so. The patient's own attitude is perhaps the most important factor: those who have the determination to walk will do so in any situation.

Every amputee must have some means of getting about when he is not wearing his prosthesis and when other conditions restrict mobility. All bilateral amputees have a wheelchair, but in the case of the single amputee there is a choice between a wheelchair and crutches. *Table VII* shows that 18 single amputees were not issued with a wheelchair. They were supplied with crutches. Many elderly patients cannot walk safely with crutches, and they may not be able to get outside their home without a wheelchair. Fourteen single amputees required a wheelchair in addition to their prosthesis. A wheelchair can enable the elderly amputee to achieve maximum independence (Hamilton and Nichols, 1972), but it should be used as a complement to the prosthesis and not as a replacement for it.

Table VIII shows the relation between the level of amputation and independence. The value of this table depends upon our definition of independence. A patient had to fulfil the following criteria, whether he walked or led a wheelchair life, to be classified as personally independent. He had to be capable of dressing and undressing himself, preparing food and feeding himself, transferring to a chair, bed, and toilet, and washing and personal toilet. It was desirable that he should be capable of venturing outside, at least to the local shops, in an emergency. It was felt to be unfair to call a patient dependent if he fulfilled all the other criteria but could not get outside in a wheelchair because of difficult steps, or because he lived in a high-rise flat. Twenty-seven patients (51·9 per cent) were considered to be personally independent.

To enable them to live at home some patients required the help of a district nurse (7 patients), a home help (7 patients), and some had midday meals provided by the meals-on-wheels service (5 patients).

Accommodation.—Accommodation was assessed for suitability, and was classed as suitable if the patient could obtain ready access to the bathroom, toilet, kitchen, living room, and bedroom, and if he could gain easy entry to the living unit by at least one door. Suitability is listed for council, private, and rented property and for specialized old people's accommodation. In many council and private properties the patient was unable to use the bathroom because of difficult stairs and narrow doorways. Most properties had entrance steps making wheelchair access difficult. Some patients found lift failure in high-rise flats an occasional hazard.

Sixteen patients were living in unsuitable homes. Recommendations for alternative accommodation had been made in each case during the patient's hospital stay following a home visit by hospital staff. Six patients living in council property wished to move and werewaiting for rehousing. Three patients in private accommodation were trying to obtain new housing. The rest of the group had either decided not to move and to accept the shortcomings of their homes or had rejected alternative accommodation.

FIG. 3.—The amputation team.

Employment.—Nine patients were working in the period prior to admission to hospital, and 7 of these returned to employment after amputation.

Recommendations.—Constructive recommendations were made in 10 cases. Further walking training was thought necessary for a bilateral below-knee amputee and a single below-knee amputee who had given up walking because of lack of confidence. After further training they continued to use their limbs when revisited. In the remaining 8 patients minor structural alterations were required in the homes of 3 patients, rehousing was required by 2, and 1 needed a home help. Two other patients and 3 of those already mentioned needed additional aids and instruction in their use.

The Amputation Team.—Amputation of a limb constitutes a major disaster to any patient. To overcome the physical and mental problems which result, particularly in the elderly, an enthusiastic team approach is necessary (Vitali, 1970). Our own team is illustrated in *Fig.* 3. A close liaison is essential between members of the team. This type of work can be time-consuming and discouraging, but not infrequently a patient who initially appears to be a hopeless medical and social problem learns to walk again and returns to a useful existence within the community. It must be remembered that the patient with an ischaemic limb may have been unable to lead a normal life for some time and that pain and incapacity lead to poor nutrition and depression. Other problems associated with advancing years have already been discussed. The team approach helps to draw attention to all these problems, which can be frequently overlooked in a busy hospital.

CONCLUSIONS

The amputees in this series have a limited life expectancy and require long hospitalization in the post-amputation period. Living units for the disabled would help to reduce the period of time that they occupy acute surgical beds. The experience of an amputation team is beneficial to the quality and rate of rehabilitation.

It is possible for a high percentage of elderly amputees to make a successful return to society, either ambulant or in a wheelchair. Most amputees returning to their own home require some adaptation of the dwelling, and it is important to make certain that recommendations have been carried out, preferably before discharge. Most of the surviving patients had maintained their standard of rehabilitation when visited in their homes. Social services play an important part in enabling the amputee to live within the community. It was disappointing to find some old people's homes discouraging ambulation in patients who had been taught to walk again.

Acknowledgements.—We wish to thank all our colleagues in the amputation team. In particular, we wish to thank Mr. K. P. Robinson and Mr. A. G. Rutter for permission to review their patients and for their encouragement and advice, and Dr. M. Vitali, Dr. I. H. M. Curwen, Dr. P. C. Puddifoot, and Dr. R. G. Redhead for ideas and suggestions.

We acknowledge financial assistance from the Governors' Discretionary Fund of the Westminster Hospital towards our expenses.

We are grateful to the staff of the Biomechanical Research and Development Unit, Roehampton, for their assistance in the drawing and photography of our illustrations.

We are grateful to Mrs. J. P. Bristow and Mrs. D. J. Browning for assistance in the preparation of the manuscript.

INFARCTION OF FIBRO-ADENOMA OF THE BREAST

BY JOSEPH NEWMAN AND LEONARD B. KAHN

DEPARTMENT OF PATHOLOGY, UNIVERSITY OF CAPE TOWN MEDICAL SCHOOL AND GROOTE SCHUUR HOSPITAL, CAPE TOWN, SOUTH AFRICA

SUMMARY

Infarction of benign lesions of the breast is very uncommon and may lead to difficulties in clinical and pathological diagnosis. Five instances of infarction occurring in a fibro-adenoma are described; in 2 of them thrombo-occlusive vascular changes were seen. The aetiology, pathogenesis, and helpful diagnostic features are discussed.

INFARCTION is an infrequently reported complication of fibro-adenoma of the breast. In a review of the literature we have been able to find only 11 such cases, of which 4 occurred during pregnancy and lactation (Delarue and Redon, 1949; Wilkinson and Green, 1964; Pambakian and Tighe, 1971); in none of these were vascular changes described. This article reports a further 5 cases and describes vascular lesions that were present in 2 of them; only 1 of the 5 cases was associated with pregnancy and lactation.

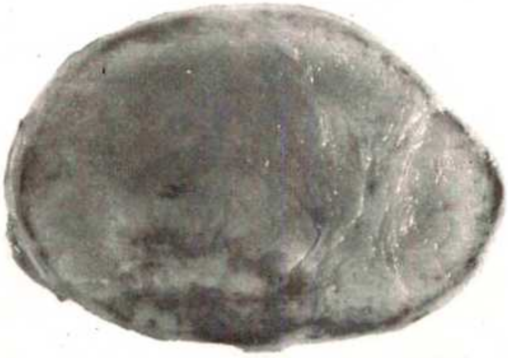

FIG. 1.—*Case* 3. Cut surface of infarcted fibro-adenoma.

CASE REPORTS

Case 1.—A 25-year-old coloured female presented with a tender lump in her breast which she had noticed 10 days prior to her admission in August, 1956. She was not pregnant and there were no other relevant clinical features. An excision biopsy was performed.

The specimen consisted of fibro-adipose tissue weighing 38 g. The cut surface revealed a 4 × 3-cm. well-encapsulated nodule with a variegated appearance. There were soft greyish-pink as well as firm white areas. Histologically, the lesion was well circumscribed and surrounded by compressed but otherwise normal breast tissue. It showed the features of a fibro-adenoma of predominantly intracanalicular type. Except for a viable rim at the periphery, the tumour was necrotic but the original architectural pattern was still discernible. Within the necrotic tissue focal areas of interstitial haemorrhage were evident. Several large vessels were seen at the periphery of the tumour and in the surrounding breast tissue, but they showed no evidence of either thrombo-occlusive or inflammatory vascular disease. Within the necrotic areas many of the vessels were intensely congested. The features were those of a fibro-adenoma which had undergone recent infarction.

Case 2.—In August, 1960, a 40-year-old Caucasian female presented with a 1-week history of a mobile lump in her right breast. An excision biopsy was performed.

The specimen consisted of breast tissue measuring 10 cm. in its greatest dimension. The cut surface showed two lobulated nodules. The larger nodule measured 6·5 cm., had a dark-red colour, and its appearance suggested a necrotic fibro-adenoma. The smaller nodule had the appearance of a typical fibro-adenoma. Histological examination confirmed the features of an intracanalicular fibro-adenoma. However, in the larger nodule there were extensive areas of necrosis with foci of interstitial haemorrhage and congestion. Within these foci the original architecture of the fibro-adenoma was still preserved. At the periphery the tumour tissue was still viable and was infiltrated by acute and chronic inflammatory cells. Within a fibrous septum separating a lobule of viable from necrotic tissue there was a medium-sized vessel which was completely occluded by thrombus. These features indicated a fibro-adenoma with large areas of recent infarction.

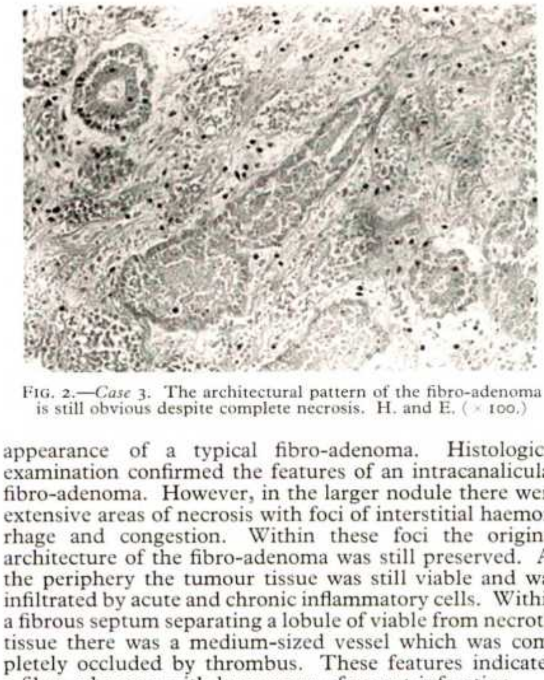

FIG. 2.—*Case* 3. The architectural pattern of the fibro-adenoma is still obvious despite complete necrosis. H. and E. (× 100.)

Case 3.—A 17-year-old coloured female presented in April, 1972, with a history of being aware of a lump in her right breast for 3 months. Before her admission she had developed a throbbing pain in the lump. There was no history of recent pregnancy or of trauma to the breast. On examination the lump was found to be mobile and non-tender; the axillary nodes were not palpable. The breast lump was excised.

The specimen consisted of a circumscribed tumour mass weighing 50 g. and measuring 4·5 × 4 × 3 cm. (*Fig.* 1). It had a lobulated bulging cut surface with geographically outlined haemorrhagic and tan-coloured areas. Microscopically, the lesion was a fibro-adenoma of mixed type. Except for a peripheral rim of viable tumour tissue, most of the lesion was necrotic but with preservation of the architectural pattern (*Fig.* 2). A mild lymphocytic infiltrate was present at the margins of the infarcted areas. A small artery was located adjacent to an infarcted area and its lumen was occluded by recanalized thrombus (*Figs.* 3, 4). The features were those of a fibro-adenoma with large areas of infarction.

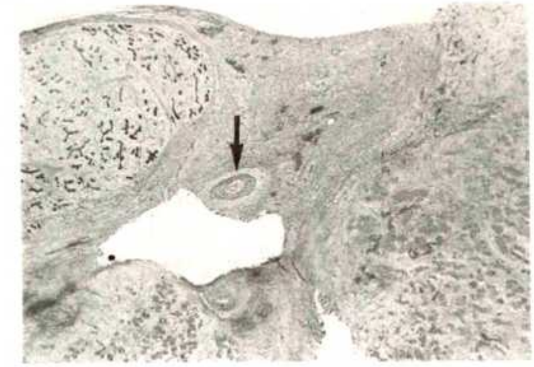

FIG. 3.—*Case* 3. Viable fibro-adenoma is seen on the left and necrotic fibro-adenoma on the right. An artery showing occlusion of its lumen by recanalized thrombus is present in the fibrous septum (arrow). H. and E. (× 90.)

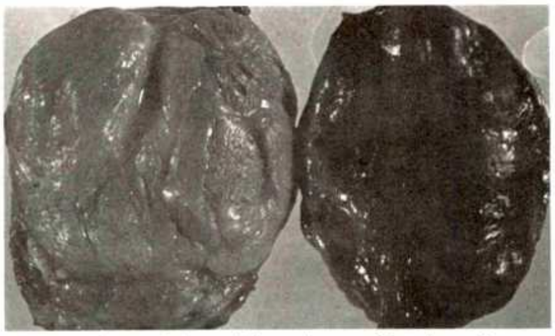

FIG. 5.—*Case* 4. Infarcted fibro-adenoma. Capsular surface on the right and cut surface on the left.

Case 4.—In July, 1972, an 18-year-old coloured female presented with a 2-year history of a lump in her breast. She had first noticed the lump following trauma to her breast during a game of netball. The lump had slowly increased in size and was occasionally painful. Four months prior to her admission she had given birth and had breast-fed the baby from the opposite breast. The lump had not decreased in size during puerperium or lactation. On examination the presence of a mobile lump in the left upper outer quadrant was confirmed. The axillary nodes were not palpable. The lump was excised.

The specimen consisted of a well-circumscribed spherical mass measuring 6 cm. in diameter (*Fig.* 5). It had a bulging cut surface and a distinct tan colour. Most of the tumour mass appeared to be necrotic. Microscopically, the lesion was a fibro-adenoma in which the acinar epithelial cells showed lactational change. The circumscribed mass was surrounded by a compressed rim of breast tissue showing regressive postpartum change. Except for a rim of peripheral viable tumour tissue, most of the lesion was necrotic. In areas of necrosis there was a marked histiocytic infiltrate in response to liberated secretions (*Fig.* 6). At the junction between the viable and necrotic tissue an infiltrate of acute and chronic inflammatory cells as well as fibroblastic proliferation was present. There was no evidence of thrombo-occlusive or inflammatory vascular disease. The features were those of a fibro-adenoma showing lactational change and extensive recent infarction.

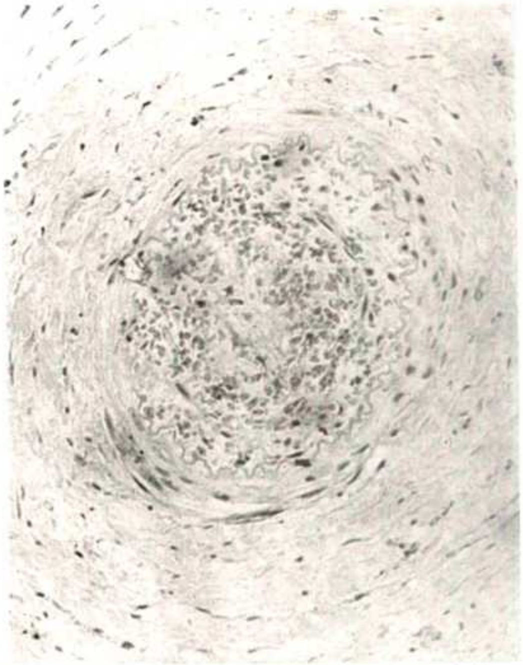

FIG. 4.—*Case* 3. Detail of recanalized thrombus occluding a medium-sized artery in a fibrous septum. H. and E. (× 150.)

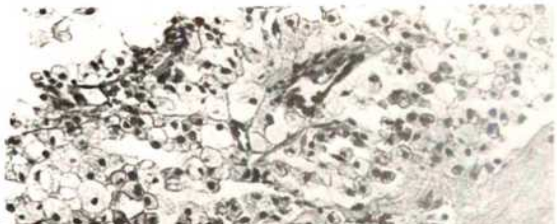

FIG. 6.—*Case* 4. Histiocytic reaction in response to the liberation of secretions from the infarcted fibro-adenoma showing lactational change. H. and E. (× 94.)

Case 5.—A 17-year-old coloured female presented with a mass in the right breast of 1 month's duration. Initially the lump was tender and the patient complained of a throbbing pain associated with it but these symptoms had subsided. She had been given antibiotics by her doctor who had diagnosed a breast abscess. There was no history of trauma. On examination a 5-cm. firm well-circumscribed mass was palpated and was thought to be a treated breast abscess or a fibro-adenoma; it was excised.

The specimen consisted of a well-encapsulated nodule 4·5 cm. in diameter with a necrotic-looking grey cut surface. Histologically, the peripheral rim of the lesion showed features of a pericanalicular fibro-adenoma while the bulk of the tumour was completely infarcted. No occluded feeding vessels were noted.

DISCUSSION

Fibro-adenomas are common benign breast lesions and in one large series (Wright and Symmers, 1966) they constituted 19 per cent of all benign breast lumps. There are very few reports of necrosis occurring in these lesions and several standard textbooks of pathology fail to mention this complication (Wright and Symmers, 1966; Ackerman, 1968; Anderson, 1968; Evans, 1968; McDivitt, Stewart, and Berg, 1968). We have been able to find only a few references to infarction occurring in fibro-adenomas. Six such lesions occurring in non-pregnant women are recorded in the French literature by Delarue and Redon (1949). Wilkinson and Green (1964) have reported 2 instances of infarction in fibro-adenoma occurring during pregnancy and lactation, while Pambakian and Tighe (1971) recently reported 1 case of infarction of a fibro-adenoma unassociated with pregnancy and 2 cases occurring in association with pregnancy and lactation. We have been able to find 5 cases of infarction in a fibro-adenoma recorded in the surgical pathology files of the Groote Schuur Hospital from 1950 to 1972 but we have not systematically reviewed all the fibro-adenomas seen in this department. Two of these 5 cases were seen during the past 6 months; only 1 of the 5 was associated with pregnancy and lactation.

Other authors have been unable to demonstrate an anatomical cause for the infarction of fibro-adenomas and have postulated a relative vascular insufficiency secondary to an increased metabolic requirement such as occurs during pregnancy and lactation. Pambakian and Tighe (1971) were unable to account for the infarction of the fibro-adenoma that occurred in a postmenopausal patient. The infarcted fibro-adenoma in the present *Case* 4, who had recently been pregnant, displayed similar histological features to those described by Wilkinson and Green (1964), viz., a fibro-adenoma with lactational changes and infarction without obvious anatomical cause. Two of the present lesions resembled one of the cases described by Pambakian and Tighe (1971) in that the infarction occurred in the absence of pregnancy and without demonstrable vascular lesions to account for the infarction. However, in the two other lesions we were able to demonstrate thrombo-occlusive vascular changes in the feeding vessels. As far as we are aware this is the first documentation of such changes in this condition. These vessels subtended the areas of infarction and were situated in fibrous septa separating areas of infarcted from viable tumour. The areas of infarction seemed disproportionately large, considering the size of the vessel involved. Although it is possible that these thrombosed vessels may have been the primary cause of the infarction, the possibility of secondary thrombosis following the infarction cannot be entirely excluded. It is interesting to speculate on the possible role of mechanical factors, as fibro-adenomas are usually very mobile in the breast and could theoretically undergo torsion with compromise of their blood-supply. If this were an important aetiological factor it is surprising that infarction is not a more frequent complication in fibro-adenomas. The theory of relative vascular insufficiency occurring during phases of increased metabolic activity and nutritional requirement may explain the necrosis described in fibro-adenomas in pregnancy (Wilkinson and Green, 1964; Pambakian and Tighe, 1971). This same mechanism has been postulated to be the cause of necrosis that occurs in lactational adenomas (Hasson and Pope, 1961). However, it is difficult to understand why infarction of fibro-adenomas during pregnancy and lactation is so infrequently recorded.

It is of paramount importance for the pathologist to recognize infarction in a fibro-adenoma and not to mistake it for necrotic breast carcinoma. Delarue and Redon (1949) described these tumours as having clinically simulated carcinoma, viz., hardness, fixation, and enlarged axillary nodes. The clinical diagnosis of carcinoma was made with such confidence that 4 of their 6 patients underwent mastectomy without the benefit of prior excision biopsy and frozen-section examination. In none of our patients was the diagnosis of carcinoma considered. However, the surgical pathologist always regards necrosis in tumours with suspicion so that examination of necrotic areas in a fibro-adenoma may give rise to diagnostic difficulties, especially on frozen-section examination. The necrotic ductular and glandular outlines may bear a superficial resemblance to adenocarcinoma, while the collection of foamy histiocytes lying loosely within the necrotic tumour tissue spaces, as seen in our *Case* 4, may simulate a mucoid carcinoma. However, the macroscopical features as well as the architectural pattern, even in the necrotic areas, are quite obviously those of necrosis in a fibro-adenoma. Sections taken from the periphery usually reveal viable fibro-adenomatous tissue so that confusion between carcinoma and necrosis in a fibro-adenoma should not occasion diagnostic difficulty, even on frozen-section examination.

First and for all.

In severe neo-natal infections

In septicaemias

In serious post-operative situations

G-DAY-those first vital 24 hours in serious bacterial infections:

- when effective therapy must be initiated to prevent rapid deterioration in the patient's condition
- when the causative organism is unknown or uncertain
- when there is no time for trial and error

When these situations occur in acute or acute on chronic infections, Genticin Injectable, the antibiotic with the broadest bactericidal spectrum of all, has proved eminently successful as first-line therapy in a wide range of conditions.

"It therefore follows that on sensitivity testing alone, gentamicin (Genticin) would be the best single antibiotic for blind chemotherapy."[1]

[1]Reference: J Irish med Ass, 65, No 20, 514, 1972.

Genticin Injectable is available in 2 ml multidose vials and snap-off ampoules. Each 2 ml contains 80 mg gentamicin base as gentamicin sulphate.

Further details are available on request from:

THE TECHNIQUE AND POSSIBLE APPLICATION OF SUPRA-ORBITAL ARTERY BLOOD-PRESSURE ESTIMATION

By A. P. WYATT, K. RATNAVEL, and G. E. LOXTON

BROOK GENERAL HOSPITAL, LONDON

SUMMARY

An indirect method of measuring systolic blood-pressure in the supra-orbital arteries by an ultrasonic technique is described. The results are repeatable and the expected differences are shown with changes of posture. Calculation of pressure indices has shown significant variation between normal, hypertensive, and arteriosclerotic subjects. The method should be of value in assessing the significance of occlusive lesions of the carotid vessels.

A SIMPLE method of indirect measurement of blood-pressure in the supra-orbital artery should be of value in elucidating the haemodynamics of the cerebral circulation. There are many techniques available at present, such as ophthalmodynamometry (Eastcott, 1969), tonometry with carotid compression (Percival and Ridgway, 1968), and thermography (Maudsley, Samuel, Sumerling, and Young, 1968) of the face which probably reflect changes in cerebral circulation, but these are not as easily understood or interpreted as a blood-pressure measurement. Doppler ultrasound studies of blood-flow in vessels of the carotid distribution have also been reported (Brockenborough, 1973). Reversal of flow, if it can be demonstrated in vessels around the orbit, is certainly of significance.

In this article a device incorporating the probe of a Doppler ultrasound blood-flow detector which enables indirect measurement of systolic blood-pressure in the supra-orbital arteries is described.

The Doppler ultrasonic blood-flow detector now in use in clinical practice in most obstetric and vascular units has been well documented (Yao, Gourmos, Hobbs, and Irvine, 1970). The supra-orbital artery is a branch of the ophthalmic artery which itself is the first major branch of the internal carotid artery, so that lateral blood-pressure in this artery should reflect to a degree, depending on anastomotic vessels, the blood-pressure in the distal internal carotid artery. As the supra-orbital artery leaves the orbit to pass over the forehead it lies over the smooth frontal bone and can be compressed against it. Preliminary experiments showed that the ultrasound beam of a Parkes Model 802 blood-flow detector would pass with little attenuation through a thin rubber diaphragm liberally coated on both sides with coupling jelly. A capsule was therefore developed with a lax rubber diaphragm in which the ultrasound probe could be incorporated and in which the pressure, and thus the pressure of the diaphragm on the forehead, could be raised. Increasing pressure in the capsule, balanced against a mercury column, eventually stops flow in the artery as registered by the flow detector and should give a systolic blood-pressure reading as accurately as a sphygmomanometer placed around an arm. The technique which has previously been briefly reported (Wyatt, Ratnavel, and Loxton, 1971) is now described in detail.

MATERIALS AND METHODS

The Apparatus.—The pressure capsule was made of a Perspex box with external dimensions of 3·0 × 3·0 × 3·75 cm. Into the upper surface the probe of a Doppler blood-flow detector (Parkes Model 802) is introduced through an air-tight 'gland'. A connexion through the lateral wall is attached to an air reservoir, rubber bulb pump, and mercury column. A window 2·0 cm. in diameter is cut in the lower surface of the capsule to which the rubber diaphragm is attached by a circular metal clamp. The diaphragm was initially formed from specially manufactured latex rubber, but the thumb tip of a large rubber surgical glove has been found equally useful. The Perspex capsule is mounted at the corners on small rubber feet which are adjustable to allow for contour differences on the forehead. To prepare the capsule for use a liberal quantity of ultrasound contact jelly is introduced into the capsule to reach the concave surface of the diaphragm and the ultrasound probe is manipulated into the jelly to as low a level as possible without interfering with the action of the diaphragm. The outer surface of the diaphragm is also coated with the jelly.

The Examination.—The subject is examined lying supine on a couch. The arm blood-pressure is recorded. The supra-orbital artery is then identified with an unmodified Doppler probe and the capsule is placed in position over the site of the artery. The legs of the capsule are adjusted so that with firm manual approximation of the capsule to the forehead the rubber diaphragm (but not the end of the Doppler probe) rests on the forehead. Small adjustments of the position of the probe are now required until flow in the vessel is identified. Pressure in the capsule is raised and the values necessary just to obliterate flow and at which flow returns are noted. The mean of these is recorded. This is repeated three times. The readings are then repeated with pressure first on one and then on both temporal arteries to make sure that the vessel concerned is not a branch of these. The brachial systolic pressure is recorded once more. Next the subject sits in a chair against a wall and the measurements are repeated in this position.

Subjects.—Three categories of people were selected for examination in the preliminary investigation of this device.

Normal Subjects.—By this we meant subjects under 40 years of age in normal health. These subjects were nurses, medical students, doctors, and patients in the surgical ward for hernia repair.

Hypertensive Subjects.—These were young patients under investigation for hypertension who, as far as could be ascertained, did not yet suffer from degenerative arterial disease.

Arteriosclerotic Subjects.—These were patients attending the arterial clinic with intermittent claudication but without evidence of cerebrovascular disease, diabetes, or gross hypertension.

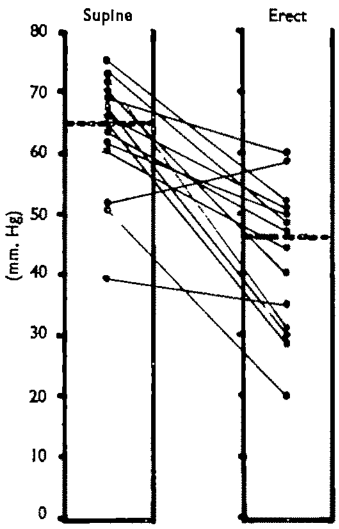

Fig. 1.—Differences between supra-orbital artery pressures in normal subjects in supine and erect positions.

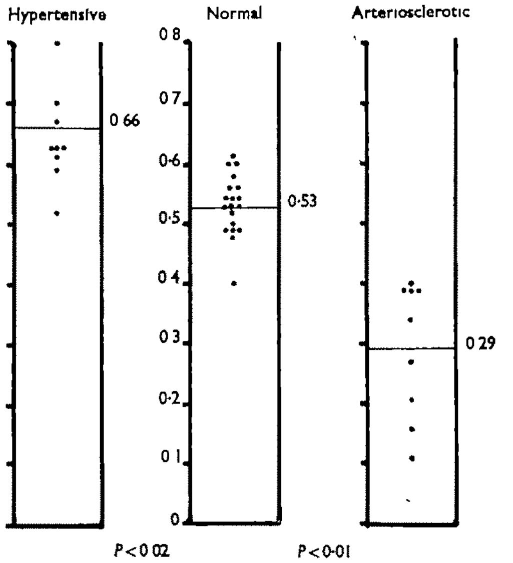

Fig. 3.—Comparison of the pressure index in normal, hypertensive, and arteriosclerotic subjects.

RESULTS

The number of subjects in each category is set out in *Table I*. It will be seen that in 1 'normal' subject only one supra-orbital artery could be found and recorded.

Table II sets out, in a somewhat foreshortened form, the values obtained in 1 subject, illustrating that the results are repeatable.

An analysis was made of the differences measured between right and left arteries in each category of patient in both erect and supine positions. In none of the six categories thus obtained and subjected to Student's t-test was there any significant difference between the left and the right supra-orbital pressures, nor was there any difference in the whole series.

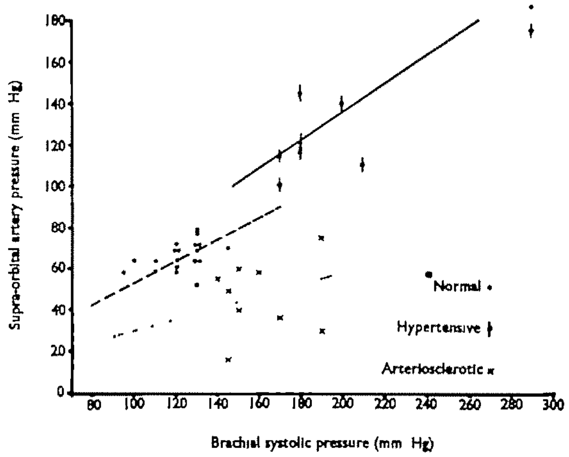

Fig. 2.—Composite graph of all the values obtained in the supine position expressing supra-orbital artery pressure in terms of brachial systolic pressure.

Table I.—Number of Subjects and Arteries examined in Each Category

Subjects	*No. of Subjects*	*No. of Arteries*
Normal	19	37
Hypertensive	9	18
Arteriosclerotic	9	18
Total	37	73

Table II.—Supra-orbital Artery Pressure Estimations obtained in a Normal 29-year-old Male

	Supra-orbital Artery Pressure (mm. Hg)	
	Right	Left
Lying supine*	63 62 63	64 65 68
Ipsilateral temporal artery occlusion	61	68
Bilateral temporal artery occlusion	61	70
Sitting erect†	45	30

* Brachial blood-pressure 110/75 mm. Hg.
† Brachial blood-pressure 110/70 mm Hg

When pressure differences in the supine and erect position were sought significant values were obtained. *Fig.* 1 illustrates these differences in the normal subjects. It can clearly be seen that the pressures are significantly higher in the supine position. The mean difference in the normal group was 19 mm. Hg ($P<0{\cdot}01$), in the hypertensive group it was 18 mm. Hg ($P<0{\cdot}02$), and in the arteriosclerotic group it was 15 mm. Hg ($P<0{\cdot}05$). There is no significant difference between these three means.

Fig. 2 is a composite graph of all the values measured in the supine position. The three categories of patients are clearly grouped. It is obvious that the pressure recorded will be related to the brachial systolic pressure. A valid comparison between these groups must take the variations of systemic blood-pressure into account. A pressure index has therefore been calculated after Yao, Hobbs, and Irvine (1969):—

$$\text{Pressure index} = \frac{\text{Supra-orbital artery pressure}}{\text{Brachial systolic pressure}}.$$

Using the mean of right and left supine supra-orbital artery pressures the mean pressure index in normal subjects was found to be 0·53. In the hypertensive group of subjects the mean pressure index was 0·66. These means are significantly different ($P < 0{\cdot}02$). The mean pressure index of arteriosclerotic subjects was 0·29. This again is significantly different from the normal ($P < 0{\cdot}01$; *Fig.* 3).

DISCUSSION

The results obtained with this apparatus strongly suggest that a function of the blood-pressure in the supra-orbital artery is being recorded, if not the true pressure. Particularly significant is the change in pressure related to the change in posture from supine to erect. The mean difference of 17 mm. Hg found is equivalent to 23 cm. H_2O and this is about what would be expected taking the hydrostatic effect of the blood column in the erect posture into account. The repeatability of the measurements and absence of any significant difference between left and right sides are also arguments for their validity. Occlusion of the superficial temporal vessels should have ruled out erroneous measurement of pressure in branches of the external carotid system. Only 1 out of 74 possible arteries could not be located and examined in this series (1·3 per cent). This may well have been due to an anatomical abnormality.

Somewhat unexpected was the apparently low value of systolic pressure in the supra-orbital artery compared with that in the brachial artery. So far we have not been successful in making direct measurements in this vessel to confirm these values, but one would expect errors as a result of pressurizing the capsule to give readings on the high rather than on the low side of normal. Wisnant, Siekert, and Milliken (1962), using ophthalmodynamometry, suggested that ophthalmic artery systolic pressure is approximately 55 per cent of the corresponding pressure in the brachial artery. This agrees very closely with our figure of 53 per cent amongst the normal subjects.

Hypertensive patients were studied to give a wide spread of systolic pressures and thus indicate the relationship of supra-orbital and brachial pressures clearly. However, a difference in the mean pressure index between the normal and hypertensive groups has been demonstrated and must be due to a difference in resistance of the vessels concerned. In a similar way, with the claudicating patients it appears that we have demonstrated at least a relative increase in resistance of these branches of the internal carotid system which may well reflect the presence of the disease process in these vessels.

This method of measurement is rather more easily learnt and simpler to perform than ophthalmodynamometry. It may be more accurate and should be useful in exactly the same situations. Preliminary measurements in a small number of patients with internal carotid stenoses and occlusions have shown distinct differences in the comparison of right- and left-sided supra-orbital pressure measurements (Wyatt, Ratnavel, and Loxton, 1973).

Acknowledgements.—We wish to acknowledge the help of Mr. J. H. Savage, F.I.E.E., who designed and made the capsule. Thanks are also due to L.R. Industries who made the rubber diaphragms. The ultrasound equipment was purchased with an Ernest Hart Research Award given by the British Medical Association.

TREATMENT OF COMBINED EXTERNAL ILIAC ARTERY AND VEIN INJURY BY CROSS-OVER FEMOROFEMORAL ARTERIAL AND VENOUS GRAFTS WITH TEMPORARY ARTERIOVENOUS SHUNT

By A. M. N. GARDNER
TORBAY HOSPITAL, TORQUAY

SUMMARY

The case is presented of a patient whose left external iliac artery and vein were inadvertently divided during attempted intestinal resection for diverticulitis of the sigmoid colon.

Gangrene of the leg was almost inevitable, direct vascular surgery was impossible, but an indirect approach by thrombectomy and double cross-over femorofemoral arterial and venous grafts with temporary arteriovenous shunt fully restored the life of the limb.

During the operation severe bleeding occurred through the mesh of the woven Teflon prosthesis.

THE external iliac artery and vein may together be severed in gunshot wounds or may be intentionally or accidentally divided during pelvic operations, particularly in neoplastic disease.

In the absence of infection, local replacement surgery with an arterial prosthesis and a venous vein-graft may be possible, although for reasons discussed in this paper the latter is often unsuccessful. Likely major complications are arterial and venous thromboses resulting from circulatory stasis.

It is suggested that these problems may be resolved by the surgical treatment described here.

CASE REPORT

Mrs. D. P., a 76-year-old housewife with chronic rheumatoid arthritis, presented at another hospital complaining of a painful mass in the left iliac fossa, fever, and diarrhoea. A barium-enema examination showed extensive diverticular disease and suggested an intraluminal filling defect. After sigmoidoscopy had shown no lesion, laparotomy was performed. During 'trial dissection' of a fixed mass in the lower pelvic colon, which in retrospect was certainly an area of diverticulitis, torrential haemorrhage from the iliac vessels was encountered; this was controlled by ligature, transverse colostomy was performed, and the operation was abandoned.

Postoperatively the left leg was noted to be blue and cold, the toes were hypo-aesthetic, and pulses were absent, but the superficial veins were distended. It therefore seemed certain that both the external iliac artery and the vein had been transected and that in the absence of treatment gangrene was inevitable.

The patient was transferred to Torbay Hospital for vascular surgery. Since direct operation on the iliac vessels was out of the question it was decided to perform combined arterial and venous femoral cross-over grafts with an arteriovenous shunt to improve the chances of maintaining venous patency.

Eleven hours after her first operation the left femoral vessels were exposed in the groin by a vertical incision under general anaesthesia. Already both the artery and vein were solid with thrombus which in the latter case extended down into the calf. After intravenous administration of 5000 units of heparin, arterial and venous thrombectomies were done with Fogarty catheters and complete obstruction of the iliac vessels about 4 cm. above the inguinal ligament was confirmed. The right long saphenous vein was then exposed, divided just below the mid-thigh, and mobilized up to the saphenofemoral junction; this vein was then brought across suprapubically in a subcutaneous tunnel to the left groin wound where the arteriovenous shunt was first formed by joining it end to side* to the left femoral artery (*Fig.* 1A) to provide a venous outflow path from the left leg. The thrombectomy opening in the left femoral vein was then anastomosed side to side to the transposed right long saphenous vein. It was thus arranged that the vein-graft would be perfused by a mixture of arterial and venous blood. With venous drainage now restored, an arterial supply to the left leg was provided by a woven Teflon cross-over femorofemoral graft placed proximally, parallel to the vein-graft, in a separate subcutaneous tunnel. On removing the clamps very severe bleeding through the interstices of the graft ensued despite neutralization of heparin with protamine sulphate and empirical administration of epsilon aminocaproic acid; eventually, when hope was fading after 17 units (8500 ml.) of blood had been transfused, bleeding eventually stopped; subsequent investigation failed to reveal any underlying haemorrhagic tendency. In view o the primary intra-abdominal sepsis trimethoprim and sulphamethoxazole were given in the postoperative period. The only transient complication was a deep venous thrombosis in the left calf on the thirteenth day, which was treated with anticoagulants.

Angiography 10 weeks after operation confirmed that both the arterial and venous grafts were patent (*Fig.* 1).

It is proposed to close the arteriovenous shunt at the time of the patient's elective colonic surgery.

DISCUSSION

Combined injuries of the external iliac artery and vein are usually repaired by direct surgery. Because of the size of the artery a woven or knitted prosthesis is usually employed, and in the case of the iliac vein reliance is placed on a saphenous graft. Unfortunately grafts in the venous system commonly thrombose unless a temporary peripheral arteriovenous fistula is fashioned (Dumanian, Santschi, Park, Walker, and Frahn, 1968). The direct surgical approach, and particularly the use of a synthetic arterial prosthesis, is not uncommonly precluded by bacterial contamination, frank sepsis, or malignancy, and it is in such circumstances that limbs may be saved by an indirect approach with cross-over arterial and venous femorofemoral grafts as described here.

Simple autogenous vein-grafts in the venous system commonly thrombose. Vein walls depend on the vasa vasorum for their arterial supply and venous drainage, but in venous grafts virtually the only source of nourishment to the wall is by diffusion from the lumen; venous blood, however, has a low oxygen content and is also under reduced pressure.

---

* For all anastomoses 50 Mersalene was used.

Temporary arteriovenous shunts increase the patency rate of venous vein-grafts (Johnson and Eiseman, 1969; Levin, Rich, Hutton, Barker, and Zeller, 1971). This favourable influence is probably the result of, first, improvement in the diffusion gradients across the vein wall during the critical time before the vein acquires a new blood-supply from the surrounding tissues, and, secondly, increased flow and pressure which discourage thrombosis and help to prevent apposition and adhesion of opposite sides of the ischaemic vein wall during any temporary compression or kinking.

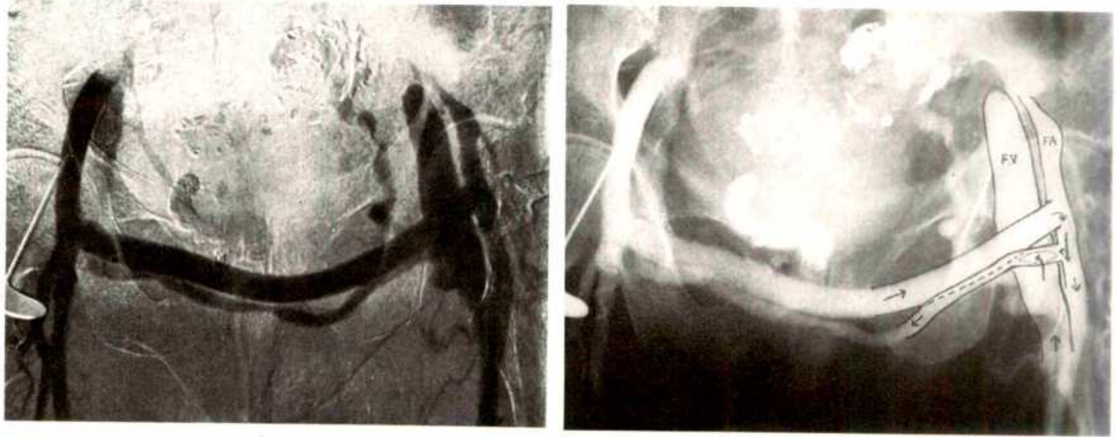

FIG. 1.—Angiograms via the right femoral artery showing contrast medium flowing across suprapubically through the Teflon prosthesis to the left femoral artery whence part is perfusing the left femoral arterial tree and part is returning with venous blood from the left femoral vein through the saphenous graft to the right femoral vein. A is a positive print made by the photographic subtraction technique. B is a diagram superimposed on the photographic negative.

The severe bleeding through the mesh of the woven Teflon graft in our patient seems most likely to have been caused by a consumption coagulopathy associated with recent operation and extensive thrombosis in the iliac and femoral veins and arteries. In such cases prostheses with as fine an impervious mesh as possible seem to be indicated.

Acknowledgement.—I would like to thank Dr. Victor Mitchell, Consultant Radiologist at the Torbay Hospital, for the angiograms.

PHYTOHAEMAGGLUTININ-STIMULATED TRANSFORMATION OF PERIPHERAL AND LYMPH-NODE LYMPHOCYTES IN PATIENTS WITH GASTRO-INTESTINAL CANCER

BY P. J. GUILLOU, T. G. BRENNAN, AND G. R. GILES
UNIVERSITY DEPARTMENT OF SURGERY, LEEDS (ST. JAMES'S) UNIVERSITY HOSPITAL, LEEDS

SUMMARY

Phytohaemagglutinin-induced lymphocyte transformation has been studied in 10 patients with gastro-intestinal cancer and in 8 control subjects. When cultured in autologous serum, peripheral lymphocytes from cancer patients exhibited lower transformation indices (L.T.I.) than did those of control subjects. Culture in AB serum resulted in an elevation of the L.T.I. of peripheral lymphocytes from cancer patients whilst those of the controls were essentially unchanged. Of 6 control subjects, 5 showed reduced L.T.I.'s when their circulating lymphocytes were cultured in serum from cancer patients. Mesenteric lymph-node lymphocytes from patients with cancer also showed lower indices compared with the control group and these were elevated by culture in AB serum.

THERE is currently much interest in the role of lymph-nodes in the immunological control of malignant disease in man. In the experimental situation it can be shown that the implantation of tumour cells provokes an increase in the number of transformed lymphocytes appearing in the lymph-nodes draining the tumour (Hall and Morris, 1963), though this is not necessarily tumour-specific. Similarly, the recent work on immunological defence mechanisms in breast cancer has suggested that enhanced lymphocytic activity is present in the axillary lymph-nodes draining the tumour provided that neoplastic involvement has not yet occurred (Humphrey, Barker, Bohesch, Fetter, Amerson, and Boehm, 1971; Deodhar, Crile, and Esselstyn, 1972). Indeed, these findings have influenced the approach to the clinical management of breast cancer (Crile, 1965).

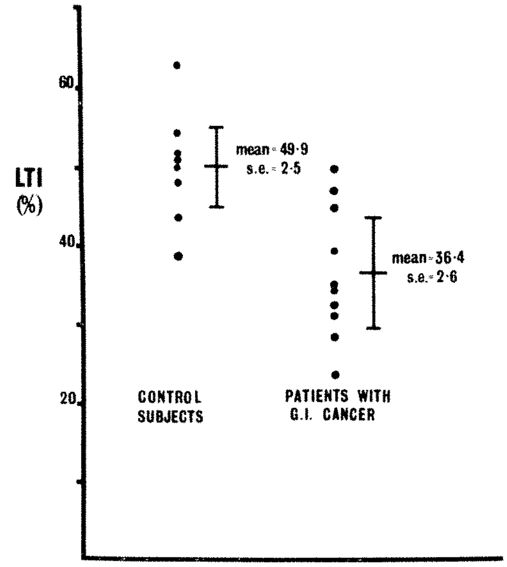

FIG. 1.—The transformation indices of peripheral lymphocytes of control subjects and patients with gastro-intestinal cancer after exposure to PHA and culture in autologous serum.

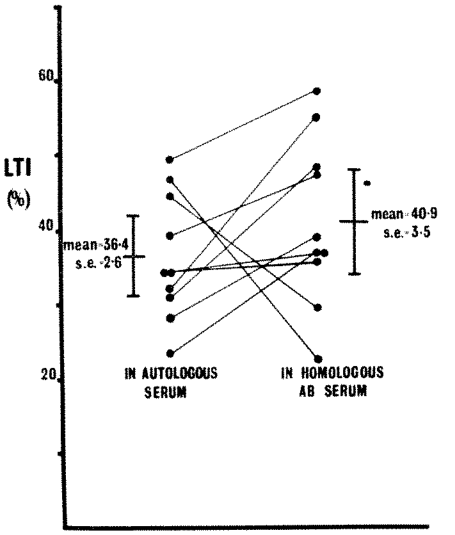

FIG. 2.—The transformation indices of peripheral lymphocytes in response to PHA of 10 patients with gastro-intestinal cancer comparing the degree of transformation obtained by culture in autologous serum with that in homologous AB serum.

Since these observations may apply to other neoplasms we have commenced a series of investigations into the immunological responses of lymph-nodes draining gastro-intestinal cancer in man. The purpose of the present study was to investigate the responses of lymph-node lymphocytes and circulating lymphocytes to stimulation with phytohaemagglutinin (PHA), comparing the results obtained from patients with cancer with those found in control subjects.

MATERIAL AND METHODS

Peripheral lymphocytes were obtained from 20 ml. of defibrinated venous blood by a modification of the method of Coulson and Chalmers (1964), utilizing methyl-cellulose sedimentation with the addition of carbonyl iron to remove polymorphs. Lymph-node lymphocytes were obtained from all lymph-nodes under study by fine mincing and filtration through a sterile 33 μ diameter sieve.

All the lymphocytes were cultured at a cell concentration of 10^6 per ml. of medium 199 (Burroughs Wellcome) containing 20 per cent serum and antibiotics. The serum in use was either autologous serum or homologous AB serum obtained from a pool of 7 healthy donors. PHA was added at a concentration of 0·05 ml. per ml. of culture medium. All the cultures were performed in duplicate in plastic tissue-culture flasks (Falcon Plastics 3012) using 5-ml. aliquots per culture. The cultures were incubated at 37° C. for 72 hours, the final half-hour of culture being accompanied by the addition of 0·1 μc. of tritiated thymidine (Radiochemicals, Amersham). At the end of this period the cells were harvested, washed three times in T.C. 199, and smeared on glass slides. Following fixation in methanol, autoradiography was performed on these smears which were then stained by routine haematological methods (Giemsa). For each culture performed at least 3000 cells were counted microscopically and the number of labelled cells demonstrating radioactive uptake was expressed as a percentage of the total number of cells counted. This expression we have termed the lymphocyte transformation index (L.T.I.).

Clinical Groups.—

1. *Patients suffering from Gastro-intestinal Cancer.*—Ten patients suffering from cancer were studied and consisted of 5 patients with carcinoma of the rectum, 4 with colonic carcinoma, and 1 patient with a carcinoma of the stomach. Peripheral blood and lymph-node lymphocytes were obtained from all these patients and the lymphocytes were cultured both in autologous serum and in pooled homologous AB serum. All the patients underwent laparotomy and resection, at which time lymph-nodes were removed from the root of the mesentery and from an area directly draining the cancer wherever possible. Altogether 15 lymph-nodes were studied from these patients.

2. *Control Subjects.*—There were 8 control subjects who were all undergoing laparotomy for non-malignant conditions (cholelithiasis, duodenal ulceration, hysterectomy, or diverticular disease), at which time mesenteric and juxta-intestinal lymph-nodes were obtained. Seventeen nodes were obtained from these subjects and lymphocytes isolated from them were cultured in autologous serum only. Peripheral blood lymphocytes were obtained from the control subjects just prior to operation and were cultured in

both autologous serum and in pooled homologous serum. In addition, the peripheral lymphocytes of 6 of the control subjects were also cultured in 20 per cent pooled serum from the patients suffering from cancer.

One-half of each lymph-node under study was also fixed in formol–saline for subsequent histological examination.

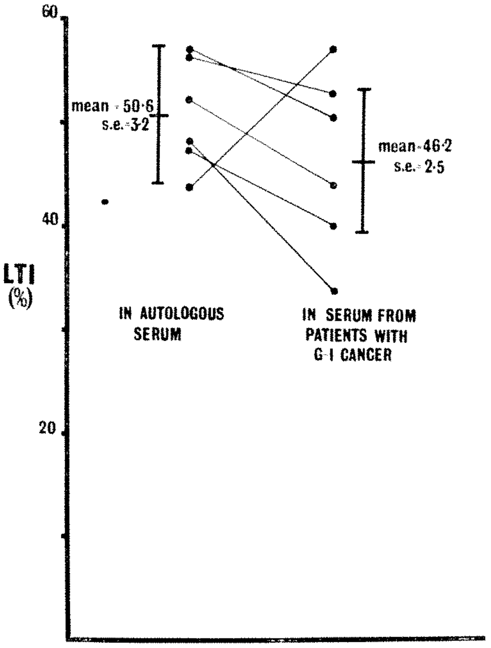

FIG. 3.—The transformation indices of 6 control subjects whose peripheral lymphocytes were cultured in autologous serum and a pooled serum from patients with gastro-intestinal cancer.

RESULTS

Peripheral Blood Studies.—

Culture in Autologous Serum.—The mean L.T.I. of the 8 control subjects whose lymphocytes were cultured in autologous serum was 49·9 ± 5·0 (± 2 S.E.M.). Similar studies using the peripheral cells from the 10 patients with cancer resulted in a mean L.T.I. of 36·4 ± 5·2. The difference between the L.T.I.'s obtained for these two groups was statistically significant at less than the 2 per cent level ($t = 3{\cdot}89$; *Fig.* 1).

Culture in Homologous AB Serum.—The effect of culture in pooled homologous AB serum was variable, with 3 control subjects showing minor elevations in the L.T.I. when compared with culture in autologous serum, 2 showing minor diminutions in L.T.I., and the remainder showing no change. The mean L.T.I. for the group as a whole, however, remained at 50·5 ± 4 and the differences observed for the control group when culture was performed in homologous AB serum rather than autologous serum were not statistically significant ($t = 1{\cdot}49$). When the lymphocytes from the patients with cancer were cultured in homologous AB serum, 8 of the 10 patients demonstrated increased transformation indices when compared with culture in autologous serum (*Fig.* 2). The remaining 2 samples showed marked decreases. The mean transformation index for this group of patients was 40·7 ± 9 and this increase in the mean value above that obtained for culture of the same cells in autologous serum is just significant at the 5 per cent level using the Wilcoxen signed rank test.

Culture of Control Lymphocytes in the Serum of Patients suffering from Cancer.—Of the 6 control subjects whose peripheral lymphocytes were cultured in the pooled serum from the patients with cancer, 5 showed a diminution in their transformation indices but 1 showed a marked elevation (*Fig.* 3). The mean transformation index for this group of 6 subjects fell from 50·6 ± 6·4 when cultured in autologous serum to 46·2 ± 5 when culture was performed in serum from the patients with cancer. This difference, however, does not reach statistical significance.

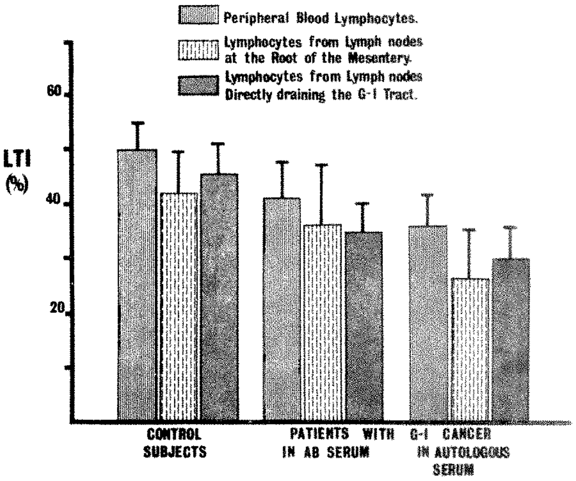

FIG. 4.—The lymphocyte transformation indices of cells obtained from the peripheral blood, root of mesentery lymph-nodes, and lymph-nodes directly draining the colon and associated neoplasm (mean values ± 2 S.E.M.).

Lymph-node Studies.—

Culture in Autologous Serum.—Lymphocyte cultures in autologous serum were prepared from all 17 lymph-nodes taken at laparotomy from the control subjects. The mean L.T.I. for this group was 43·6 ± 4·5 and the results were similar in all respects to those obtained from peripheral lymphocytes in the same subjects. When lymph-nodes in a juxta-intestinal position were considered the mean L.T.I. was 44·9 ± 2·8 compared with a mean L.T.I. of 41·2 ± 8 in lymphocytes obtained from lymph-nodes at the root of the mesentery (*Fig.* 4).

The mean L.T.I. of cells taken from the 15 nodes obtained at operation from the patients with gastro-intestinal cancer was 28·6 ± 5·8. This value was significantly lower than that observed for cells obtained from the nodes of the control subjects ($t = 5{\cdot}11$, $P < 0{\cdot}02$). Lymph-node lymphocyte values were also significantly lower than those obtained for the peripheral lymphocytes of these patients with cancer ($t = 2{\cdot}64$, $P = 0{\cdot}05$). When lymph-nodes directly draining the lesion were considered the mean L.T.I. obtained for these cells was 30·6 ± 6·4 compared with a mean L.T.I. of 26·8 ± 9·6 for cells from the root of the mesentery (*Fig.* 4). This difference, however, was not statistically significant.

Culture in Homologous AB Serum.—Only the lymphocytes isolated from the lymph-nodes obtained from the patients with cancer were cultured in homologous AB serum and this resulted in a mean transformation index of 35·8 ± 6·2. This figure is significantly different at the 5 per cent level from the results obtained for the same nodal lymphocytes when culture was performed in autologous serum ($t = 2{\cdot}48$). Again considering the results with regard to whether the cells were obtained from lymph-nodes directly draining the lesion or those at the root of the mesentery the former gave a result of 34·8 ± 5·4 whilst the latter gave a result of 36·7 ± 11·2. The difference between these two figures is not statistically significant.

Histological Studies.—Foci of metastatic disease were found to be present in the investigated lymph-nodes removed from alongside the lesions of 3 of the patients with gastro-intestinal cancer. The lymphocyte transformation indices of the cells obtained from these nodes varied little from the mean for the group as a whole. In addition, the transformation indices for both the peripheral and lymph-node lymphocytes bore no relationship to the final pathological grading of the lesion, the 10 cases being eventually divided equally between the Dukes classification B and C (Dukes, 1957).

DISCUSSION

Gastro-intestinal cancer may spread by local invasion and along lymphatic channels. Thus, the neoplasms involve mesenteric nodes draining the tumour and ultimately the lymph-nodes alongside the aorta. This tendency has led to the classification of the extent of invasion by these carcinomas described by Dukes (1957) which has proved useful in predicting the eventual outcome for the individual patient. The principles of surgical excision have, therefore, been directed to removal of the primary tumour and the regional nodes draining it as far as the aortic chain. While this is still an accepted surgical procedure, clinicians treating other tumours, notably breast cancer, have argued that not only is this practice unnecessary but that it may adversely affect the ultimate prognosis (Crile, 1968). The rationale of this argument is that the lymph-nodes which drain the tumour may be the site of a delayed hypersensitivity response against antigens present in the tumour and thus removal of these nodes deprives the patient of this natural defence.

Experimentally it has been demonstrated that following the administration of an antigenic inoculum increased numbers of immunoblasts are found in the regional lymph-nodes draining the site of injection. It has been suggested that this recruitment of sensitized lymphocytes involves their recognition of and commitment to particular antigens and is amongst the earliest of events in the initiation of an immune response. Lymphocytes removed from stimulated nodes and labelled with ^{51}Cr will home into the regional nodes of syngeneic animals immunized with the same antigen (Hall and Morris, 1963; Delorme, Hodgett, Hall, and Alexander, 1969; Zatz and Lance, 1971).

However, it has become apparent from the work of Alexander, Benstead, Delorme, Hall, and Hodgett (1969) that lymph-nodes draining experimental tumours will not release these committed cells into the general circulation until the bulk of the tumour has been removed. These observations have encouraged some surgeons to modify their management of early breast cancer in the hope that by extirpation of the tumour alone, immunoblasts will be released from uninvolved axillary nodes and impair the growth of residual tumour (Crile, 1965). It is too early to comment upon the clinical results of this approach.

It has been shown that adenocarcinomas of the gastro-intestinal tract possess surface antigens which may be capable of evoking an immune response in the patient (Gold and Freedman, 1965; Hellstrom, Hellstrom, and Shepard, 1970; Kleinman, Harwell, and Turner, 1971). It therefore seems pertinent to examine the immune competence of lymphocytes present in the lymph-nodes draining such tumours. In this study lymphocytes extracted from the peripheral blood and from mesenteric lymph-nodes have been investigated with regard to their ability to undergo blast-cell transformation *in vitro* in response to PHA. In control subjects 45–50 per cent of lymphocytes from each of these sites were observed to undergo transformation. In patients with gastro-intestinal cancer, however, lymphocytes from the peripheral blood and from the mesenteric nodes exhibited significantly lower transformation indices than those from the corresponding sites in the control subjects. Furthermore, cells from nodes directly draining the tumours of these patients exhibited significantly lower transformation responses than those observed for their circulating lymphocytes. A similar gradient of response of mesenteric lymph-node and peripheral lymphocytes has been described previously by us in relation to Crohn's disease of the ileum (Guillou, Brennan, and Giles, 1973).

The significance of these results is far from clear. Since PHA produces blast-cell transformation only in cells which are thymic-derived, the results of this study might be interpreted as indicating a reduction in the number of such lymphocytes in the circulating and lymph-node populations in patients with gastro-intestinal cancer. An alternative explanation would involve the concept that the immunological function of the lymphocytes of these patients is impaired by factors as yet undefined or that the lymphocytes are already immunologically committed and thus rendered unresponsive to PHA.

It would appear that a lymphocyte depressive factor is circulating in the patients with gastro-intestinal cancer since after thorough washing and culture of these lymphocytes in homologous AB serum, the response to PHA becomes significantly elevated. Similar depressive factors have been reported in a number of chronic infective illnesses associated with massive antigenic stimulation (Gatti, 1971) and in other forms of malignant diseases (Silk, 1967; Whittaker, Rees, and Clark, 1971). The nature of these factors is as yet unknown, though α-globulins, antibody excess, and circulating antigen have been implicated in this role (Cooperband, Boudevik, Schmid, and Mannick, 1968; Currie and Basham, 1972; Oppenheim, 1972). Whatever the nature of these factors, it is apparent that they are only partially responsible for the altered responses to PHA, for even when culture is performed in homologous serum the lymphocytes do not transform as frequently as in control subjects. Thus it must be presumed that the lymphocytes themselves are in some way affected by the presence of the cancer.

It remains unclear whether the lymph-nodes draining gastro-intestinal cancer behave in the same manner as those draining experimental animal tumours. Lymphocyte transformation indices in the nodes containing tumour metastases were similar to those which were free of tumour and it is not clear whether the lymph-node cells were sensitized by the tumour. It will be of importance to test the response of these lymph-node lymphocytes to specific tumour antigens by the use of other techniques. In this way we may be able to determine precisely the role of lymph-nodes in the immunological control of gastro-intestinal cancer.

SHORT NOTES OF RARE OR OBSCURE CASES

PRIMARY ARGENTAFFINOMA OF THE OVARY

BY W. S. JAGOE, N. G. GALLAGHER, G. F. GEARTY, AND P. J. LOGAN
ROYAL CITY OF DUBLIN HOSPITAL, DUBLIN

SUMMARY

A case is presented of primary argentaffinoma of the ovary, without metastases, that gave rise to the systemic manifestation of the carcinoid syndrome. Removal of the tumour led to regression of all symptoms. This case illustrates that single argentaffinoma tumours which drain directly into the systemic venous system may cause the carcinoid syndrome and removal may be curative in that the disease process is arrested.

CARCINOID tumour arising as part of a teratoma of the ovary was first described by Stewart, Willis, and de Saran (1939). Since then, Gabrilove (1941), Falkmer (1956), Betson and Golden (1959), and Evans, Harris, and McDougall (1959) have described cases. Somewhat more rare, however, must be the appearance of the carcinoid syndrome associated with an argentaffin tumour of the ovary. The first case was described by Sauer, Dearing, Flock, Waugh, Dockerty, and Roth (1958), and up to 1965 only 3 more cases had been described (Thorson, Pernon, Soderstrom, Waldenstrom, Winblad, and Wulff, 1958; Torvick, 1960; Kephart, Jackson, and Caylor, 1960). A further case is reported here of the carcinoid syndrome produced by a primary argentaffinoma of the ovary.

CASE REPORT

A 29-year-old woman was admitted to hospital with a 2-year history of amenorrhoea and a 3-month history of weight-loss, diarrhoea, and intermittent dyspnoea. She had been married 6 months prior to admission. On examination she had a marked cyanotic malar flush extending over the bridge of the nose. There was a moderate-sized pleural effusion on the left side, ascites, and a large, hard mass arising out of the pelvis. She had a Grade 3 pulmonary systolic murmur, a Grade 2 tricuspid diastolic murmur, and a marked expiratory wheeze over both lung fields. The haemoglobin was 12·4 g., white-cell count 6300 per c.mm., differential count normal, and erythrocyte-sedimentation rate 41 mm. per hour. The urinary 5-hydroxy-indole acetic acid was 188 mg. per g. of creatinine (normal, 10 mg.).

Laparotomy was performed 1 week later and a large tumour was found arising from the site of the left ovary and was adherent to the left Fallopian tube. While the tumour was being handled the malar flush increased in intensity and spread to involve the whole face and neck. The tumour and Fallopian tube were removed completely. Postoperative recovery was uneventful, the bronchospasm disappeared immediately, and the malar flush gradually faded over the next 4 weeks. Two days postoperatively the urinary 5-hydroxy-indole acetic acid had fallen to normal limits.

The patient has been observed for the past 5 years. Her progress has been excellent; she regained her normal weight in 6 months and began menstruation again at 3 months postoperatively. The malar flush has disappeared completely but the cardiac murmurs have remained the same.

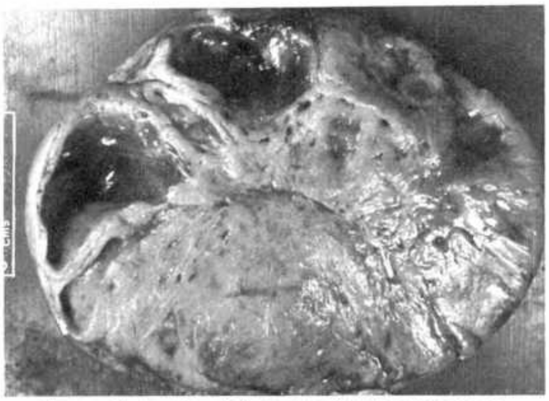

FIG. 1.—Cut surface of the tumour showing cystic spaces.

Three years later she became pregnant but miscarried at 7 months. Repeated checks of the urinary 5-hydroxy-indole acetic acid have remained normal up to the present time.

PATHOLOGY.—Macroscopically, the tumour measured 16 × 12 × 8 cm. and the cut surface showed the presence of three cysts, the largest of which measured 5·5 cm. in diameter. The remainder of the tumour was of solid, slightly yellow tissue of very firm consistency (*Fig.* 1). Microscopically, the picture was that of replacement of ovarian tissue by clumps and columns of uniform, darkly staining cells in a background of fibrous tissue, which was rather hyaline in areas. The appearance was typical of argentaffinoma and the cells showed positive silver- and diazo-staining reactions. No teratomatous tissues were found (*Fig.* 2).

DISCUSSION

The description of the pathological findings is in keeping with that already given by other authors for primary ovarian argentaffinoma (Evans and others, 1959; Willis, 1960). Most ovarian argentaffinomas have clearly shown teratomatous elements, the carcinoid sometimes lying in close proximity to intestinal or respiratory elements (Stewart and others, 1939; Thorson and others, 1958). Williams and Sandler (1963), in their classification of carcinoid tumours, distinguish three divisions on an embryological basis: bronchial, gastric, and pancreatic carcinoids are foregut derivatives; intestinal carcinoids from the mid-duodenum to the proximal half of the colon are of midgut origin; those of the distal colon and rectum are of hindgut origin, and these carcinoids have a trabecular pattern, the cells of which are negative to silver stains. In the present case the tumour cells were reactive to silver and therefore the carcinoid is unlikely to be of hindgut origin.

It is generally accepted that extensive hepatic metastases must be present in intestinal argentaffinomas before the systemic effects are found. The importance of recognizing that the carcinoid syndrome can be caused by argentaffinoma of the ovary lies in the fact that the veins of the ovary drain directly into the caval system and, therefore, the secretion from the tumour is not inactivated in the liver. If the primary tumour is in the ovary its removal, as in the present case, may well be curative, at least in the sense that the disease process is arrested.

DUPLICATION OF THE MALE URETHRA

By T. H. CULLEN
KETTERING GENERAL HOSPITAL, NORTHAMPTONSHIRE

SUMMARY

A brief report of 3 cases of duplication of the male urethra, 2 of which were complete duplications, is presented.
